**DALROMS-NWA12 v1.0, a coupled circulation-ice-
biogeochemistry modelling system for the northwest Atlantic
Ocean: Development and validation**

13 **Abstract.** This study presents DalROMS-NWA12 v1.0, a coupled ocean circulation-sea ice-
14 biogeochemistry modelling system for the northwest Atlantic Ocean (NWA) in which the
15 circulation and biogeochemistry modules are based on ROMS (Regional Ocean Modeling
16 System). The circulation module is coupled to a sea ice module based on the Community Ice
17 Code (CICE), and the physical ocean state simulated by the circulation module drives the
18 biogeochemical module. Study of the biological carbon pump in the NWA is one of the main
19 intended applications of this model. Global atmospheric and ocean reanalyses are used
20 respectively to force DalROMS-NWA12 at the sea surface and as part of its lateral boundary
21 input. The modelling system is also forced by tides, riverine freshwater input, and continental
22 runoff. The physical ocean state and sea ice from two simulations of the period 2015–2018, with
23 and without nudging of the simulated temperature and salinity towards a blend of observations
24 and reanalysis, are examined in this study. Statistical comparisons between model results and
25 observations or reanalyses show the control (nudged) simulation outperforms the prognostic (un-
26 nudged) simulation in reproducing the paths of the Gulf Stream and the West Greenland Current,
27 as well as propagation of the estuarine plume in the Gulf of St. Lawrence. The prognostic
28 simulation performs better in simulating the sea ice concentration. The biogeochemical module,
29 which is run only in the control simulation, performs reasonably well in reproducing the
30 observed spatiotemporal variations of oxygen, nitrate, alkalinity, and total inorganic carbon. To
31 examine the effects of tides and sea ice on the physical fields in the study area, results of
32 simulations from which either component is absent are compared to results of the prognostic
33 simulation. In the absence of tides, Ungava Bay in summer experiences a simulated surface
34 salinity that is higher by up to ~7 psu than in the simulation with tides, as well as changes in
35 horizontal distributions of surface temperature and sea ice. Without coupling to the sea ice
36 module, the circulation module produces summertime sea surface temperatures that are higher by
37 up to ~5°C in Baffin Bay.

38 **1 Introduction**

39 The northwest North Atlantic Ocean (hereafter NWA) is characterized by interactions among
40 physical and biogeochemical processes that affect the global atmosphere-ocean system. Air-to-
41 sea flux of CO₂ per unit area is estimated to be largest in the world in the Atlantic Ocean north of
42 50° N, due to factors such as strong winds in winter and high primary production in spring
43 (Takahashi et al., 2009). The sinking of particles formed during primary production has the effect
44 of transporting atmospheric CO₂ to the deep ocean and is referred to as the biological carbon
45 pump (BCP; Volk and Hoffert, 1985). The BCP is influenced by various physical processes over
46 an annual cycle. The presence of sea ice in winter can, on one hand, drive upward transport of
47 nutrients through brine rejection-induced vertical mixing (Jin et al., 2018) but on the other hand
48 can reduce wind-induced mixing (Rainville et al., 2011) and attenuate the solar radiation
49 (Legendre et al., 1992) by isolating the water column from the atmosphere. Seasonal changes of
50 the mixed layer depth is another physical process that governs the BCP. Shoaling of the layer in
51 spring, driven by freshwater input from runoff and sea ice, promotes primary production (Wu et
52 al., 2007 and 2008; Frajka-Williams and Rhines, 2010), while deepening of the layer in winter
53 can result in entrainment of dissolved inorganic carbon and respiratory CO₂ that had been in
54 shallow sub-surface waters (Körtzinger et al., 2008). In the Labrador Sea, deep convection in
55 winter is thought to be an additional pathway for removal of carbon from near-surface waters
56 (Tian et al., 2004).

57 Several field programs have been conducted to quantify the major processes at work in the
58 NWA, such as the Labrador Sea Deep Convection Experiment (The Lab Sea Group, 1998),
59 which focused on atmospheric and physical oceanographic processes, and the Atlantic Zone
60 Monitoring Program (Pepin et al., 2005) and its off-shelf counterpart (e.g., Yashayaev and Loder,
61 2017), which have made regular shipboard measurements of physical and biogeochemical (BGC)
62 fields at fixed locations. Simultaneous measurements of physical and BGC fields at moorings
63 (e.g., Martz et al., 2009; Strutton et al., 2011) and by profiling floats (e.g., Yang et al., 2020;
64 Wang and Fennel 2022) have expanded the coverage of observations, which is crucial given the
65 spatiotemporal variability in the processes that govern the BCP (Garçon et al., 2001).

66 Process-based numerical models can complement observations of oceanic processes by
67 providing four-dimensional estimates of relevant fields and by enabling experiments in which the
68 effects of key inputs are isolated or the future state of oceans under various climate scenarios are
69 simulated (Fennel et al., 2022). Early numerical studies of the NWA using coupled ocean
70 circulation-sea ice models focused mainly on specific processes, such as climatological sea ice
71 conditions (Mysak et al., 1991), sea ice variabilities on the interannual (Ikeda et al., 1996) and
72 intra-seasonal (Yao et al., 2000) time scales, and changes in sea ice and mixed layer properties
73 under different atmospheric conditions (Tang et al., 1999). As process-based numerical models
74 grew in complexity they yielded new insights, such as the role of sea ice's heat capacity in the
75 timing of ice melt (Zhang et al., 2004). Advances in computational power have led to realistic
76 simulations spanning a decade or more covering limited areas, such as the Canadian Arctic
77 Archipelago and Davis Strait (Lu et al., 2014) or the Labrador and Newfoundland Shelves (Ma et
78 al., 2016). Other ocean-ice models of areas within the NWA include that of the Gulf of St.
79 Lawrence and surrounding waters (Urrego-Blanco and Sheng, 2014; Wang et al., 2020), Hudson
80 Bay (Saucier et al., 2004), and the Labrador Sea (Pennelly and Myers, 2020). Canadian
81 government agencies have developed coupled ocean-ice or atmosphere-ocean-ice models to
82 support activities such as hazard management, with domains ranging from the regional (e.g.,
83 Smith et al., 2013 for the Gulf of St. Lawrence) to basin-wide (Dupont et al., 2015; Wang et al.,
84 2018). Other modelling studies have focused on hydrodynamics in coastal and shelf waters of the
85 NWA, such as Han et al. (1997) for the Scotian Shelf, Wu et al. (2012) for the area between the
86 Gulf of Maine and Baffin Bay, and Chen and He (2015) for the Mid-Atlantic Bight and the Gulf
87 of Maine.

88 As for coupled physical-BGC modelling studies, three-dimensional models with high resolutions
89 have generally focused on the shelf and slope areas of the NWA. Pei (2022) used a simple
90 oxygen model to study seasonal changes in dissolved oxygen over the Scotian Shelf, while more
91 complex models have been used to study the biogeochemistry and plankton dynamics of the
92 Scotian Shelf and surrounding waters (Laurent et al., 2021, Rutherford and Fennel, 2022) and the
93 Gulf of St. Lawrence (LeFouest et al., 2010; Lavoie et al., 2021). Ross et al. (2023) developed a
94 coupled physical-BGC model for the North Atlantic Ocean from the Caribbean Sea to the
95 southern Labrador Sea, designed primarily for marine resource management.

