Abstract. Plate coupling play a fundamental role in the way in which seismic energy is released during the seismic cycle. This process includes quasi-instantaneous release during megathrust earthquakes and long-term creep. Both mechanisms can coexist in a given subducting margin, defining a seismotectonic segmentation in which seismically active segments are separated by zones in which ruptures stop, classified for simplicity as asperities and barrier, respectively. The spatiotemporal stability of this segmentation has been a matter of debate in the seismological community for decades. At this regard, we explore in this paper the potential role of the interaction between geological heterogeneities in the overriding plate and fluids released from the subducting slab towards the subduction channel. As a case study, we take the convergence between the Nazca and South American plates between 18°-40° S, given its relatively simple convergence style and the availability of a high-quality instrumental and historical record. We postulate that trans-lithospheric faults striking at a high angle with respect to the trench behave as large fluid sinks that create the appropriate conditions for the development of barriers and promote the growth of highly coupled asperity domains in their periphery. We tested this hypothesis against key short- and long-term observations in the study area, [seismological, geodetic, and geological](#), obtaining consistent results. If the spatial distribution of asperities is controlled by the geology of the overriding plate, seismic risk assessment could be established with better confidence.

1 Introduction

Subduction margins accommodate short-term (years to tens of years) and long-term (thousands to millions of years) deformation. The most evident effects of these two deformational behaviours are earthquakes (short-term) and mountain-building (long-term) (e.g. Avouac, 2007). The concept of the seismic cycle, introduced by Fedotov (1968) and further elaborated by Mogi (1977, 1985), identifies two stages: a long inter-seismic period (several tens of years), followed by a short co-seismic period (minutes at most) where the elastic energy stored

Con formato: Español (Chile)

Con formato: Español (Chile)

Con formato: Español (Chile)

Código de campo cambiado

34 during the previous stage is released as an earthquake. For earthquake magnitudes in the range of Mw 7.5–9.5,
35 the observed mean slip displacement varies from 0.8–10 meters (Thingbaijam et al., 2017). Even though the
36 maximum mean slip in megathrust events is 10 meters, the zones of maximum slip, equated to asperities (e.g.,
37 Aki, 1984, Lay & Bileck 2007, Lay 2015) can reach 20–40 meters in wavelength patches in the range of 20–
38 100 kilometres (see, e.g., <http://equake-rc.info/srcmod/>). However, the release of elastic energy during the
39 seismic cycle only accounts for 90–95% of the deformation accumulated interseismically in convergent margins;
40 the remaining 5–10% produces permanent deformation in the overriding plate, expressed as crustal shortening
41 and mountain building (e.g. Yañez and Cembrano, 2004). This long-term process lasts for hundreds to
42 thousands of seismic cycles (time windows of millions of years). Therefore, both phenomena — earthquakes
43 and mountain building — are extreme responses to the same process: the convergence between oceanic and
44 continental plates, ~~including the development of asperities and barriers in the same spatial and time frame.~~
45 The concepts of asperities and barriers were proposed by Lay et al. (1982) and Aki (1984) to describe the
46 process during the occurrence of an earthquake and intimately related to the concept of plate coupling. More
47 recent studies (e.g. Bileck and Lay, 2007) propose a more complex mechanism at the subduction plate contact,
48 in which domains of unstable stick-slip state coexist with other domains in a conditionally stable stick-slip state,
49 and zones that develop aseismic slip/stable behaviour. These three states — unstable, conditionally stable, and
50 stable stick-slip behaviour — represent different slip modes that can be represented as asperities and barriers in
51 the old ~~nomenclature-nomenclature~~ (Scholz, 1990). However, the conceptualization of Bileck and Lay (2007)
52 proposes an along-dip (depth) distribution of the different slip behaviours: (1) aseismic-stable at depths of 5–
53 10 kilometres, (2) mostly conditionally stable at depths of 10–15 kilometres, and (3) unstable stick-slip
54 behaviour (Brace and Byerlee (1966) and Burridge and Knopoff (1967)) at depths of 15–25 kilometres. Recent
55 studies on exhumed subduction domains in California (Platt et al., 2018) corroborate this along-dip transition
56 from seismic zone to transition zone. One interesting characteristic of these domains is that unstable domains
57 are generally surrounded by conditionally stable domains and aseismic domains in their outermost periphery.
58 To date, there is no clear evidence on whether the geological/tectonic process(es) control to some extent these
59 seismogenic behaviours and/or their stability across several seismic cycles or geological time frames. Potential
60 candidates already proposed include: (1) the roughness of the subducting plate (aseismic ridges, fracture zones,
61 horst/graben structures, etc.) (e.g. Bilek et al., 2003, Wang and Bilek, 2011; Gersen et al., 2015; Philibosian and
62 Meltzner, 2020; Molina et al., 2021); (2) fluid-controlled overpressure (Peacock, 1990; Safer and Tobin, 2011;
63 Safer, 2017; Menant et al., 2019); (3) the shape of the subducting plate (e.g. Gutscher et al., 1999); (4) the
64 geology of the overriding plate (i.e. Kimura et al., 2018; Philibosian and Meltzner, 2020; Molina et al., 2021),
65 among others, including various combinations of these different possible factors.
66 The role of fluids released from the subducting slab has emerged as a first-order factor in the plate-coupling
67 processes at subduction margins. Direct observations (e.g., Saffer and Tobin, 2011; Tsuji et al., 2014, [Moreno](#)
68 [et al., 2014](#)) and numerical modelling (Menant et al., 2019) demonstrate that fluids released from the subducting
69 oceanic crust and subduction channel define segments at the plate-coupling zone with distinct pore pressure
70 characteristics. Overpressure domains are associated with zones of weak coupling, and strong coupling is
71 observed in the case of zones showing low pore pressure behaviour. The first type of domain is in direct

72 association with creep zones or slow slip events, while the other one is in direct association with locked zones,
73 or in the seismological nomenclature, the barrier and asperity domains, respectively. Seismic imaging of the
74 forearc wedge (e.g. Tsuji et al., 2014) and numerical modelling also show that fluids percolate upwards in the
75 zones of maximum overpressure, including the emplacement of serpentinite bodies along weak zones or faults.
76

77 In this paper, we propose a causal relationship between the presence of trans-lithospheric faults (TLF) in the
78 overriding plate and seismic segmentation, involving the control of TLF on the movement/storage/release of
79 overpressure fluids along and across the subduction zone. We use the Central Southern Andes as a case study,
80 as it is one of the most active seismogenic sites worldwide, is well studied, and has a relatively simple
81 subduction geometry (Hayes, 2018). In addition, recent structural and geophysical mapping has revealed the
82 role of TLF in the tectono-magmatic evolution of the continental margin of this region (e.g. [Yañez-Yanez et al.,](#)
83 1988, Santibáñez et al., 2019; Cembrano and Lara, 2009; Melnick and Echtler, 2006; Yañez and Rivera, 2019;
84 Piquer et al., 2019, 2021a). We aim to demonstrate that the interaction between these TLF and the fluid
85 circulating through the subduction channel provides a simple first-order explanation for the Andean
86 seismotectonic organization through a long-lived geological control.

87 **2 Data and methods**

88 **2.1 Tectonic background**

89 The Nazca-South American plate convergence is a subduction-type margin that has been active in this segment
90 of the Andes since at least the Cretaceous without the accretion of new terrains (Mpodozis and Ramos, 1990).
91 Since 15 Ma, the convergence has been slightly oblique (E10°N) at a velocity of around 6.5 cm/yr (Angermann
92 et al., 1999). The age of the oceanic plate varies between 0 Ma at the triple junction of Taitao (44°S) to 45 Ma
93 at the Orocline bending of Bolivia (18°S) (Figure 1). A flat slab segment is located between 28°S and 33°S
94 latitude, affecting the development of an asthenospheric wedge landward and inhibiting the occurrence of active
95 volcanism since the last 5 Ma (Kay and Mpodozis, 2002). However, the Wadati-Benioff plane is roughly
96 homogenous in dip along the plate coupling between the Nazca and South American plates (Slab 2.0, Hayes,
97 2018). The roughness of the Nazca plate is affected by a progressively older oceanic crust northward, with some
98 fracture zones offsetting the plate, the subduction of a triple junction with an active spreading centre (now at
99 Taitao Peninsula), some episodic magmatic activity along the Juan Fernandez Ridge (33°S, Yañez et al., 2001),
100 and eventually a smaller ridge at 20°S (Perdida Ridge, Cahill and Isacks, 1992). Overall, these features can be
101 described as minor obstacles to the subduction of a relatively young oceanic plate underneath a continental plate
102 in a highly coupled convergence margin (Section 2.5).
103

104 **2.2 Compilation of trans-lithospheric faults in the Andean active margin and their role as long-lived** 105 **high-permeability domains**

106 Trans-lithospheric faults (TLF) correspond to long-lived, high-angle fault systems, which have been identified
107 in several segments of the Andean margin, based on geological mapping (e.g. Santibañez et al. 2019; Cembrano
108 and Lara, 2009; Melnick and Echtler, 2006; Piquer et al., 2021a; Farrar et al., 2023; Wiemer et al., 2023), crustal
109 seismicity (e.g. Talwani, 2014.), a combination of indirect geophysical techniques (Yañez et al., 1998), or a
110 combination of all of these (Yañez and Rivera, 2019; Piquer et al., 2019; Pearce et al., 2020). The geometry and
111 depth extension of TLF is unknown, but based on their control of the continental-scale magmatic and
112 hydrothermal processes and their surface traces in the order of hundreds of kms, we consider that they involve,
113 exclusively, the whole lithosphere.

114 In Table 1 we present a synthesis of the current status of knowledge regarding TLF definition and the major
115 geological/geophysical evidences that described them. The number assigned in each case is used later on in
116 Figure 1 as an identificatory.

117 Detailed structural mapping in various segments of the Andean margin has provided direct geological evidence
118 for the presence of TLF. They are manifested in the field as networks of individual high-angle faults, defining
119 deformation zones with widths of up to several kilometres, and lengths in the order of hundreds of kilometres,
120 being possible to follow their trace across the entire continental margin (Lanza et al., 2013; Yañez and Rivera,
121 2019; Piquer et al., 2021a). These fault networks correspond to the expression at the present-day surface of a
122 pre-existing TLF, as a result of its vertical propagation through Mesozoic and Cenozoic igneous and
123 sedimentary rocks (McCuaig and Hronsky, 2014; Piquer et al., 2019). Field observations also show that,
124 consistent with their high dip angle (commonly $>60^\circ$ and in several cases sub-vertical, although individual fault
125 segments can dip at slightly lower angles), TLF tend to be reactivated as basin-bounding faults during
126 extensional episodes, and are thus associated with violent changes in the stratigraphic record (Piquer et al.,
127 2015, 2021a; Yañez and Rivera, 2019). They also control the distribution of exhumed basement blocks (Yañez
128 and Rivera, 2019).

129 The geological record demonstrates that TLF are long-lived structures, which have played a major role in the
130 long-term evolution of the Chilean continental margin, being reactivated with different kinematics under
131 varying tectonic regimes. It is likely that several TLF were originated in the Proterozoic and the Palaeozoic
132 (Yañez and Rivera, 2019); there is strong geological evidence suggesting the present-day TLF architecture was
133 already in place by the Permo-Triassic, a period in which these structures acted as master and transfer faults for
134 intra-continental rift systems (Niemeyer et al., 2004; Sagripanti et al., 2014; Espinoza et al., 2019). Syn-tectonic
135 emplacement of magma along TLF has been documented at least since the Jurassic (Creixell et al., 2011).

136 Geophysical support for the TLF architecture in the continental margin is provided by the geometry of magnetic
137 and gravimetric anomalies (Piquer et al., 2019; Yañez and Rivera, 2019) and also by magnetotelluric data
138 (Pearce et al., 2020) and seismic tomography (Yañez and Rivera, 2019). Evidence of seismic activity in some
139 of these TLF has been recorded, for example, a precursory event to the 9.3 Mw 1960 Valdivia Earthquake
140 (Lanahue fault, Melnick et al., 2009), and the coseismic rebound associated with the 8.8 Mw 2010 Maule
141 earthquake (Pichilemu fault, e.g. Farías et al, 2011; Aron et al., 2013). Additionally, researchers have
142 documented a strong spatial relationship between a TLF and a major seismic swarm (Valparaíso seismic
143 sequence of 2017, Nealy et al., 2017) at the subduction megathrust (Piquer et al., 2021a).

144 Regarding the role of TLF as long-lived high-permeability domains, Yañez and Rivera (2019) postulated that
145 they represent weak lithospheric domains that favour fluid flow and the emplacement of different types of ore
146 deposits over large time periods (tens of millions of years), beginning with stratabound and IOCG-type deposits
147 in the Jurassic. A similar conclusion has been reached by Farrar et al. (2023) for the emplacement of porphyry
148 copper deposits of various ages, and by Wiemer et al. (2023) for gold-rich superclusters of various types of
149 mineral deposits. The strong relationship between the locations of TLF and those of giant ore deposits at specific
150 metallogenic belts has been discussed more specifically in the Andes of Northern (e.g., Chernicoff et al., 2002)
151 and Central Chile (e.g., Piquer et al., 2016) and neighbouring regions in Argentina. Similarly, there is a well-
152 established relationship between the locations of TLF and volcanic/geothermal activity in the Andes of Southern
153 Chile (e.g., Cembrano and Lara, 2009). Moreover, high Vp/Vs ratios that were documented during the
154 Pichilemu seismic sequence following the 2010 Maule earthquake have been interpreted as strong evidence of
155 fluid migration (Fariás et al., 2011, [Calle-Gardella et al., 2021](#)).

156 Various authors have discussed how the type of magmatic-hydrothermal product and fluid flow regime varies
157 depending on the orientation of a specific high-angle fault system (in several cases, a TLF) relative to the
158 predominant stress tensor (Lara et al., 2006; Cembrano and Lara, 2009; Roquer et al., 2017; Piquer et al.,
159 2021b). Of particular relevance is the orientation of the fault system relative to the maximum stress (σ_1); if the
160 fault system is sub-parallel or strikes at a low angle relative to σ_1 , it is well-oriented for opening and reactivation
161 respectively, allowing the rapid ascent of magma and hydrothermal fluids through different crustal segments.
162 On the other hand, if the fault system is sub-perpendicular or strikes at a high angle relative to σ_1 , it would be
163 poorly oriented or misoriented for reactivation and would promote the storage of magma and hydrothermal
164 fluids at depth (e.g. Cembrano and Lara, 2009; Stanton-Yonge et al., 2016; Piquer et al., 2021b). In the latter
165 case, a requirement for fault reactivation and the release of the accumulated fluids is that supra-lithostatic fluid
166 pressures are achieved; once this occurs, the fault system would allow the discharge of the accumulated fluids
167 towards upper crustal levels and would act as a fluid pump (“fault-valve behaviour”), concentrating fluids in
168 the fractured areas within the fault system and leading to the depletion of fluids in the surrounding regions
169 (Sibson, 1990, 2020; Cox, 2016). These fluid discharge events cause seismic swarms (Cox, 2016), which
170 concentrate at the base of the high-angle fault system (Sibson, 2020).

171 Figure 1 presents the main array of NW- and NE-striking TLF observed in the Andean margin; their seaward
172 trend has been extrapolated following the observed trend in the continental lithosphere, in particular south of
173 36°S, following the trace of submarine canyons.

180

181 **Figure 1:** The spatial distribution of trans-lithospheric faults (TLF) over the regional geology of the Chilean
 182 continental margin (from SERNAGEOMIN, 2003). The traces of the TLF's are based on the models of Yáñez and
 183 Rivera (2019) and Piquer et al. (2019) in Northern and Central Chile, and after the model of Melnick and Echlter
 184 (2006) in Southern Chile. Also shown are the locations of the main ore deposits (from north to south, Chuquicamata,
 185 Mantos Blancos, Escondida, Salvador, Cerro Casale, El Indio, Andacollo, Los Pelambres, Río Blanco-Los Bronces
 186 and El Teniente), and active volcanoes (from north to south, Lásca, Lullaillaco, Ojos del Salado, Tupungatito,
 187 Maipo, Planchón-Peteroa, Laguna del Maule, Chillán, Callaqui, Villarrica and Osorno) to show their
 188 correspondence with the TLF array. TLF are extended until the trench, following their main trend and the canyons
 189 trace to the south of 36°S, using segmented red lines to highlight the uncertainty of this offshore extension. In the
 190 seaward side of the figure, the age map of Müller et al. (2019) is included with the bathymetry of the seafloor

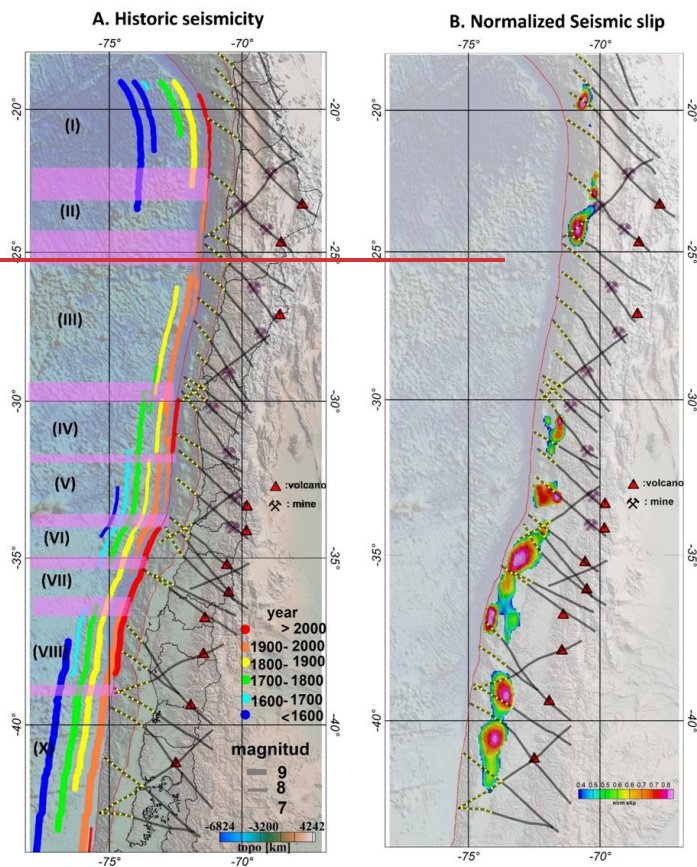

191

192 **2.3 Historic seismicity and Slip solutions during the last 50 years Trans-lithospheric faults (TLF)**
193 **correspond**