97 As coupled simulations that include more processes and cover larger extents of space and time
98 become feasible, they are expected to enhance our understanding of how the ocean functions as
99 an integrated system, as well as how this system might change under various scenarios of the
100 future climate. In this study, we present and assess a coupled ocean circulation-sea ice-BGC
101 model that has been developed recently with the primary goal of studying the interactions
102 between physical and BGC processes in the NWA, including the BCP. Advantages of this
103 model's configuration include: (a) a domain that spans the area from the Mid-Atlantic Bight to
104 Baffin Bay, allowing for a wide range of oceanographic processes that can be examined; (b) a
105 horizontal grid size of $O(1\text{ km})$ that decreases with latitude, such that the first baroclinic Rossby
106 radius of deformation (Chelton et al., 1998) is spanned by about four grid boxes everywhere; (c)
107 the use of a terrain-following vertical coordinate system, which can produce more realistic near-
108 bottom vertical mixing and bottom boundary layer structures than the step-wise bottom
109 topography of z-level grids (Ezer and Mellor, 2004); (d) the inclusion of tides (as one of the
110 model inputs) and sea ice (through coupling between the circulation and sea ice modules), both
111 of which are important elements of the ocean system in this region, and (e) the inclusion of a
112 BGC module, which enables the study of how processes such as the BCP are driven by the
113 coupled ocean circulation-sea ice system. This paper provides an assessment of the coupled
114 model's performance as well as sensitivity studies designed to elucidate the role of two physical
115 processes, tides and sea ice. The components of the coupled model and the simulations are
116 described in the next section. In Sect. 3, the results of two simulations, with and without nudging
117 of the temperature and salinity towards a blend of observations and reanalysis (referred to
118 respectively as the control and prognostic simulations), are described and quantitatively
119 compared to observations or reanalysis. [In addition, depth vs. time plots of simulated](#)
120 [temperature are used to qualitatively assess the model's performance in reproducing the effects](#)
121 [of winter convection in the Labrador Sea.](#) In Sect. 4, the roles of tides and sea ice in the physical
122 fields of the NWA are examined by comparing the results of two additional simulations, one
123 without tidal forcing and the other without the simulation of sea ice, to results of the prognostic
124 simulation described in Sect. 3. A summary of our findings is presented in the concluding
125 section.

126 **2 Model setup and forcing**

127 The coupled circulation-sea ice-BGC modelling system used in this study consists of three
128 modules: an ocean circulation module based on ROMS (Regional Ocean Modeling System,
129 version 3.9; Haidvogel et al., 2008), a sea ice module based on CICE (Community Ice Code,
130 version 5.1; Hunke et al., 2015), and a BGC module within ROMS based on the work of Fennel
131 et al. (2006, 2008) with updates as described by Laurent et al. (2021). The circulation and sea ice
132 modules are coupled using the software MCT (Model Coupling Toolkit, version 2.10; Jacob et
133 al., 2005; Larson et al., 2005) in a manner similar to Kristensen et al. (2017). Yang et al. (2023)
134 found good agreement between simulated and observed values of tides and storm surges
135 simulated by a barotropic version of the ocean circulation module.

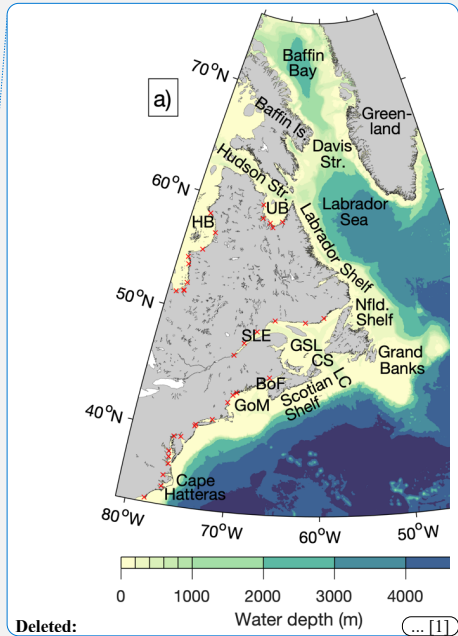

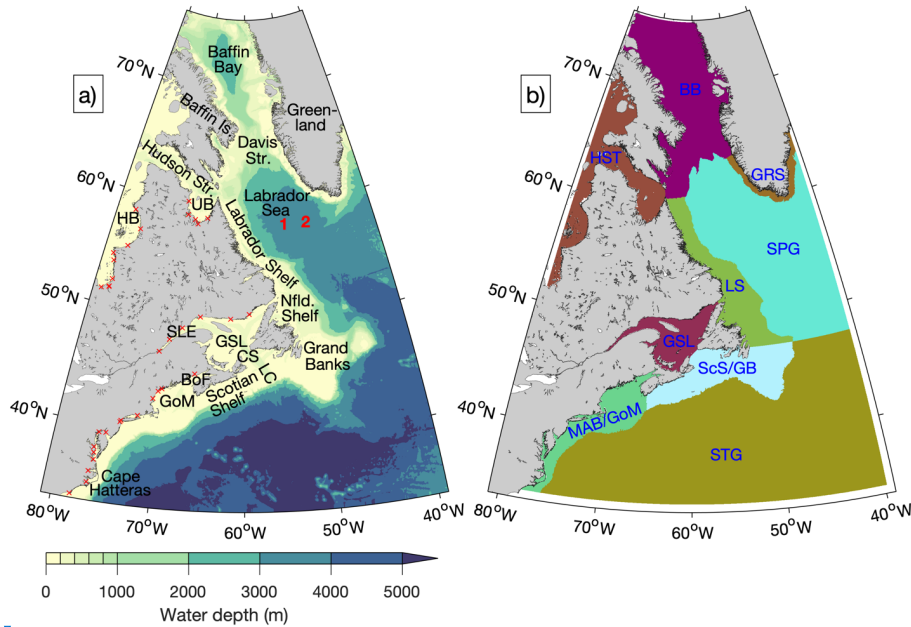

136 ROMS is a three-dimensional (3D) numerical circulation model with a free surface and the
137 terrain-following S-coordinate system (originally developed by Song and Haidvogel (1994)) in
138 the vertical. The vertical layers are placed more densely near the surface and bottom in deep
139 waters, and more uniformly in shallow waters. In this study ROMS has 40 vertical S-layers,
140 whose configuration is described in Appendix A. ROMS and CICE use the same horizontal grid
141 and bathymetry, with the domain covering the area between $\sim 81^\circ$ W and $\sim 39^\circ$ W and between
142 $\sim 33.5^\circ$ N and $\sim 76^\circ$ N (Fig. 1a). The grid resolution in the east-west direction is $1/12^\circ$, resulting
143 in grid box dimensions of ~ 8 km on each side near the grid's southern boundary and ~ 2 km on
144 each side near the northern boundary.

145 The model bathymetry is derived from the $1/240^\circ$ -resolution data set GEBCO_2019 (GEBCO
146 Compilation Group, 2019). After the GEBCO data were linearly interpolated onto the model
147 grid, the Shapiro filter (Shapiro, 1975) was applied to seamounts in deep waters from $\sim 67.5^\circ$ W
148 to $\sim 42^\circ$ W and from $\sim 34^\circ$ N to $\sim 48^\circ$ N to reduce currents caused by spurious pressure gradients.
149 No other smoothing was applied to the bathymetry. To avoid model instability caused by strong
150 currents entering the model domain at an angle, the model bathymetry and land-sea mask in the
151 first four grid boxes from each lateral boundary were set to the same values as in the fifth grid
152 box from the boundary.

153 The advection schemes used in ROMS for physical fields are: (a) the third-order upstream
154 scheme for horizontal advection of physical tracers and 3D momentum and (b) the fourth-order

155 centered scheme for horizontal advection of two-dimensional momentum and for vertical
 156 advection of physical tracers and 3D momentum. The horizontal eddy viscosity and diffusivity in
 157 ROMS are set to zero because the third-order upstream scheme generates some numerical
 158 diffusion which is large enough to eliminate small-scale features associated with numerical
 159 noise. Vertical mixing is parameterized using the “2.5-level” scheme of Mellor and Yamada
 160 (1982) with modifications as described by Allen et al. (1995). The time step is 6 seconds for the
 161 external (barotropic) mode and 120 seconds for the internal (baroclinic) mode.

 163 **Figure 1. (a)** Model domain and bathymetry. Locations of river mouths are indicated by red X marks. Locations for
 164 which depth profiles of simulated temperature are shown in Fig. 16 are indicated by numbers in red. Abbreviations
 165 are used for: Island (Is.), Strait (Str.), Hudson Bay (HB), Ungava Bay (UB), Newfoundland (Nfd.), St. Lawrence
 166 Estuary (SLE), Gulf of St. Lawrence (GSL), Cabot Strait (CS), Laurentian Channel (LC), Bay of Fundy (BoF), and
 167 Gulf of Maine (GoM). **(b)** Regions in which metrics of model performance are calculated. The regions are: GRS
 168 (Greenland Shelf), HST (Hudson Strait), BB (Baffin Bay), LS (Labrador Shelf), SPG (Subpolar Gyre), GSL (Gulf of
 169 St. Lawrence), ScS/GB (Scotian Shelf/Grand Banks), MAB/GoM (Mid-Atlantic Bight/Gulf of Maine), and STG
 170 (Subtropical Gyre). Areas within 10 grid points of lateral boundaries are excluded from the error metric calculations.

177 Atmospheric fields used to drive the coupled model are derived from the hourly reanalysis data
178 set [known as ECMWF Reanalysis v5 \(ERA5; Hersbach et al., 2018\)](#) which has a horizontal grid
179 spacing of 1/4°. Within ROMS, the bulk flux scheme of Fairall et al. (1996a, 1996b) is used to
180 calculate the surface fluxes of heat and fresh water. Lateral open boundary conditions are
181 specified using the explicit scheme of Chapman (1985) for sea surface elevation, the Shchepetkin
182 scheme (Mason et al., 2010) for [the normal component and the implicit scheme of Chapman](#)
183 [\(1985\) for the tangential component of](#) depth-averaged currents, and the adaptive scheme of
184 Marchesiello et al. (2001) for [the normal and tangential components of](#) depth-varying currents as
185 [well as](#) all tracers. In the adaptive boundary condition, the nudging time scale is three days for
186 inflow and 360 days for outflow. The values of currents, temperature, salinity, and sea surface
187 elevation specified at the lateral boundaries are derived from the daily [fields of Copernicus](#)
188 [global 1/12° oceanic and sea ice reanalysis \(GLORYS12V1, hereafter GLORYS; Lellouche et](#)
189 [al., 2021\) for the simulation period.](#) [In order to ensure that the simulated ocean states near lateral](#)
190 [open boundaries are as realistic as possible,](#) the lateral boundary conditions of currents,
191 temperature, and salinity are supplemented by nudging the simulated values near boundaries
192 towards GLORYS values. The nudging time scale is three days at the grid point closest to a
193 lateral boundary and decreases linearly to zero over ten grid points moving away from the
194 boundary. Tidal elevation and currents are specified at the lateral boundaries from the global tidal
195 model solution TPXO9v2a (an updated version of the model by Egbert and Erofeeva (2002)),
196 with a horizontal grid size of 1/6° and 15 tidal constituents.

197 Riverine freshwater input from 35 rivers (Table 1) is specified as volume flux through the bottom
198 of a model grid cell (www.myroms.org/forum/viewtopic.php?t=5156). Each river is represented
199 by a channel normal to the model's coastline, at the head of which the surface elevation, vertical
200 velocity, and tracer values are adjusted according to the river discharge. The river water has a
201 salinity of 0.4 [psu \(salinity in the Practical Salinity Scale is dimensionless but we use the unit](#)
202 [“psu” for clarity\)](#) and a temperature equal to that of the GLORYS sea surface temperature at the
203 grid point closest to the river mouth. For the St. Lawrence River, we use the monthly-mean
204 discharge at Quebec City estimated by the St. Lawrence Global Observatory (2023) using the
205 regression model of Bourgault and Koutitonsky (1999). For all other rivers, we use the monthly-
206 mean data set of Dai (2017) that was updated in May 2019, substituting climatological values

217 calculated over the period 1900–2018 for months with no data. Freshwater flux across coastlines
 218 due to the melting of ice and snow over land is specified as an addition to the sea surface height
 219 and the surface freshwater flux at the appropriate model grid boxes. This freshwater flux is
 220 derived from the monthly data set of Bamber et al. (2018), who combined satellite observations
 221 of glaciers with the output of a regional climate model. A monthly climatology of this data set,
 222 which covers the period 1958–2016, is used in simulations of the period after December 2016.
 223 Both the riverine and continental freshwater fluxes are converted to “pseudo-means” (monthly

225 means that are adjusted such that daily-mean values temporally interpolated from them, when
226 summed over a month, results in the true monthly means) following Killworth (1996). [Another](#)
227 [source of salt/freshwater flux at the sea surface is sea ice, which is a source of salt through brine](#)
228 [rejection at the time of freezing and a source of fresh water at the time of melting. Lateral](#)
229 [movement of sea ice results in these two surface fluxes occurring at different locations.](#)

230 The sea ice model CICE consists of four main components: (a) a thermodynamic component that
231 calculates local growth or decay of sea ice due to snowfall and heat fluxes (Bitz and Lipscomb,
232 1999; Briegleb and Light, 2007); (b) a dynamic component that calculates the material properties
233 of the ice (Hunke and Dukowicz, 1997; Bouillon et al., 2013); (c) a transport component that
234 calculates the horizontal advection of the ice (Lipscomb and Hunke, 2004); and (d) a component
235 that calculates the distribution of ice among thickness categories due to ridging and mechanical
236 processes (Hunke et al., 2015). There are seven ice layers and five ice thickness categories. We
237 implemented the clamped boundary condition, in which GLORYS-derived values of sea ice
238 concentration (as a fraction of the model grid box area) and thickness are specified at the model's
239 lateral open boundaries. The sea ice specified at the lateral boundaries is uniformly covered with
240 snow of 0.2-m thickness. The time step in CICE is 1200 seconds.

241 Coupling between ROMS and CICE via MCT occurs every 1200 seconds, equivalent to every 10
242 internal time steps in ROMS and every time step in CICE. At each coupling step, ROMS sends
243 CICE the ERA5-derived atmospheric fields that drive both modules, as well as ROMS-simulated
244 values of currents, sea surface tilt, and sea-surface values of temperature and salinity. CICE
245 sends ROMS the ice-attenuated value of shortwave radiation and ice-ocean fluxes of stress, heat,
246 and salt or freshwater.

247 The BGC module includes the nitrogen cycle (Fennel et al., 2006), the carbonate system (Fennel
248 et al., 2008), and oxygen (Fennel et al., 2013). Particulate organic matter variables
249 (phytoplankton, zooplankton, and detritus) are split into small and large size classes, and rates of
250 biological processes are temperature-dependent (Laurent et al., 2021). The HSIMT advection
251 scheme (Wu and Zhu, 2010), which ensures no spurious negative values occur, is used for both
252 horizontal and vertical advection of BGC tracers. Initial and boundary conditions for nitrate,
253 phosphate, dissolved inorganic carbon, alkalinity, and oxygen are interpolated from the

254 climatology of GLODAP (Global Ocean Data Analysis Project; Lauvset et al., 2021) and set to a
255 small constant value for all other biogeochemical variables.

256 Four simulations will be examined in this paper. In the control simulation (hereafter Ctrl), the
257 ocean temperature and salinity at all grid points are nudged with a restoring time scale of 60 days
258 toward the monthly data set of in situ observations known as CORA (CORiolis dataset for Re-
259 Analysis; Cabanes et al., 2013) above the 2000-m depth and GLORYS below 2000 m (where
260 CORA data are not available). The control simulation includes biogeochemistry. The second
261 simulation is a prognostic one (hereafter Prog), i.e., without any nudging of the simulation. There
262 are three reasons for presenting these simulations: 1) the ways in which either simulation
263 outperforms the other can shed light on potential ways in which the model can be improved; 2)
264 Ctrl, by including nudging of the temperature and salinity, produces a physical state of the ocean
265 that is generally realistic and acts as a foundation for the biogeochemical simulation; and 3) this
266 modelling system is being used in regional climate simulations (Renkl et al., in prep.), and the
267 lack of an option to nudge simulations of future conditions necessitates assessment of a
268 prognostic simulation. The performances of Ctrl and Prog will be evaluated in the next section.
269 Two more simulations are carried out for the sensitivity studies discussed in Sect. 4. Both are
270 identical to Prog but one is made without the specification of tidal elevation and currents at the
271 lateral boundaries (hereafter NoTides) and the other is made without coupling of ROMS to CICE
272 (hereafter NoIce). Configurations of the simulations are summarized in Table 2. All simulations
273 are made from 1 September 2013 to 31 December 2018 and are initialized with an ice-free ocean
274 in which the ocean's state consists of GLORYS fields for 1 September 2013 interpolated to the
275 model grid. The simulation results of January 2015 onwards (December 2014 onwards in the
276 case of seasonal averages) will be discussed in the following sections.