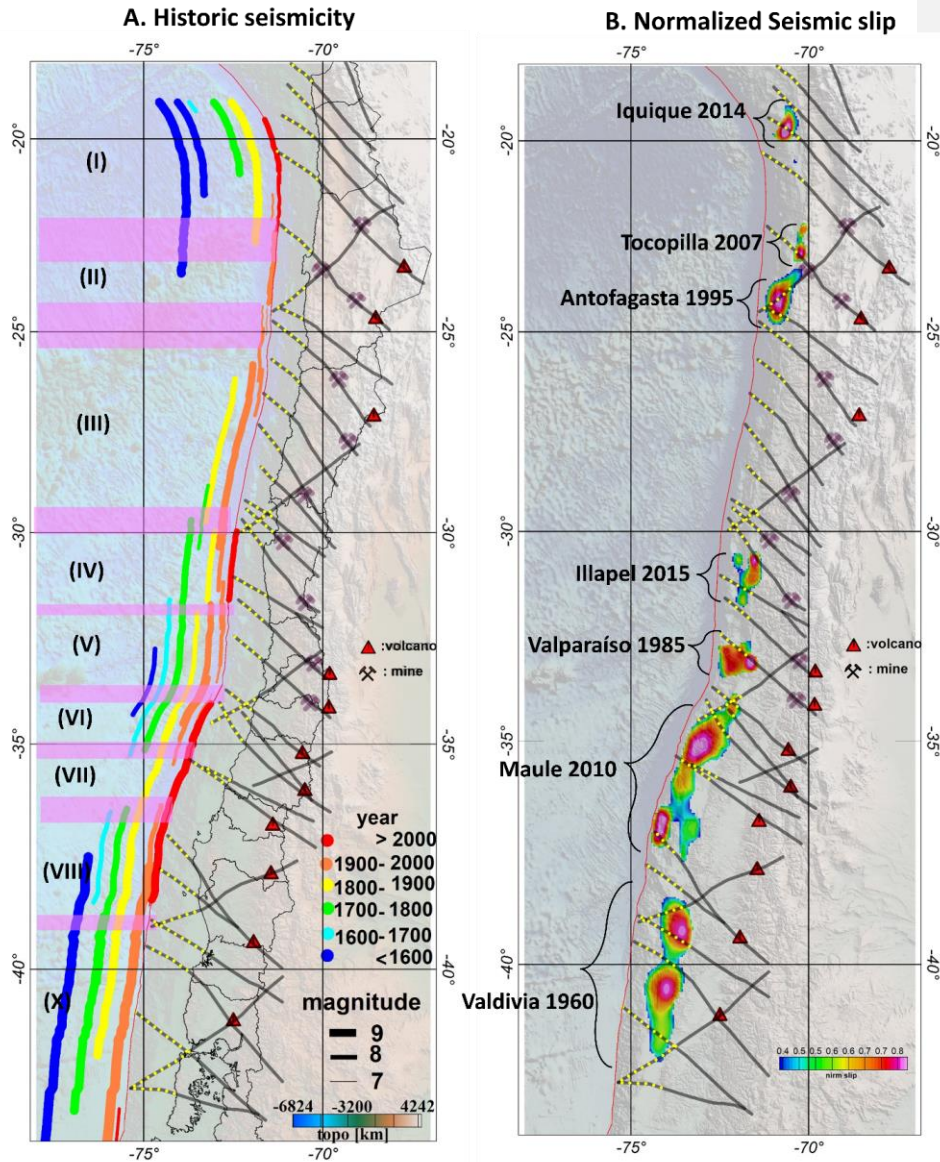

194 The historic seismic record in the region is short, extending from the start of the Spanish Colonization in the
195 region (present territories of Perú and Chile, circa 1500 ac). Compilations of historic seismicity and subsequent
196 interpretation to assess the magnitude and longitudinal extension of the events have been provided in Ruiz and
197 Madariaga (2018) and Scholz and Campos (2012), among others. Figure 2, panel A, includes all the historic
198 events described by these authors, as well as events above 7 Mw from the USGS catalogue. As noted by several
199 authors (Ruiz and Madariaga, 2018, and references therein), there is evidence of seismo-tectonic segmentation
200 in the historic record. For the present analysis, we define seven domains from north to south ~~with some~~
201 ~~distinctive characteristics~~; the ~~boundaries-boundary~~ between ~~each-domains are-is~~ defined by a ~~width~~
202 ~~domain/region~~ of roughly 100-200 kilometres that represents the uncertainty in the rupture length of the major
203 events. ~~We consider-~~ wider boundaries for the cases of lacking information, in particular in the northern area
204 where the historic record is scarce. Domain I, in the northernmost part of the study region, shows a sequence
205 of events close to magnitude 8 Mw and separated by 100–150 years. Domain II has no large events (above 8
206 Mw) in the historic record, instead having a series of intermediate events of magnitude 7–7.7 Mw between 1960
207 and 2020. Domain III has two events with magnitudes in the range 8.3–8.5 Mw separated by almost 10 years,
208 but with a current seismic gap of 100 years. Domain IV is less than 200 kilometres in length and includes a
209 series of seismic events of magnitude 8 Mw or above. According to Ruiz and Madariaga (2018), the three major
210 events in this domain show relatively consistent recurrence times (60–80 years) and magnitudes (8–8.4 Mw),
211 namely, the earthquakes of 2015 (Illapel, 8.3 Mw), 1943, and 1880. Domain V is also relatively small, about
212 300 km, and includes regular events of around magnitude 8 Mw, including the Valparaiso 1985 8 Mw event
213 and the 1906 8.4 Mw event. Domain ~~VI~~, VII and VIII include part of the Maule 2010 8.8 Mw and Concepción
214 1835 8.6 Mw events, but are defined as such based on some less than 8 Mw events, Domain X, the southernmost
215 domain, is dominated by the giant events of Valdivia 1960, ~~9.3-5~~ Mw, and 1737, 9.0 Mw.

216 Adequate seismic coverage is available since 1985 in Chile. In this period, six large earthquakes have been
217 recorded: Valparaiso 1985, 8.0 Mw (Comte et al., 1986; Mendoza et al., 1994); Antofagasta 1995, 8.0 Mw
218 (Ruegg et al.; 1996, Delouis et al., 1997; Pritchard et al., 2002 and Chlieh et al., 2004); Tocopilla 2007, 7.8 Mw
219 (Schurr et al., 2012); Maule 2010, 8.8 Mw (Delouis et al., 2010; Lay et al., 2010; Vigny et al., 2011; Koper et
220 al., 2012; Ruiz et al., 2012; Moreno et al., 2012; Lorito et al., 2011; Lin et al., 2013; Yue et al., 2014); Iquique
221 2014, 8.2 Mw (Ruiz et al., 2014; Hayes et al., 2014; Schurr et al., 2014; Lay et al., 2014), and Illapel 2015, 8.3
222 Mw (Melgar et al., 2016; Heidarzadeh et al., 2016; Li et al., 2016; Lee et al., 2016; Satake and Heidarzadeh,
223 2017). Given the large size of the Valdivia 1960 earthquake (~~9.3-5~~ Mw), we also include slip estimates for this
224 event based on surface deformation data (Barrientos and Ward, 1990). The slip distribution of these events
225 ranges from 1 meter (e.g. Tocopilla 2007, Antofagasta 1995), several meters (e.g. Illapel 2015, Iquique 2014),
226 and more than 10 meters (Valdivia 1960, Maule 2010); however, in Figure 2, panel B, we normalize the slip

227 distribution with respect to the corresponding maximum slip in each case, plotting over the slab surface to
228 highlight its spatial distribution. This approach aims to highlight the zones of maximum slip in each case and
229 to appreciate their spatial and temporal distribution, under the working hypothesis that they represent the zones
230 of maximum slip and are most likely a good proxy to identify asperities in the plate contact zone. These
231 maximum slip zones are generally distributed between the TLF network (Figure 2).

 239
 240

Figure 2: Panel A: historical seismicity from the years 1450 to 2020 (for a full description of each event, see Table A.1 of the supplementary material). The lateral extent of each event indicates the NS estimate of the event name; the colour scale corresponds to the year window of each event; the Mw magnitude in each case is represented by the width of the line. Seismo-tectonic segmentation is indicated by yellow-pink semi-transparent ribbons, which are extended downwards to the lower panels. Panel B: zones of maximum slip in the megathrust events registered at the margin of Chile since 1960, colour code represents a normalized slip to the maximum slip in each event.