277 **Table 2.** Descriptions of the simulations discussed in this study.

Simulation name	Description	Temperature & salinity nudging	Tidal forcing at lateral boundaries	Coupling to sea ice model
Ctrl	Control	On	On	On
Prog	Prognostic	Off	On	On
NoTides	No tidal forcing	Off	Off	On
NoIce	No sea ice simulation	Off	On	Off

278 **3 Model results and evaluation**

279 **3.1 Simulated currents, temperature, and salinity**

280 We first examine four-year (1 January 2015–31 December 2018) averages of currents, salinity,
 281 and temperature produced by DalROMS-NWA12 v1.0 in runs Ctrl and Prog (Figs. 2 and 3
 282 respectively). Both model runs reproduce the major features of the circulation in this region.
 283 They include: (a) the East and West Greenland Currents forming a clockwise flow around the
 284 southern tip of Greenland; (b) bifurcation of the West Greenland Current, with one branch
 285 continuing northward along the west coast of Greenland and the other flowing westward across
 286 the Labrador Sea; and (c) the westward flow across the Labrador Sea merging with the
 287 southward Baffin Island Current out of Baffin Bay and southeastward flow out of Hudson Strait
 288 to form the Labrador Current, the equatorward limb of the North Atlantic Subpolar Gyre. This
 289 current has branches along the Labrador coast and the shelf break. Near the Grand Banks, the
 290 Labrador Current meets the poleward Gulf Stream, the poleward limb of the North Atlantic
 291 Subtropical Gyre. Both simulations also reproduce the relatively cold and fresh water over
 292 continental shelves, with especially low values of salinity in Hudson Bay and the St. Lawrence
 293 Estuary. The three major differences between the simulations are that: (a) the bifurcation of the
 294 West Greenland Current has a stronger northward branch in Prog; (b) the Gulf Stream in Prog is
 295 closer to the continental shelf; and (c) the Gulf of St. Lawrence is warmer and saltier in Prog,
 296 both at the surface and in model results interpolated to the 100-m depth. As discussed below,
 297 comparison of model results to observations or reanalysis suggests the results of Ctrl are more
 298 realistic than those from Prog. Seasonal-means of these simulated fields, shown in Appendix B,
 299 indicate that differences between the simulations are more prominent in summer than in winter.

300 **3.2 Model performance for currents, temperature, and salinity**

301 To assess the model’s performance in simulating currents, temperature, and salinity, we divide
302 the model domain into nine regions (Fig. 1b) and calculate metrics in each region for model
303 results at the sea surface and interpolated to the 100-m depth. Within a given region, each model
304 grid point is weighted by its horizontal area when regional averages are calculated. The areas
305 along the model’s lateral boundaries in which the simulated tracers and currents are nudged
306 towards GLORYS are not included in the calculations.

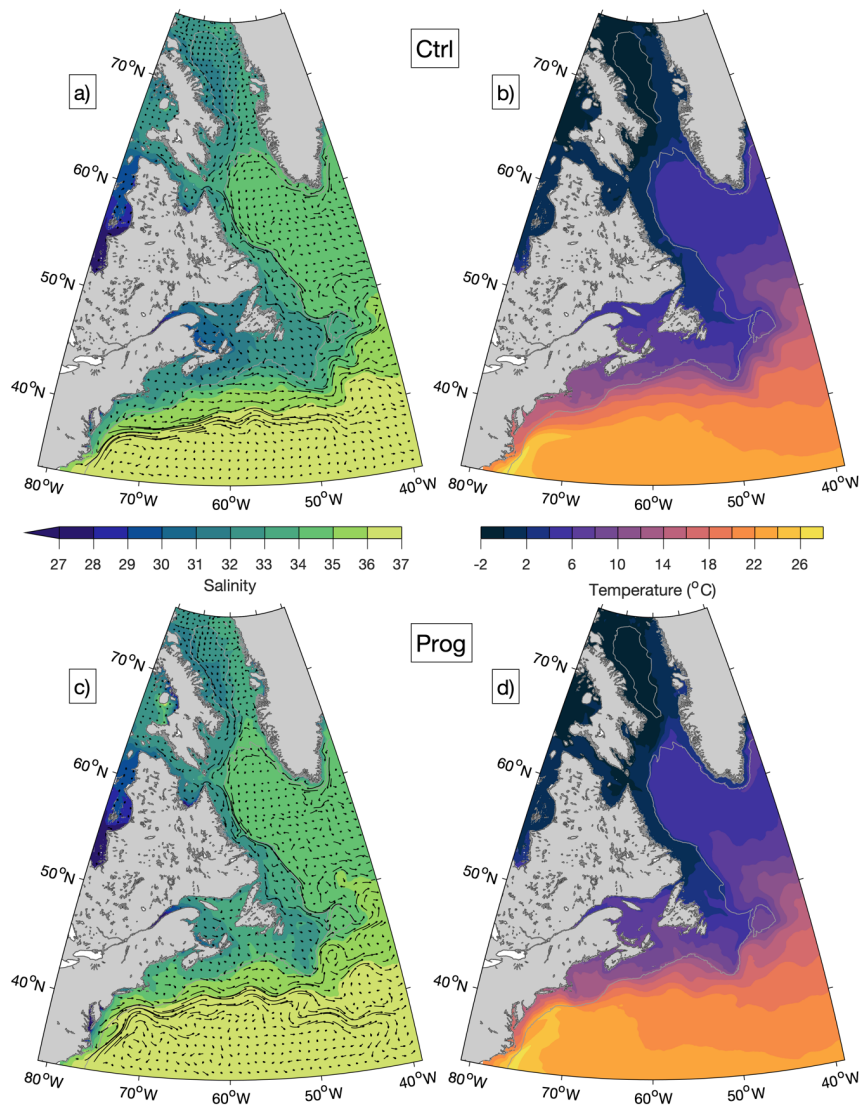

307 To quantify model performance for temperature and salinity at the sea surface, root-mean-square
308 errors (RMSE) of monthly-mean model results are calculated with respect to monthly means of
309 observations that are linearly interpolated to the model grid. Temperature and salinity at the
310 surface are compared to 1/4°-grid analysed data sets that combine satellite and in situ
311 observations: the daily data set OISST (Optimum Interpolation Sea Surface Temperature, v2.0
312 for 2015–2017 and v2.1 for 2018; Huang et al., 2021) for temperature and the weekly data set
313 SMOS (Soil Moisture Ocean Salinity; Buongiorno Nardelli et al., 2016) for salinity. For model
314 results interpolated to the 100-m depth, where gridded observational data sets are not available,
315 root-mean-square differences (RMSD) of temperature and salinity are calculated with respect to
316 their respective GLORYS values. It should be noted that GLORYS is based on simulations that
317 do not include tides (Lellouche et al., 2018), which may affect the accuracy of its temperature
318 and salinity distributions in addition to that of its currents, particularly over areas with strong
319 tidal currents. It should also be noted that the oceanographic observations used in generating
320 GLORYS are highly sparse in both time and space. As a result, data assimilation cannot
321 eliminate biases associated with the exclusion of tidal forcing in the monthly mean fields of
322 GLORYS. ▾

323 The RMSE and RMSD of temperature from the two simulations (Figs. 4–5) are similar over the
324 northern part of the model domain in that the largest errors tend to occur at the surface in GRS
325 (Greenland Shelf) throughout the year, and in HST (Hudson Strait) and BB (Baffin Bay) during
326 the summer. Within these three areas, the largest values of RMSE/RMSD occur in HST at the
327 surface (about 3.5°C in Ctrl and 2.9°C in Prog, both in July). The corresponding biases of surface
328 temperatures (not shown) indicate a tendency for overestimation (+0.3°C–+2.2°C in GRS, and -
329 0.4°C–+1.9°C and -0.5°C–+1.0°C during summer in HST and BB respectively for Prog). Thus,

347
348
349
350

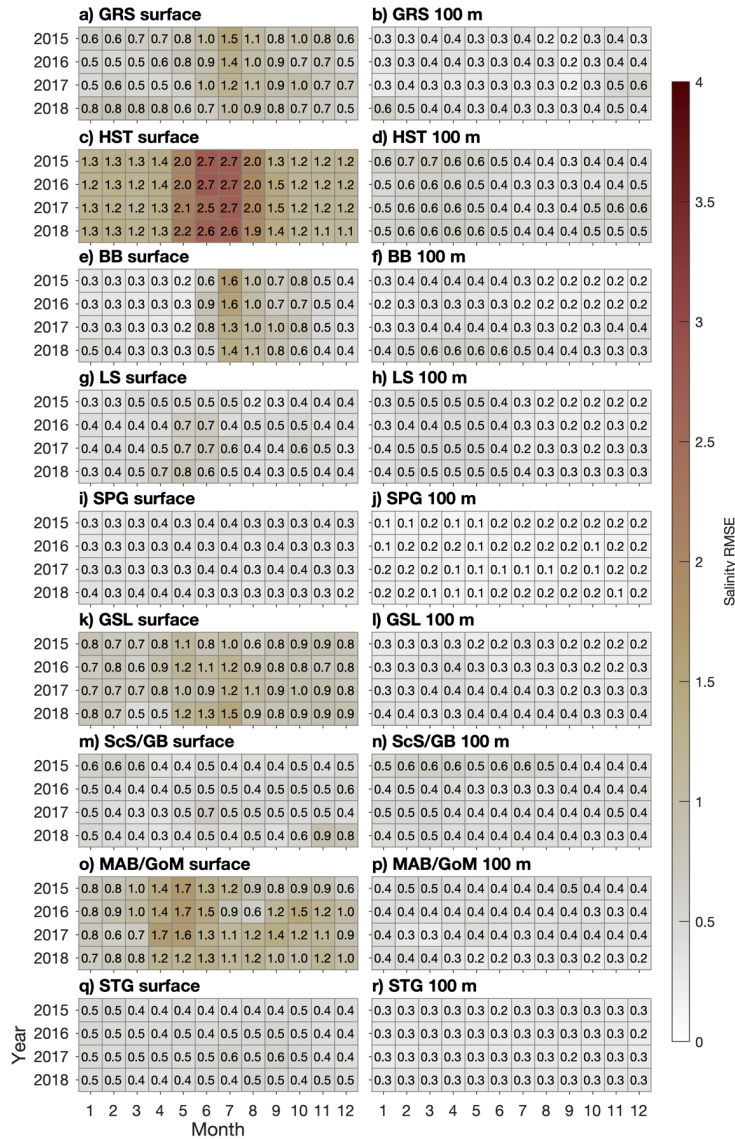

Figure 5. Similar to Fig. 4 but for temperatures simulated in Prog.

351 the largest errors occur near the model's lateral open boundaries, during periods when sea ice
352 (which would tend to keep the temperature near freezing) is less in HST and BB, and at the
353 surface where the performance metrics are calculated with respect to an independent
354 observational data set instead of GLORYS which is also used as lateral boundary input. This
355 suggests GLORYS as a possible source of model errors, although a detailed examination is
356 beyond the scope of this study. The slightly larger RMSE of the simulated surface temperature in
357 Ctrl than in Prog over these areas may be related to the larger underestimation of sea ice in Ctrl,
358 which will be discussed in Sect. 3.3.

359 Further south, in SPG (Subpolar Gyre), the RMSE/RMSD are smaller in Ctrl than in Prog. The
360 RMSE at the surface has the range of 0.6–1.6°C in Ctrl and 0.9–2.1°C in Prog, and the RMSD for
361 model results interpolated to the 100-m depth has the range of 0.7–1.4°C in Ctrl and 0.9–2.0°C in
362 Prog. This suggests the West Greenland Current simulated in Ctrl, in which the branch of the
363 current that separates from the Greenland coast dominates, and its associated temperature
364 distribution are more realistic. The RMSE/RMSD in LS (Labrador Shelf) are similar between the
365 simulations, ranging from 0.4 to 1.9°C in Ctrl and from 0.4 to 1.4°C in Prog.

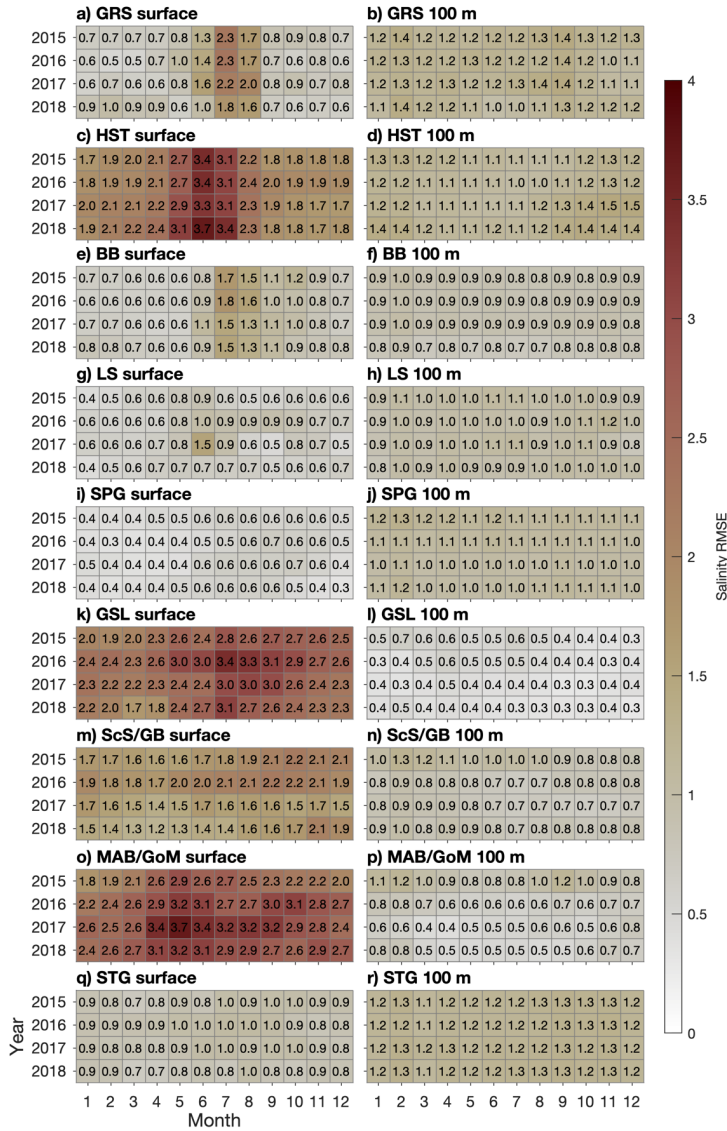

366 The results of Ctrl clearly outperform those of Prog over the southern part of the model domain,
367 with a maximum RMSE/RMSD of ~2.5°C in the former and ~5.2°C in the latter, both occurring
368 in ScS/GB (Scotian Shelf/Grand Banks) for model results interpolated to the 100-m depth. This
369 indicates the Gulf Stream simulated in Ctrl, flowing further from the coast than in Prog (Figs. 2–
370 3), is more realistic. In addition to STG (Subtropical Gyre) where the Gulf Stream itself flows,
371 the RMSE/RMSD in Ctrl are smaller both at the surface and the 100-m depth in ScS/GB,
372 MAB/GoM (Mid-Atlantic Bight/Gulf of Maine), and GSL (Gulf of St. Lawrence), all of which
373 are influenced by the warm and salty slope water of which the Gulf Stream water is one
374 component (Gatien, 1976). The influence of the slope water extending into the GSL at the 100-m
375 depth (which can also be seen in Fig. 3) is consistent with the observed (e.g., Richaud et al.,
376 2016) intrusion of slope water into the Gulf of St. Lawrence along the Laurentian Channel.

377 The RMSE and RMSD of salinity for both simulations (Figs. 6–7) in the northern part of the
378 domain are similar to those of temperature in that they tend to be largest at the surface in
379 summer, especially in HST where the RMSE has maximum values of ~2.7 psu in Ctrl and ~3.7

380
381
382
383
384

Figure 6. Root-mean-square-errors/differences of salinity (psu) simulated in Ctrl, calculated for the regions shown in Fig. 1b with respect to the observation-derived SMOS data set at the surface and GLORYS reanalysis for model results interpolated to the 100-m depth.