241 **2.4 Cumulative seismic spatial distribution in the last 20 years**

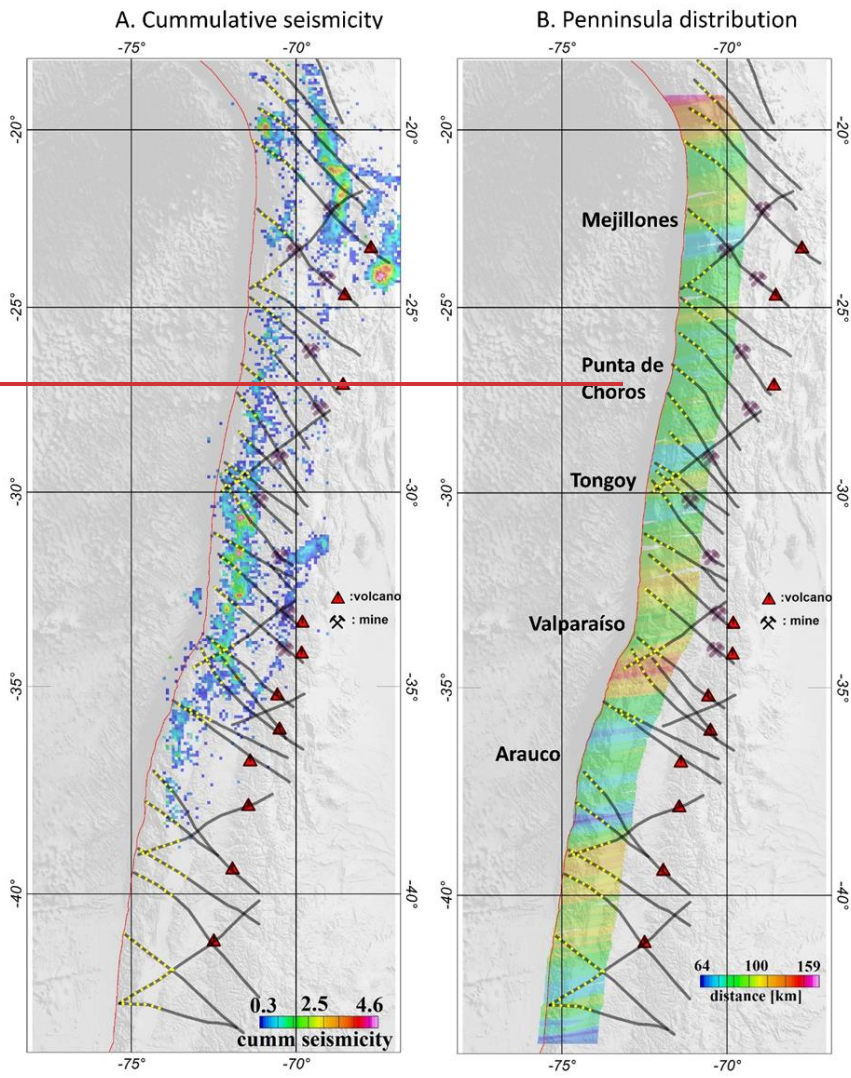

242 The seismic activity, apart from its spatiotemporal distribution around megathrust events (occasionally with
243 foreshocks and normally with a hyperbolic distribution of aftershocks in time (Omori's law)), shows some
244 clustering (denominated in general as seismic swarms), that may be triggered by aseismic creep events
245 (Forsyth et al., 2003; Roland and McGuire, 2009) associated with the presence of fluids in the fault zone. In
246 the Andean plate convergence margin, recent studies also show examples of seismic swarm distribution
247 attributable to fluid pore-pressure processes (e.g. Poli et al., 2017, Pasten-Araya et al., 2018). To contextualise
248 the spatial distribution of this seismicity, we compute a normalised seismic density distribution along the
249 margin for the last 20 years in which the seismic network is complete above magnitude 3 Mw. We exclude
250 most of the seismicity associated with major thrust events in this period, filtering out the events at distances of
251 less than 200 kilometres from the rupture zone in a temporal window of 200 days. We acknowledge that this
252 20-year time window is too short to obtain a broad and complete picture of the distribution of swarms along
253 the margin. However, as swarms normally last for just a few weeks or 1–2 months at most, the cases observed
254 in this time window provide insights into their spatial distribution. The data used in this analysis were
255 obtained from the database of the National Seismological Centre (CNS in Spanish). We selected data
256 attributable to the seismogenic plate contact within a 10-kilometre-thick volume following the slab 2.0
257 Wadati-Benioff plane (Hayes 2018). The seismic density distribution is shown in Figure 3A, panel A, we can
258 see that seismicity tends to cluster in the vicinity of the seaward projection of the TLF.

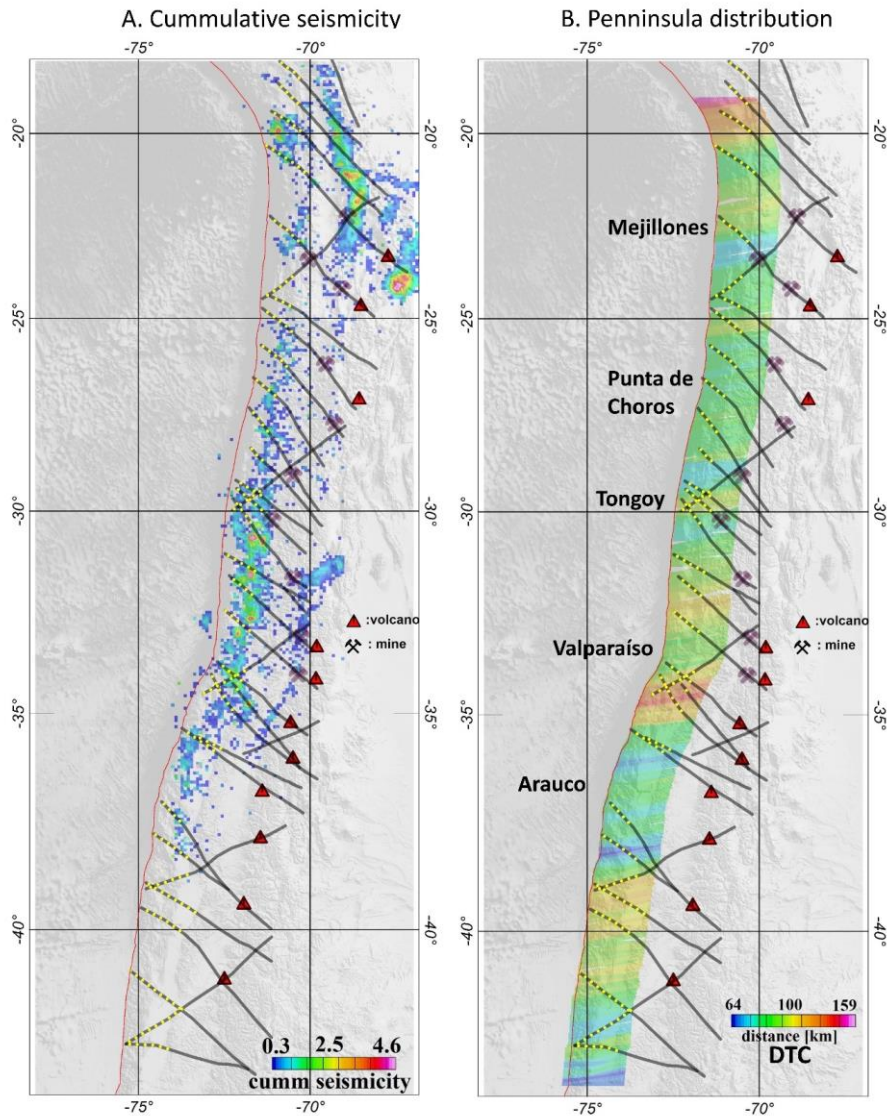

259

260 **2.5 Distance from the trench to the shelf brake**

261 Saillard et al. (2016), show that peninsulas along subduction zones cost lines present a long-term permanent
262 coastal uplift that can be associated with creep and aseismic slip domains. Thus, distance from the trench to
263 the coast (DTC) constitutes a proxy to separate seismotectonic segmentation due to the weak plate coupling.
264 The physics behind this proposal lies in the dragging force that subduction force induces on the overriding
265 plate, thus with less traction (weak plate coupling in the long term), the fore-arc region close to the trench
266 should be shallower than the surroundings. To gain a broader perspective of the peninsula's distribution,
267 Figure 3B contours the distance to the shelf brake, which is probably a better proxy for a potential uplifted
268 domain in the coastal region. As shown in this figure, the DTC presents variations along the trench. We
269 identify domains of short DTC associated with peninsulas in the region near to: Arauco; Valparaíso; Tongoy;
270 Punta de Choros; and Mejillones. Based on geological and geochronological evidence in three of these
271 peninsulas (Mejillones, Tongoy, and Arauco), Saillard et al. (2016) determined uplift rates in the range of
272 0.6–2 meters per thousand years in the associated terraces. These terraces have been continuously uplifting for
273 at least the last 0.5–0.8 Myr, indicating a long-term process compared to the seismic cycle of less than 500
274 years. Using this evidence, in addition to the inter-seismic GPS coupling, Saillard et al. (2016) infer that these
275 peninsula zones are associated with weak plate coupling where deformation is mostly accommodated by
276 creep. Again, qualitatively speaking, there is a tendency to find peninsula distribution where TLF tend to
277 concentrate in the coastal region.