385
386
387
388

Figure 7. Similar to Figure 6 but for salinity simulated in Prog.

389 psu in Prog. In contrast to the temperature metrics, the surface salinity metrics in GRS undergo
390 an annual cycle similar to those in HST and BB, being larger during summer and fall than during
391 the rest of the year. During the months when the RMSE are largest, the surface salinity biases for
392 Prog are negative in GRS and BB (~-1.0 psu) and positive in HST (up to ~+1.5 psu). In SPG and
393 LS the RMSE/RMSD are generally smaller in Ctrl than in Prog (0.1–0.8 psu for Ctrl and 0.4–1.5
394 psu in Prog for the two regions combined), which is consistent with the metrics for temperatures
395 discussed above.

396 In the southern part of the domain, Ctrl has much smaller RMSE than Prog in GSL, ScS/GB, and
397 MAB/GoM (e.g., the maximum value is ~1.7 psu for Ctrl and ~3.7 psu for Prog in MAB/GoM).
398 The corresponding biases for Prog in these areas are consistently positive (up to ~+3.3 psu in
399 GSL), indicating overestimation. However, within GSL, the 2015–2018 mean of summer surface
400 salinity simulated by Prog is lower than its counterpart from Ctrl by up to ~3.5 psu in the St.
401 Lawrence Estuary, but higher by ~2.0 psu further downstream in the Gulf of St. Lawrence (not
402 shown). This suggests the model is not able to fully reproduce the propagation of low-salinity
403 water from the St. Lawrence Estuary (where the salinity is underestimated) to areas downstream
404 of it (where the salinity is overestimated).

405 A possible cause of this discrepancy between observed and simulated salinity values in the St.
406 Lawrence Estuary-Gulf system is spurious diapycnal mixing generated by the third-order
407 upstream advection scheme used for tracers in this study (Marchesiello et al., 2009). We found
408 that switching to the fourth-order Akima scheme (with a horizontal eddy diffusivity of 5 m² s⁻¹)
409 leads to more realistic simulations of three-dimensional salinity distributions and sea ice
410 distributions in the Gulf, but this option was not pursued further because the scheme is prone to
411 over- or under-shooting, which resulted in patches of unrealistic tracer values in areas such as the
412 Grand Banks where strong horizontal gradients occur. The same problem was reported by
413 Naughten et al. (2017) in simulating circulation in the Southern Ocean using ROMS and CICE.
414 A potential solution is a fourth-order advection scheme with a flux limiter to eliminate the
415 spurious over- and under-shooting, as demonstrated by Sheng (2002) for a z-level ocean model.

416 For currents, the model performance is evaluated using a metric known as ε^2 (Schwab et al.,
417 1989; Urrego-Blanco and Sheng, 2014):

Deleted: produced

Deleted: that were generally more realistic

$$\varepsilon^2 = \frac{\sum_{i=1}^N [(u_i^O - u_i^O - u_i^M + u_i^M)^2 + (v_i^O - v_i^O - v_i^M + v_i^M)^2]}{\sum_{i=1}^N [(u_i^O - u_i^O)^2 + (v_i^O - v_i^O)^2]}, \quad (1)$$

430 where the superscripts *O* and *M* denote observed and simulated values respectively, overbars
 431 denote spatial averaging over each validation region, and the summation is made over the
 432 validation region. Thus, this metric combines errors for the zonal and meridional current
 433 components and assesses model performance in terms of spatial averages as well as at individual
 434 points, with a value of zero corresponding to perfect agreement between model results and
 435 observations. The metric is calculated with respect to GLORYS both at the surface and for model
 436 results interpolated to the 100-m depth.

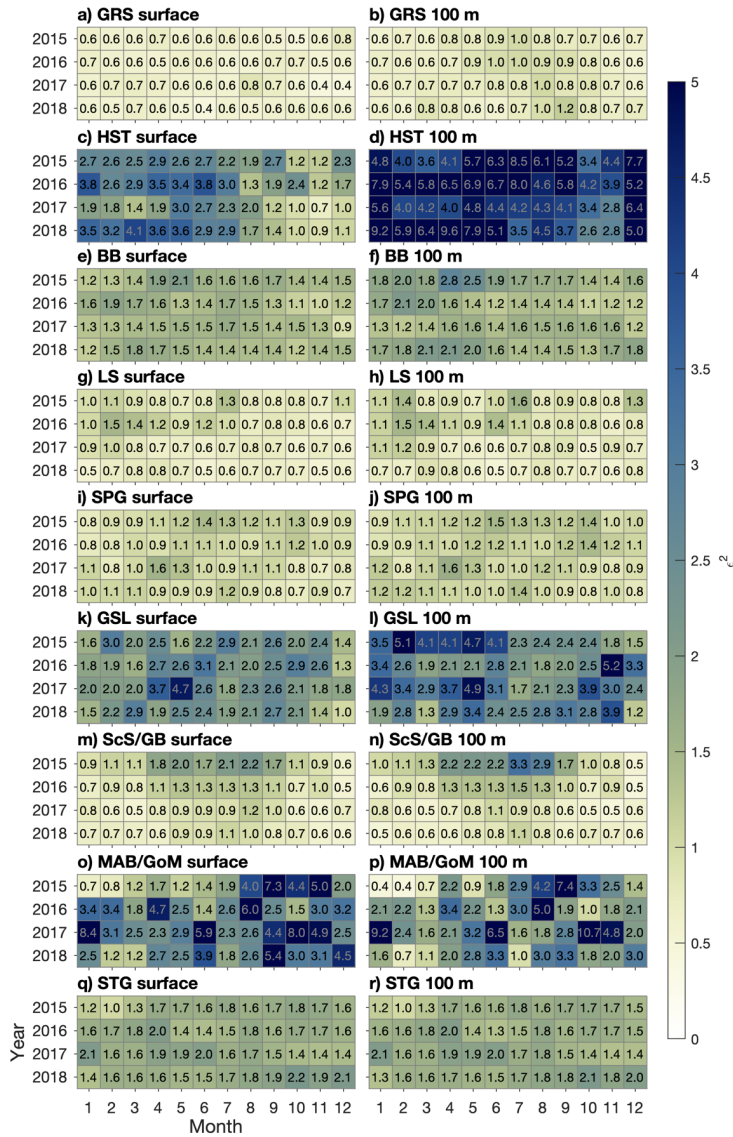

437 For both simulations, values of ε^2 (Figs. 8–9) in the southern part of the model domain are
 438 generally smaller in Ctrl than in Prog (e.g., about 0.7–1.3 for Ctrl vs. 1.0–2.2 for Prog in STG),
 439 consistent with the more realistic simulation of the Gulf Stream due to the nudging of salinity
 440 and temperature in Ctrl. In SPG and LS, values of ε^2 are similar between the regions and smaller
 441 in Ctrl than in Prog (about 0.4–1.1 in Ctrl and 0.5–1.6 in Prog for the two regions combined).
 442 This suggests the Labrador Current is more realistic in Ctrl than in Prog, which is consistent with
 443 the conclusion drawn from the temperature metrics that the separation of the West Greenland
 444 Current from the Greenland coast is simulated more accurately in Ctrl.

445 The model errors for both runs are largest in HST, mostly due to the southeastward flow along
 446 the south side of Hudson Strait being stronger in the model than in GLORYS (not shown).
 447 Taking as an example the 2015–2018 mean of monthly-mean currents produced by Prog in
 448 September, the southeastward flow is stronger than that in GLORYS by $\sim 0.25 \text{ m s}^{-1}$ at the surface
 449 and $\sim 0.15 \text{ m s}^{-1}$ at the 100-m depth. One possible reason for this large discrepancy is that the
 450 model is likely to be unable to accurately simulate the circulation in Hudson Bay, which is the
 451 source of the southeastward flow through Hudson Strait. Circulation in the Bay consists of
 452 several gyres and is sensitive to river discharge (Ridenour et al., 2019). Our model domain
 453 includes only the eastern part of the Bay (Fig. 1a) and, due to a lack of observations, we use
 454 climatological discharge (mostly calculated from observations in the 1960s or 1970s) for all but
 455 one of the ten rivers emptying into the eastern Bay; these factors cast doubt on the model’s
 456 ability to realistically simulate the flow within and out of the Bay.

461
462
463
464

Figure 9. Similar to Fig. 8 but for currents simulated in Prog.

465 It should also be noted that Hudson Strait is characterized by tides of typically 3–6 m in
466 amplitude (Drinkwater, 1988). While our model includes tidal forcing, GLORYS, as stated
467 above, does not. This raises questions about how appropriate GLORYS is as a basis of evaluating
468 simulated currents in this area. Drinkwater (1988) deployed an array of current meters across
469 Hudson Strait between August and October of 1982. While exact coordinates of this array are not
470 available, the grid point in our model closest to the southwestern end of the array (station HS1)
471 can be approximated as (69.47° W, 61.15° N), with a water depth of 272 m, from Figs. 1–2 of
472 Drinkwater (1988). The eight-week average of residual current speeds at this location was
473 observed to be about 0.29 m s⁻¹ and 0.12 m s⁻¹ at the 30-m and 100-m depths respectively. The
474 2015–2018 average of September-mean current speeds simulated by Prog and from GLORYS at
475 the corresponding model grid point are similar to each other and somewhat less than the
476 observed value at the 30-m depth (about 0.24 m s⁻¹ and 0.23 m s⁻¹ respectively vs. 0.29 m s⁻¹).
477 However, at the 100-m depth, the simulated mean current speed (0.10 m s⁻¹) is more similar to
478 the observation (0.12 m s⁻¹) than the GLORYS value (0.03 m s⁻¹). [Although we need to keep in
479 mind the existence of interannual variability and long-term trends which limit the conclusions we
480 can derive, these comparisons point](#) to the possibility that the inclusion of tides in our model may
481 result in a more realistic vertical structure of currents in areas where both tides and baroclinity
482 play significant roles. The role of tides in the NWA is explored further in Sect. 4.1.

483 The temperature and salinity simulated in Prog have also been compared to observations made
484 along transects from the Atlantic Zone Monitoring Program and its off-shelf counterpart (not
485 shown). RMSE along the AR7W transect, which spans the Labrador Sea between southern
486 Labrador and southern Greenland, are largest near the surface, reaching ~2°C for temperature
487 and ~0.5 for salinity. The errors are larger in transects across Cabot Strait and across the Scotian
488 Shelf (up to ~4°C for temperature and ~3 for salinity), reflecting the difficulty Prog has in
489 reproducing the estuarine circulation in the Gulf of St. Lawrence and the positions of the Gulf
490 Stream and slope waters.

491 The preceding description and evaluation of the simulated circulation and hydrography have
492 highlighted two features in which the nudging of temperature and salinity in Ctrl leads to
493 improved model performance: (a) the separation of currents (the Gulf Stream and West
494 Greenland Current) from their respective coasts and (b) propagation of the low-salinity plume

Deleted: This points

496 from the St. Lawrence Estuary. Chassignet and Xu (2017) and Pennelly and Myers (2020)
497 showed respectively that increasing the horizontal resolution of their model grids from $1/12^\circ$ to
498 $1/50^\circ$ or $1/60^\circ$ resulted in more realistic representations of the Gulf Stream or the West Greenland
499 Current. Given the computational costs of making coupled physical-biogeochemical simulations
500 with a finer horizontal grid than what we currently use, a possible way to improve our modelling
501 system's performance in prognostic simulations would be to nest a finer-resolution grid covering
502 an area of particular interest (e.g., the Labrador Sea) within the existing $1/12^\circ$ grid. As discussed
503 earlier, a fourth-order horizontal advection scheme with a flux limiter is a possible way to
504 improve our model's simulation of estuarine plumes in prognostic simulations.

505 3.3 Sea ice

506 February-mean values of sea ice cover and effective sea ice thickness (sea ice cover multiplied
507 by thickness), averaged over 2015–2018, are shown in Fig. 10. Model results from Ctrl and Prog
508 are similar in that the ice cover spans Hudson Strait and adjoining areas to its west as well as
509 most of Baffin Bay, and the thickest ice (thickness $>>3.0$ m) occurs along the coasts of those
510 areas. The two runs are different in that Ctrl produces more ice along the west coast of Greenland
511 and in the northwest Gulf of St. Lawrence, while Prog produces more ice along the north side of
512 Hudson Strait and on the Labrador Shelf. The larger sea ice production by Ctrl for the west coast
513 of Greenland and the northwest GSL is consistent with the lower sea-surface salinity and
514 temperature in this simulation due to the nudging (Fig. 2). For northern Hudson Strait and the
515 Labrador Shelf, a possible factor in the larger sea ice production by Prog is the fact that, in these
516 areas, offshore winds tend to cause ice divergence, which in turn leads to new ice formation
517 (Babb et al., 2021; Prinsenberg and Peterson, 1992). The cycle of open water formation,
518 freezing, and ice divergence implies changes in the surface temperature and salinity over
519 relatively small spatiotemporal scales, which could be dampened by the nudging of Ctrl to the
520 monthly CORA data set which has a horizontal resolution of 0.2° – 0.5° in our study area
521 (Szekely, 2023). The role of sea ice on the physical oceanography of our study area is studied
522 further in Sect. 4.2.

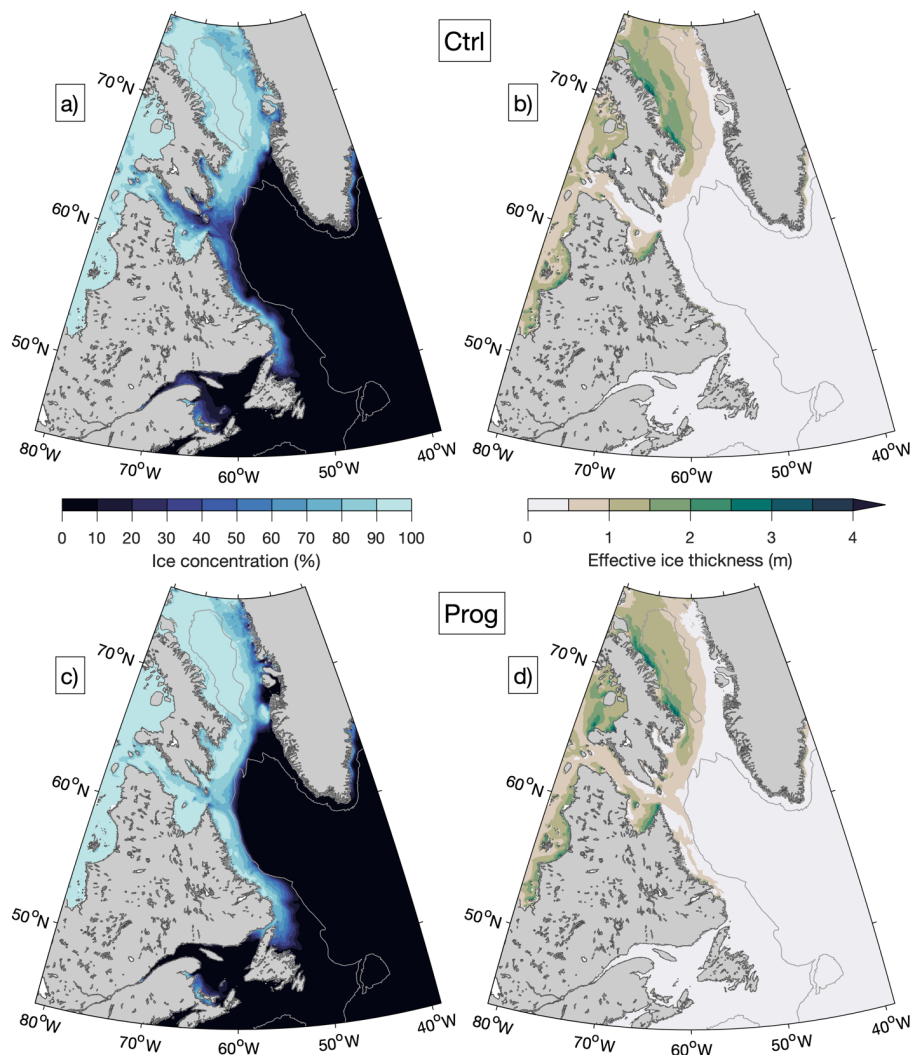

523 The ice model's performance is evaluated in terms of RMSE with respect to daily AMSR2
524 (Advanced Microwave Satellite Radiometer) observations, available on a 6.5-km grid

525 (Melsheimer and Spreen, 2019). The model errors in HST, BB, and LS are generally larger in
526 Ctrl (Fig. 11) than in Prog (Fig. 12), consistent with the smaller sea ice production in these areas
527 by the former. In HST, the increase in model error during May for both runs is mostly due to
528 underestimation, indicating a too-early melting of the ice. Given that this seasonal increase in
529 model error occurs in both runs, the cause of the underestimation may be related to ice advection
530 instead of thermodynamics. Examination of sea ice budgets for areas within the NWA is a
531 possible topic of future studies.