278

280
 281 **Figure 3:** Panel A: density distribution of the last 20 years of seismicity in the margin (data from [National](#)
 282 [Seismological Centre, CSN](#)); values are normalized to better define the zones where seismicity has been
 283 concentrated, filtering out all the aftershocks associated with major megathrust activity (Taltal 2001, Maule 2010,
 284 Iquique 2014, and [Valleparaiso-Illapel](#) 2015). Panel B: distance from the trench to the shelf brake, projected to the
 285 convergence direction (10E).
 286
 287

288 **2.6 Viscous coupling**

289 The negative free-air anomaly along the Chile-Perú Trench is the response to dynamic equilibrium between
290 buoyancy and tectonic forces (Yáñez and Cembrano, 2014). The tectonic force tends to drag the continental
291 plate downwards, whereas buoyancy restores this deformation. Assuming equilibrium between the net
292 tectonic force and the long-term deformation (flow in continuum physics) the observed bathymetry represents
293 this force equilibrium. Therefore, for each bathymetric observation, a given Slip Layer Viscosity (SLV)
294 (Wdowinski, 1992) allows a match between observations and long-term viscous plate coupling. Using the
295 methodology developed by Yáñez and Cembrano (2004), we determine the along-strike SLV in the Nazca-
296 South America plate convergence region, considering across-strike profiles every 20 kilometres. As indicated
297 earlier, zones of maximum slip involve wavelengths larger than 20 kilometres for the megathrust events, and
298 therefore, a sample interval of 20 kilometres ensures appropriate along-strike resolution. In addition,
299 following the same rationale and conclusions of Yáñez and Cembrano (2004), we estimate that the increase of
300 the SLV in the north of the study area is due to a temperature-dependent rheology. This increase in viscous
301 plate coupling in the north is likely to be responsible for the larger crustal shortening observed in the southern
302 Andes in the last 20 Ma. Although other authors (e.g. Lamb and Davies 2003) consider that the deficiency in
303 sedimentary supply in the trench in the northern Andes is the driving mechanism for the larger viscous plate
304 coupling in the region. However, this discussion is beyond the scope of the present work, and since the
305 viscous plate coupling correctly represents the observations we are interested here in the short-wavelength
306 viscous plate response as a potential tool to identify zones with different degrees of coupling along the
307 convergent margin. Therefore, we remove this regional viscous plate coupling to isolate short-wavelength
308 features. This residual slip layer viscosity (RSLV) is included in Figure 4A (see a full discussion in
309 Supplement A). This signal shows positive (high relative viscous plate coupling) and negative (weak relative
310 coupling) zones. Again, we use normalized values to highlight the spatial distribution of the signal. In the
311 supplementary material, we present a full description of the modelling used to obtain the RSLV signal. As the
312 modelling is 1D, we extend the result of each model along the strike of the convergence (10°E).

313 **2.7 Inter-seismic GPS coupling**

314 GPS data provide information on the surface deformation relative to a stable continental reference. During the
315 inter-seismic period, the slip velocity at the intraplate contact, Vinter-seismic, can be determined from a GPS
316 network under the assumption of elastic plate deformation (e.g. Okada, 1985). This inter-seismic velocity
317 depends on the degree of plate coupling, ϕ . At maximum plate coupling ($\phi=1$), Vinter-seismic is null, and at
318 minimum plate coupling ($\phi=0$), Vinter-seismic is equal to the convergence velocity ($V_{convergence}$) (e.g.
319 Nuvel1a, De Mets, et al., 1994). Or, mathematically (e.g. Metois et al., 2012), $V_{inter-seismic}=(1-\phi)*$
320 $V_{convergence}$. Inter-seismic GPS coupling is presented as GPS locking data in Panel B of Figure 4 (based in
321 a compilation of GPS information derived from different sources, Burgmann et al., 2005; Chlieh et al., 2008;
322 Loveless & Meade, 2011; McCaffrey et al., 2002; Metois et al., 2012, 2016; Moreno et al., 2010, 2012;
323 Wallace et al., 2004)). For the segment between Antofagasta and Copiapo (24-28°S), two new GPS plate
324 coupling models are available (Yáñez-Cuadra et al., (2022) and González-Vidal et al., (2023)), however, we
325 noticed that these new results share similarities do not depart significantly with the model presented in Figure
326 4b, and is therefore not necessarily thus are not included in this case. From 27°S to the north, high GPS plate

327 coupling is generally observed, although some correspondence is observed with the local minimum and TLF
328 distribution. Between 27°–33°S, the GPS coupling shows domains with lower values with better
329 correspondence with TLF segmentation and the minimum in viscous coupling. To the south of 33°S, the GPS
330 plate coupling shows a spatial distribution that again shows some coincidence with the other proxies, but also
331 some discrepancies. This is not surprising, since GPS inter-seismic plate coupling reflects the quasi-
332 instantaneous coupling of seismo-tectonic segments at different loading stages. Nevertheless, in most of the
333 studied segments, the GPS plate coupling correlates relatively well with the viscous plate coupling, and the
334 location of peninsulas and cumulative seismicity in the last 20 years.
335

336

337 **Figure 4:** Panel A: Normalized Residual slip layer viscosity (RSLV) derived from 1D modelling along profiles
 338 separated every 10 km and oriented along the Nazca-South American plate convergence (10°N); as this model
 339 involves all of the slip layer, its spatial distribution is represented from the trench until 150 km landward. high
 340 relative coupling is associated with high residual slip viscosity (see details of this computation in Supplement A).
 341 Panel B: GPS inter-seismic plate coupling, model 17 (Burgmann et al., 2005; Chlieh et al., 2008; Loveless &
 342 Meade, 2011; McCaffrey et al., 2002; Metois et al., 2012, 2016; Moreno et al., 2010, 2012; Wallace et al., 2004).
 343 Locking is restricted to the range between 0.3 to 0.9, in order to enhance the relative coupling along the plate
 344 coupling zone.

345 3. Discussion

346 3.1 Quantitative correlation between TLF and plate coupling proxies derived from seismicity 347 distribution, GPS and viscous coupling and coastal morphology.

348 In order to better quantify the correspondence between the spatial distribution of TLF and the indirect estimate
349 of plate coupling described in chapter 3 we present here an objective comparison between them. This task is
350 challenging, taking into consideration the poorly constrained data used: (a) in some cases, regional-scale
351 geological observations (TLF and peninsula distribution); (b) different time-scale coupling estimates (inter
352 seismic GPS locking and long term viscous coupling); (c) poorly resolved GPS solution offshore; (d) 1D
353 modelling of viscous coupling; and (e) The lack of completeness in the seismicity record (historical record of
354 500 years, instrumental record of megathrust events of 50 years, and cumulative seismicity of 20 years)
355 considering a seismic cycle of a couple of hundred years in the margin. Thus, none independent proxy is capable
356 to produce a reliable estimate by itself, but rather a combination of them. Therefore, a thorough analysis is
357 beyond the capabilities of the data source, and what we present here, though quantitative, should be understood
358 as a guide to determine tendencies from different and independent perspectives that as a whole, provide a more
359 robust estimate on the link between TLF and plate coupling in the margin.

360 The approach adopted considered the spatial correlation between TLF and the six proxies described in chapter
361 3, using the Pearson correlation coefficient between two variables (r_{xy}) defined as:

362

$$363 r_{xy} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}} \quad (1)$$

364 Where \bar{x} and \bar{y} are the average value of each variable. This function r_{xy} has values between -1 (opposite
365 correlation) to 1 (direct correlation). Values near zero mean weak or null correlation. In the application of the
366 Pearson correlation in this case, the spatial distribution of TLF is always the x_i , and the 6 proxies used in this
367 case are the y_i in each case. A key property of the Pearson correlation coefficient is its invariance to spatial
368 distribution of samples and scale of the two variables. This property is particularly useful in this case where we
369 are trying to correlate very different proxies in terms of spatial distribution and scale. The correlation is
370 performed in moving windows bins of 32x32 km², with an overlap of 50% between correlation estimate. The
371 correlation is calculated in a domain of 140 km width from the trench to the east, the plate coupling zone where
372 short-term and long-term processes take place.

373 TLF are defined as line traces, but in order to spatially correlate them with the other variables, we add
374 a width, considering potential spatial uncertainties and zones of influence. Thus, the width of each TLF is treated
375 as a gaussian with a value of 1 in the centre and 0 at the edge, located at 10 km from the centre, representing
376 the deformation zone and the lateral surface covered by the potential fluid release. Such a width of 20 km seems
377 a reasonable number for a fault system of more than 100km length (>20%). In fact, in recorded earthquakes,
378 like the Landers earthquake 1992 (Mw 7.3) where a rupture length of 85 km has been determined, with a shear
379 deformation zone of 12-16 km (Perrin et al., 2020). Outside the TLF domains a value of -1 indicate no spatial
380 distribution of TLF, but in practice is not relevant because the correlation is focussed inside the TLF domain

381 only. The other six proxies are treated in different manner, depending on its nature. GPS plate coupling is a
382 spatial variable covering the whole spatial range of the coupling. Looking at the GPS coupling described in
383 Figure 4b, we can see that most of the plate contact is highly coupled, well above 0.6 almost everywhere, thus
384 in order to identify some differences in coupling we setup the mean value at 0.8. Slip viscosity layer and distance
385 from the shelf brake to the trench are single values varying with latitude which are extended to spatial variables
386 projecting the value landward following the convergence direction ($\sim 10^\circ\text{E}$). In the case of the slip coupling a
387 mean value is already removed, thus a mean value of 0 is considered. For the shelf brake-trench distance we
388 use the average separation of 100km as the mean value. Seismic cumulative density and slip distribution of
389 megathrust events define restrictive domains along the plate coupling region. These areas are normalized
390 between 1 and zero, and outside the region a value of -1 is assigned (no data). The same procedure is used for
391 the boundary between historic seismicity segmentation, value 1 in the transition, and -1 outside. Since the
392 analysis is restricted to the correlation between TLF's and the six proxies, the correlation only concerns the
393 inner part of the TLF. Given the nature of each proxy, a low coupling at a given TLF implies a negative Pearson
394 correlation at GPS and viscous coupling, distance from the shelf brake to the trench, and slip distribution for
395 megathrust events (maximum slip should lie outside the TLF domain). On the contrary, positive Pearson
396 correlation is expected with the historic segmentation and cumulative seismicity, to reflect low coupling at the
397 TLF domain.

398 The results for each Pearson correlation coefficient spatial distribution are presented in Figure 5 in a
399 plan view. In Figure 6 we present the result for the 32 relevant TLF in terms of the histogram obtained for the
400 Pearson correlation inside the corresponding TLF domain. Over the histograms observations we include an
401 interpretation on the correspondence with a low plate coupling condition, depending on the shape of the
402 histogram, positive (Pearson correlation biased to the left in GPS, VISC, DIST, SLIP histograms; and biased to
403 the right in the CUMM and HIS histograms), unclear (flat for all the proxies) and negative (Pearson correlation
404 biased to the right in GPS, VISC, DIST, SLIP histograms; and biased to the left in the CUMM and HIS
405 histograms) correlation. Based on this analysis we qualify the potential of each TLF in terms of its barrier
406 potential, high, ambiguous, and poor. The criteria to establish this qualification considers the following: (a) high
407 potential: at most one correlation is negative and by majority are positive correlation; (b) ambiguous: at most
408 two correlations are negative and at least one correlation is positive; (c) poor: when more than three correlations
409 are negative or none of them are positive.

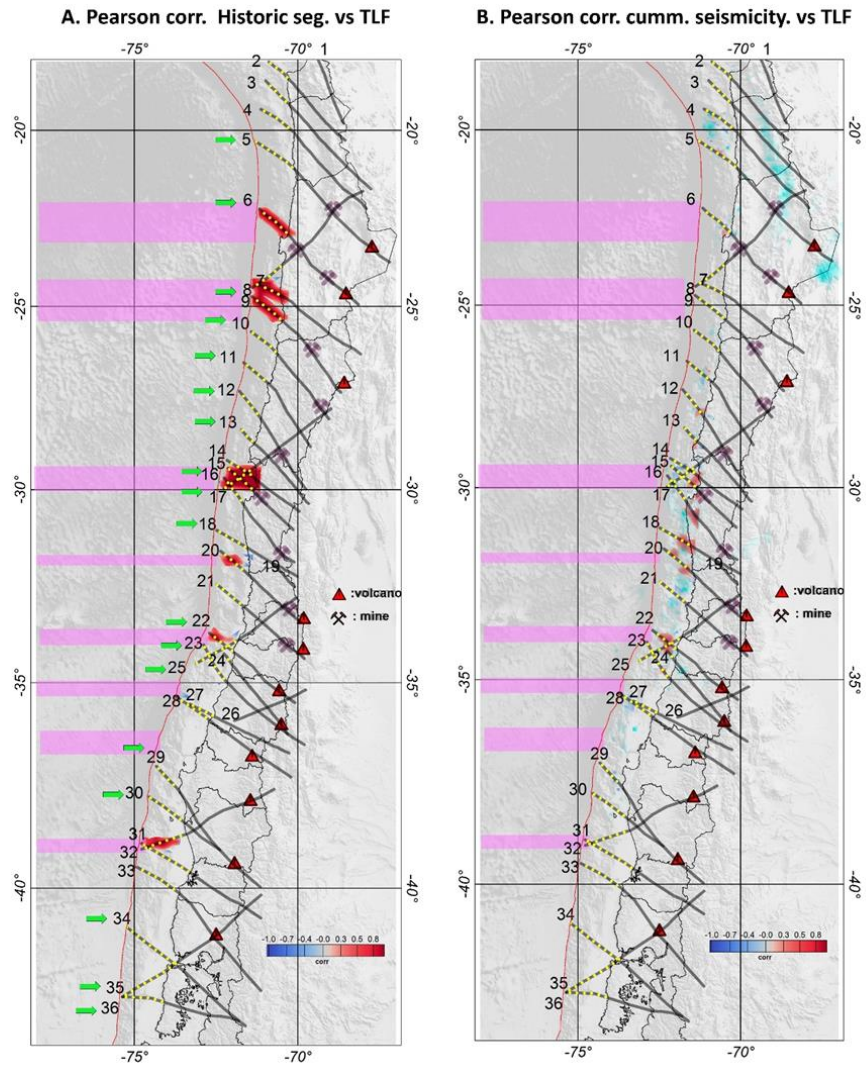

410 Some relevant conclusions arise from the spatial analysis of Figure 5 and histograms of Figure 6:

- 411 1. From the 32 relevant TLF in terms of plate coupling, 63% (20 of 32) show a high potential for a
412 barrier behaviour, 31% (10 of 32) presents some ambiguity, and only 6% (2 of 32) TLF show a poor
413 chance to become a barrier domain.
- 414 2. For the case of ambiguous potential, almost all of them present at least 2 positive correlation proxies.
- 415 3. For individual histograms, 54% histograms show a positive correlation, 28% are considered
416 ambiguous, and 18% present a negative correlation.

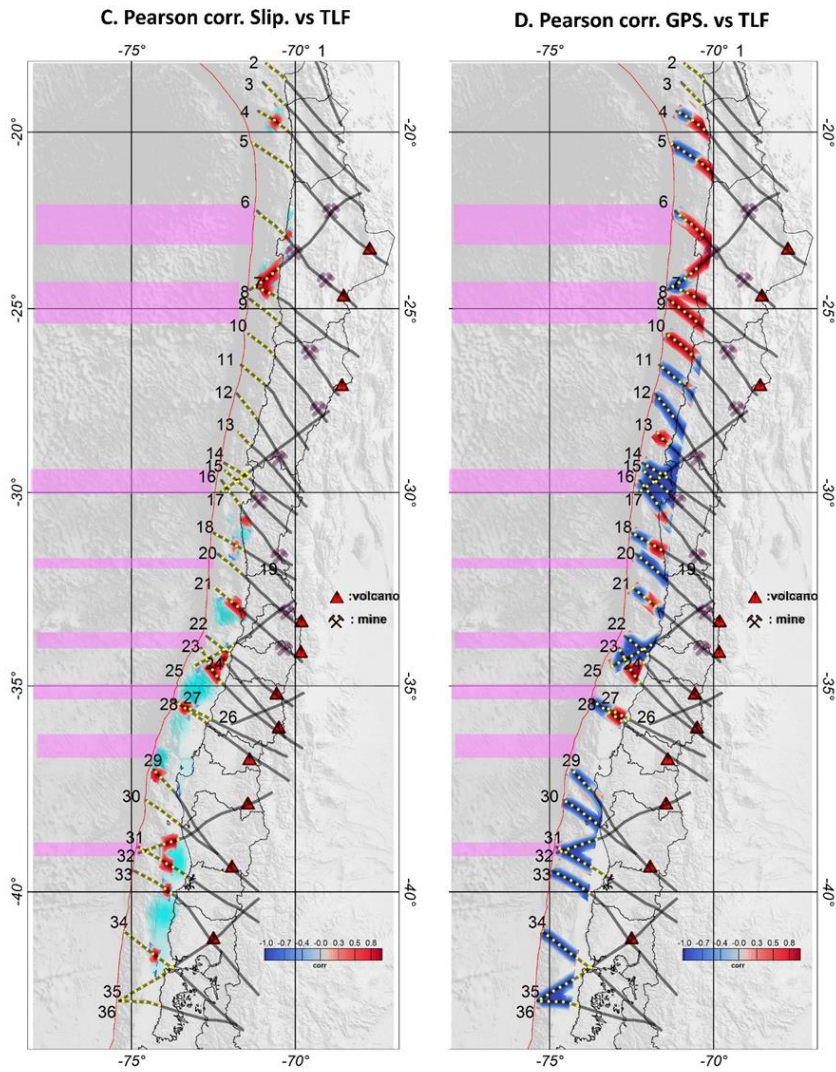

- 417 4. Five out of seven seismotectonic boundary segments present a strong correlation with TLF spatial
418 distribution (Figure 5a). In terms of particular histogram distribution, 11 out of 13 show a positive
419 correlation and none of them show a negative correlation.
- 420 5. The cumulative interseismic seismicity (Figure 5a), perhaps the weakest proxy due to the lack of
421 seismic completeness due to the very restricted time window of observation, still shows an almost
422 100% direct correlation with the TLF traces where inter-seismic activity developed (TLF 14-15-16,
423 TLF 18-20, TLF 22). In terms of the histogram distribution, shows a rather similar pattern, some
424 clear positive correlation in 6 out 18 TLF and a none conclusive solution in 12 out 18 cases.
- 425 6. The spatial distribution of the slip zones of the main megathrust events recorded in the last 50 years,
426 show a minimum positive correlation with the spatial distribution of TLF. As we can see in Figure
427 5b, less than 20% of the total slip domains, potential zones of asperities, correlate positively with
428 TLF. The most conspicuous case against the rule is the slip zone of the Antofagasta 1995 that cut
429 two TLF (7: Agua Verde-Exploradora, and 8: Antofagasta-Chonchi) and partially the Tocopilla
430 2007 event (Mejillones-Llullaillaco TLF 6). Two complementary explanations are proposed in this
431 case: (1) both are small events (8Mw) compared to the other megathrust events, (2) not necessarily
432 all TLF behave as barriers all the time. For the case of Iquique 2014 event, the seaward extension of
433 of Iquique TLF is not well constrained, and most likely run straight from landward segment, leaving
434 the slip zone entirely to the south of TLF 4. The remaining 80% lies outside the zone of influence
435 of TLF. In the histogram distribution, the same pattern is observed, 57% of negative Pearson
436 correlation (or positive correlation in terms of low plate coupling), 26% of ambiguous solution and
437 17% positive Pearson correlation. It is important to note that in several histograms of this proxy a
438 positive correlation is adopted when a low flat response is observed, but in the left side there is a
439 single column saturated at the maximum value for correlation -1 (most of the TLF is empty, or in
440 other words the slip zone lies outside the TLF domain).
- 441 7. In the GPS plate coupling-TLF Pearson correlation coefficient (Figure 5b) 50% of the cases show a
442 negative correlation (low relative coupling), whereas 30% show some mix results, with the negative
443 correlation concentrated in the deeper parts of the coupling, and only in 20% of the cases a positive
444 correlation holds, mostly concentrated in the coupling zone of the Antofagasta 1995 and Tocopilla
445 2007 earthquakes, and probably linked with some post seismic effects. Consistently, in 18 out of 32
446 (56%) histograms responses (Figure 6), the low coupling correlation is observed, whereas in 10 out
447 of 32 (31%) the response is ambiguous, and the remaining 13% is associated with relatively high
448 GPS coupling. We acknowledge that these values are very much conditioned by the choice of the
449 threshold of 80% to separate high to low GPS coupling, but the aim is to identify less coupled
450 domains in a signal almost saturated with high values.
- 451 8. The same type of analysis was performed for the Slip Layer viscosity – TLF Pearson correlation
452 coefficient (Figure 5c). In 50% of the case the correlation is opposite (low viscosity slip zones

453 corresponds with the location of TLF). In 15% of the cases, we observed mixed results, whereas in
454 35% of the cases the correspondence is positive. Similar results are obtained with histogram
455 responses (Figure 6), in 17 out of 32 (53%) the low coupling correlation is observed, whereas in 6
456 out of 32 (19%) the response is ambiguous, and the remaining 28% is associated with relative high
457 slip viscosity. One important limitation of this approach is the 1D approximation of an inherently
458 3D process. This fact is probably the main reason for its relatively low positive response compared
459 to the other proxies. Finally, figure 5c show the Pearson correlation coefficient for the distance from
460 the shelf brake to the trench. In this case, the closest shelf brake to the trench at TLF intersection is
461 a 36%, the same number of cases show an opposite behaviour and only 28% presenting mixed
462 results. In terms of the histogram distribution (Figure 6), the same tendency is observed, but with a
463 higher predominance of shorter distance shelf brake-trench (44%), whereas the opposite is observed
464 in 34% of the cases and 22% show an ambiguous response. This is the proxy that show the lowest
465 level of positiveness, probably due to the fact that other processes are also involved in the uplift of
466 the peninsula regions, for instance the density of the crust and its relative buoyancy.

467 As we point out earlier in the text, none of the proxies by itself have the merit to account for the degree of
468 coupling along the subduction zone, and the results emanated from the Pearson correlation demonstrate that.
469 However, when we integrated the individual results 63% of the TLF can potentially behave as barrier, and only
470 in two cases (6%) chances are poor. In the remaining 31% of the cases, represented as ambiguous cases, there
471 are still some evidences of positive correlations in more than one proxy. In Figure 5a, panel A, we include a
472 reference for the TLF with high potential to become a barrier (green arrow), and we can see that in almost all
473 the cases they are consistent with the tectonic segmentation derived from the historic seismicity. One peculiar
474 distribution of potentially active barrier domains is observed between 25°-30° S, the zone with less historical
475 seismicity (Figure 2). On the other hand, not necessarily all the TLF behave as barriers, due to lack of favourable
476 orientation, depth extent, age, dip angle, fluid content among other uncertainties. Therefore, we consider that
477 the previous semiquantitative analysis including all the proxies, support the presence of a geological signal of
478 low plate coupling when TLF is present. In the next section we propose a conceptual mechanism to explain
479 this phenomenon.
480

Figure 6: Histogram diagrams for Pearson correlation in each TLF (six histograms for each TLF). Histogram interpretation and TLF qualification as a potential barrier is indicated in inlet. TLF number is indicated to the left of each panel (a good resolution of this image is provided in the supplementary material). Correlation type is indicated by triangles in each histogram, while the estimate TLF barrier potential high to poor is indicated by symbols in the left side of each histogram.

509 **3.2 A simple conceptual barrier model: misoriented TLF as a store/released of fluids during the seismic**
510 **cycle.**

511 Comparing the spatial distribution of the seaward extension of the TLF and the previously discussed first-order
512 conditioning factors of the tectonic segmentation in the Andes (chapter 2), and the cross correlation described
513 in section 4.1, we can make the following conclusions:

- 514 1. The coastal termination of an TLF generally occurs close to a peninsula, where the shortest trench–
515 coast distance is observed, in spatial correspondence with zones of negative RSLV (weak viscous
516 coupling), and in some cases also corresponding to zones of weak GPS coupling. However, it should
517 be noted that the degrees of coupling inferred via RSLV and GPS do not map similar observation
518 time windows, covering geological (Ma) vs seismic cycle (300–500 years) time frames, respectively.
- 519 2. During the last 60 years, slip displacements during the major megathrust earthquakes in the margin
520 of Chile tend to be bounded by the coastal termination of an TLF in their northern and southern
521 boundaries. Thus, if these slip zones represent a spatial distribution of asperities, the TLF correspond
522 to zones potentially associated with barriers, consistent with the long-term low coupling inferred
523 from RLSV, GPS plate coupling and distributions of peninsulas. the previous long-term
524 observations.
- 525 3. Cumulative seismic activity in the last 20 years tends to nucleate in the vicinity of the seaward
526 termination of the TLF, normally with the development of seismic swarms of 100–300 events of
527 medium to low magnitudes during periods of several weeks at most.
- 528 4. The geological record demonstrates that TLF are long-lived structures of high permeability in
529 comparison with the surrounding crust and most likely the underlying mantle as well, and are thus
530 potentially efficient fluid storage structures.

531 The previous observations provide the grounds to propose a simple conceptual model to understand the role
532 played by TLF in the tectonic segmentation of a convergent margin. These observations consistently show that
533 TLF in the seismogenic zone are spatially correlated with long-term and short-term evidence of weak coupling
534 behaviour. The long-term evidence involves geological processes that build up during many seismic cycles,
535 over a time frame of millions of years, including low values of slip-layer viscosities and correspondence with
536 the spatial distribution of peninsulas. The short-term evidence involves fragments of the seismic cycle over a
537 time frame of less than 500 years, characterized by weak coupling zones as inferred by inter-seismic GPS
538 observations, the flanks of slip zones of recent mega-thrust events, and the boundaries that delimit the historical
539 record of major events. Overall, these observations consistently show that TLF domains are likely candidates
540 for barrier zones.

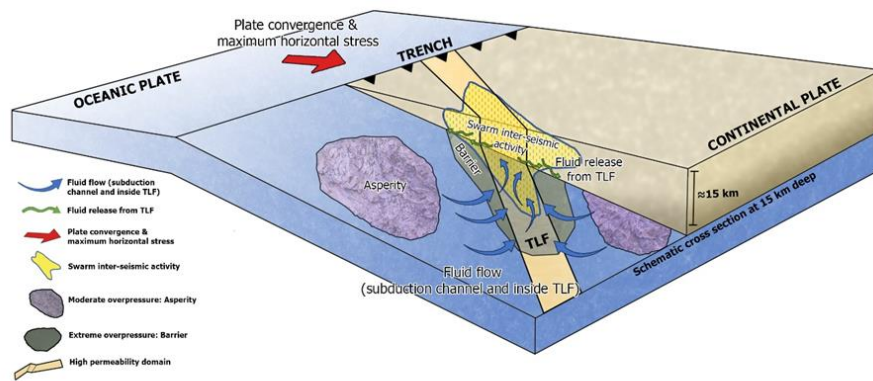

541 From basic principles, the strength of a fault is controlled by the friction at the discontinuity plane. According
542 to Amonton's law, the fault strength is proportional to the product of the normal stress and the static or dynamic
543 friction (e.g. Scholz, 1990). In the presence of fluids, pore pressure reduces the normal stress, thereby reducing
544 the strength of the fault (e.g. Scholz, 1990), eventually to zero if the pore pressure reaches the lithostatic pore

545 pressure. Under these supra-lithostatic fluid pressure conditions, even faults that are strongly misoriented for
546 frictional reactivation under the prevailing stress field can be reactivated, focusing the discharge of large
547 amounts of overpressured fluids and acting as a “fault-valve” (Sibson, 1990; Cox, 2016). Indeed, Cox (2016)
548 showed that, under supra-lithostatic fluid pressure conditions, the typical seismic response in the faults
549 corresponds to microseismic swarms, which, according to Sibson (2020), would concentrate at the roots of the
550 fault system. In the case of an TLF, which is a long-lived structure transecting the whole lithosphere (e.g., Lutz
551 et al., 2022), the root of the fault system at the Andean convergent margin corresponds to the subduction
552 channel. Low fault strength at subduction zones can be equated to barrier zones where convergence is mostly
553 accommodated by creep and/or micro-seismicity. The hydration of the subducting slab during its bending in the
554 outer rise region has been widely documented in different subduction margins (e.g., Holbrook et al., 1999;
555 Shillington et al., 2015; Contreras-Reyes et al., 2007; Moscoso and Grevemeyer, 2015; Ranero and
556 Sallarès, 2004; Fujie et al., 2018, among others), as has the slab’s subsequent dehydration during subduction
557 (Barriga et al., 1992; Maekawa et al., 1993; Peacock, 1993). Mantle hydrous phases (serpentinites) have also
558 been observed in forearc regions at subduction margins (e.g. Hyndman and Peacock, 2003; Xia et al., 2015;
559 Hansen et al., 2016), further demonstrating that subduction systems transport large amounts of water; however,
560 the amount of water transported is still unknown (Miller et al. 2022). On the other hand, fluid flow in porous
561 media is governed by Darcy’s law, in the opposite direction to the hydraulic head and proportional to the
562 hydraulic permeability. Numerical models (Menant et al., 2019) have been used to determine the path of
563 overpressured fluid flow along the subduction channel, and how strong/weak frictional channels condition the
564 flow (weak frictional channel zones percolate more water upwards compared to strong frictional channel zones).
565 These two domains determine the location of weak and strong coupling zones at the plate contact. Thus,
566 according to basic principles and numerical models, water concentrates in zones of high permeability.
567 The geological record on land shows that, in the Andean margin, TLF are associated with ore deposits
568 clustered at the intersection of magmatic arcs that become progressively younger eastward (Piquer et al.,
569 2016; Yáñez and Rivera, 2019; Piquer et al., 2021a; Farrar et al., 2023; Wiemer et al., 2023), covering the full
570 tectono-magmatic history during the Mesozoic and Cenozoic. Local seismic networks deployed in Northern
571 and Central Chile also show alignments of seismic activity along some TLF systems (Yáñez and Rivera,
572 2019; Piquer et al., 2019, 2021a; Sielfeld et al, 2019; Pearce et al., 2021). These long- and short-term
573 observations indicate the presence of long-lived high-permeability domains along the TLF systems in the
574 Andean margin of Northern and Central Chile. Therefore, we postulate that TLF act as fluid sinks in the
575 forearc region, following a continental-scale fault-valve behaviour, carrying the fluids released by slab
576 dehydration and transported from distal locations through the subduction channel and discharging the fluids
577 upwards and laterally through the TLF. Thus, if the proposed mechanism operates for long periods of time,
578 the fluid distribution at the plate contact should show an uneven distribution of fluid, delimitating domains of
579 weak and strong friction channels, which would act as seismic barriers and asperities, respectively. In this
580 context, the spatial distribution of TLF would be associated with barriers that delimitate the tectonic
581 segmentation. In the proposed model, tremor or swarm seismic activity represent episodic fluid release from
582 TLF that are poorly oriented with respect to the regional tectonic stress — in this case, the NW-striking fault

583 systems oriented at a high angle relative to the ENE convergence direction. This model provides a causal link
 584 between the presence of TLF in the upper plate and the distribution of barrier and asperity domains in the
 585 plate interface. A schematic cartoon of this model is presented in Figure 7.

586 Our proposed conceptual model in which TLF's promote the development of barrier domains along the
 587 subducting margin through the enhancement of fluid pressure complement other process at subduction zones
 588 that also enhances the budget of localized fluids at the plate contact, among them the collision of aseismic
 589 ridges and fracture zones, bending of the subducting plate (e.g. Ranero et al., 2008, Ranero et al., 2005,
 590 Martinez-Loriente et al., 2019; Arai et al., 2024). In the Nazca-South America plate interaction authors had
 591 highlighted this increase in fluids at passive ridges such as the Taltal ridge 33°S (Leon-Rios et al., 2014) and
 592 the Juan Fernandez ridge 33.5°S (Garrido et al., 2002), and fracture zones such as the Challenger Fracture
 593 zone 30°S ((Poli et al., 2017; Maksymowicz, 2015). The volume of fluids in aseismic ridges is enhanced by
 594 oceanic water percolation along the thicker oceanic crust, while in fracture zones as a result of the high
 595 permeability that provides a mechanism to increase water storage prior to the subduction. These
 596 complementary mechanisms share a common origin at the subducting plate, and in the particular case of the
 597 Nazca plate they are oblique to the margin (roughly NE). Thus, the main difference with the proposed model
 598 is their along strike migration with time, while in the proposed mechanism TLF belongs to the overriding
 599 plate.

600 -

601

602
 603 **Figure 7: Schematic conceptual model of fluid transport towards TLF, following different paths in the subduction**
 604 **channel, as well as upwards within the TLF. This model proposes that TLF are sink domains of slab-derived fluids**
 605 **that promote the development of barrier zones and dry out the neighbouring domains where asperities develop.**
 606 **Swarm clustering in spatial association with the TLF represents a mechanism for the quasi-creep release of energy**
 607 **within the barrier zone.**
 608

609 3.3 Implications

610 If TLF act as low-friction domains (barriers) due to their capacity to store fluids released from the subducting
 611 slab and thereby dry out neighbouring zones of the subduction channel, promoting the development of a high-
 612 friction domain (asperity), we can envision a series of implications derived from the proposed model.

613 The most relevant implication is the geological control of barrier zones. This geological control exerted by high-
 614 permeability domains in the continental lithosphere (TLF) implies a spatial control of barrier zones, and thus
 615 the seismotectonic segmentation should be stable for several seismic cycles as long as the capacity of TLF to
 616 store fluids is maintained. If this scenario is correct, the estimate of the seismic risk associated with each
 617 seismotectonic segment can be assessed based on empirical fault-length laws (e.g. Anderson et al., 2016). In
 618 this context, interplate seismic swarms and slow seismic events that develop in the vicinity of TLF zones would
 619 be a mechanism for the steady release of seismic energy.

620 As discussed previously, several TLF have been identified in the Andean margin; however, little is known about
 621 their origin, width, dip, depth extent, and capacity to behave as a water sink. Therefore, further study is needed
 622 to postulate a reliable map of barrier domains in this subduction system.

623 On the other hand, seismic barriers/asperities would be conditioned by the capacity of barrier zones to
 624 mobilise and store fluids, and would thus be relatively stable in space but with a variable behaviour during
 625 several seismic cycles. If the age of the subducted slab conditions the water budget at the plate interface
 626 (Rupke et al., 2004), the progressive age increase from south to north in this margin (from 0 to 45 Ma) would
 627 be a controlling factor for the efficiency of the TLF-barrier hypothesis. Although this implication is highly

628 speculative, the historical record shows that the largest megathrust events at the margin have occurred in
629 Southern Chile, including the 9.3Mw 1960 Valdivia Earthquake, the largest event recorded worldwide.

630

631 4. Conclusions

632 Based on first order geological and geophysical observations of the Nazca-South America plate convergence
633 we propose a conceptual model to understand the tectonic segmentation in the Andean region.

634 Observations include historical seismicity and the associated seismotectonic segmentation. Major thrust events
635 occurred in the region in the last 60 years, defining domains of asperities. GPS and viscous plate coupling that
636 provide independent proxies to establish potential domains of barriers (low plate coupling) and asperities (high
637 plate coupling). Location of low plate coupling domains is further associated with the spatial distribution of
638 peninsulas (less basal erosion) and cumulative seismicity during the inter-seismic period (slow interplate
639 seismic events, creeping, associated with fluid release).

640 Key element in the model is played by trans-lithospheric faults (TLF). Landward, this TLF system concentrate
641 the occurrence of major hydrothermal ore deposits and some active volcanism, denoting their intrinsic high
642 permeability. Thus, at their seaward edge the TLF domains act as sink and release of fluids during the seismic
643 cycle. The fluid is captured from the slab through the subducting channel, and continuously release to the plate
644 contact, promoting the growth of barriers beneath them (excess of fluids), and asperities laterally (reduction in
645 fluid content).

646 If the interaction of first order continental structures and the fluid content of the subducting slab plays a
647 central role in the seismotectonic segmentation of convergence zones, a carefully understanding of the
648 overriding plate geology and associated structures could be instrumental to better understand the associated
649 seismic risk.