532 **3.4 Biogeochemistry**

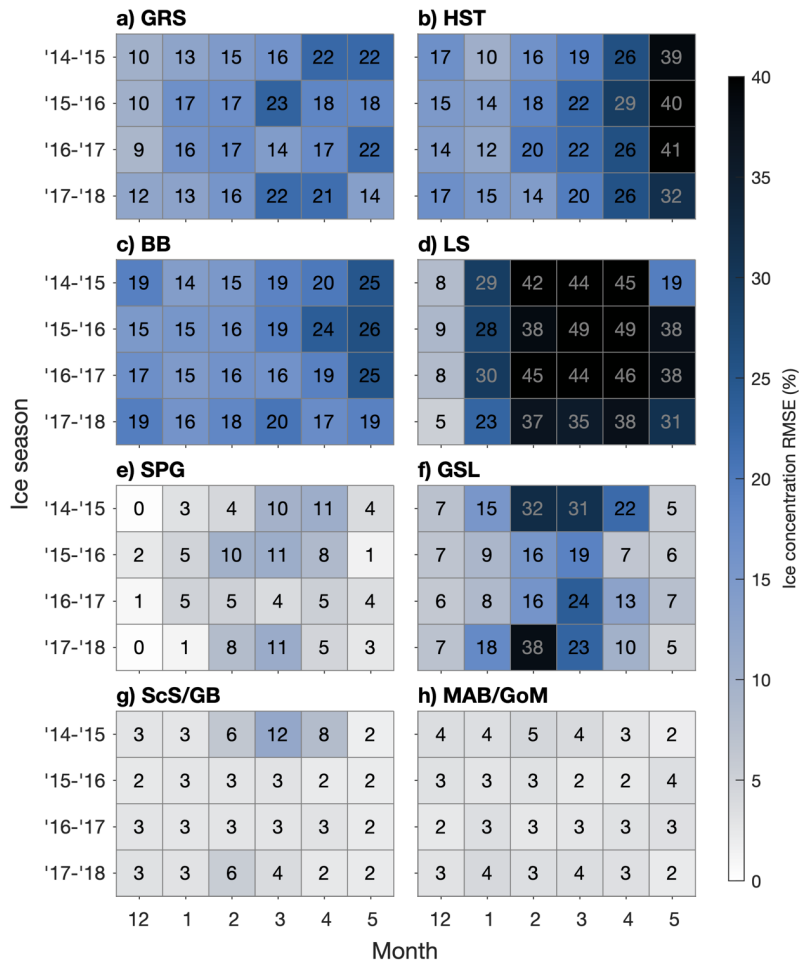

533 Snapshots of surface nitrate and subsurface oxygen in the Labrador Sea and surrounding areas at
534 the time of the Atlantic Zone Off-Shelf Monitoring Program (AZOMP) cruise in May 2015 are
535 shown in Fig. 13. The simulation indicates that nitrate starts to be depleted in the northern
536 Labrador Sea and along the Labrador shelf at this time but remains high in the deep central
537 Labrador Sea. Surface and shelf waters are well oxygenated and subsurface conditions along the
538 AR7W transect are characteristic of the water masses: oxygenated Labrador Sea Water
539 (depth < 2000 m), lower-oxygen Northeast Atlantic Deep Water (2000–3000 m), and the more
540 oxygenated Denmark Strait Overflow Water (>3000 m), which is in line with the observations
541 along the AR7W transect (Fig. 14a). Simulated nitrate is also characteristic of the three water
542 masses (Fig. 14b). As also shown in Fig. 13, surface nitrate remains high in the central Labrador
543 Sea but is low or depleted on the West Greenland and Labrador Shelves, respectively. These
544 patterns agree with the observations. The spatial variability in alkalinity (Fig. 14c) and total
545 inorganic carbon (TIC; Figure 14d) along the AR7W transect is also well represented. The largest
546 mismatch occurs for TIC which is underestimated in the subsurface layers (depths > 200 m).

547 Comparison of simulated oxygen, nitrate, alkalinity, and TIC to AZMP/AZOMP in situ
548 observations, at locations ranging from the Gulf of Maine to the Labrador Shelf, was carried out
549 for the period 2014–2018 (Fig. 15). The model simulates reasonably well the spatial and
550 temporal variability in biogeochemical variables ($0.65 < r^2 < 0.81$). Simulated oxygen has a small
551 positive bias (10.8 mmol m^{-3} , Fig. 15a) but otherwise agrees with observations. Nitrate has the
552 best match with observations ($r^2 = 0.81$) but with a small positive bias (Fig. 15b), possibly driven
553 by excess vertical mixing or by a delay in the seasonal uptake. The small bias at low TIC (i.e.,
554 surface) is likely to have the same source (Fig. 15d).

588

589 **3.5 Simulation of deep convection in the Labrador Sea**

590 One of the important hydrodynamic features of the NWA is the occurrence of deep winter
591 convection (DWC) in the Labrador Sea and a few other areas. DWC ventilates the deep ocean,
592 contributes to the removal of anthropogenic carbon from near-surface waters, and is thought to
593 influence the larger-scale Atlantic Meridional Overturning Circulation (e.g., Rhein et al., 2011).
594 In this section, we assess the model performance in reproducing the effects of DWC at two
595 locations (indicated by numbers in Fig. 1): location 1 (54.31° W, 58.29° N) which is near the
596 centre of the “convective region” identified by Luo et al. (2014), and location 2 (50.72° W,
597 58.29° N) which is on the AR7W transect and is within the area (“Central Labrador Sea”) for

Deleted: The horizontal grid size of our model ($O(km)$) is too large to resolve convective plumes, which have horizontal scales of $O(100\text{ m})$ (e.g., The Lab Sea Group, 1998), nor does our model include parameterization of deep convection. The model’s turbulent vertical mixing scheme, however, responds to the atmospheric input and water column conditions that lead to deep convection, and thus can be expected to produce vertical profiles of tracers whose temporal evolution is generally consistent with that of profiles resulting from deep convection. ¶

619 which Yashayaev (2024, hereafter Y24) composited the available observations to form time
620 series of ocean properties from the surface to the 2000-m depth. (Location 1 is near the western
621 edge of the Central Labrador Sea as defined by Y24.) The output of Prog will be used here so
622 that the model's response to the conditions that trigger DWC can be assessed. Because the time
623 series of Y24 indicated that conditions in 2014 were markedly different from those of subsequent
624 years, the model results of 2014 will be included here even though they were excluded from the
625 preceding discussions of model performance.

Deleted: convection

626 Time series of temperature profiles at the two locations are shown in Fig. 16. The time series at
627 location 1 is generally more similar to the observation-based, area-composite time series of Y24
628 (his Fig. 3) than at location 2. This is consistent with the fact that location 1 is at the centre of the
629 area where DWC occurred in the modelling study of Luo et al. (2014), which they found to agree
630 with areas of convection observed by, e.g., Lavender et al. (2000). The time series of simulated
631 temperature profiles at location 1 includes several features that appear in Y24, such as: 1) the
632 turbulent vertical mixing/convection being much stronger in 2015 than in 2014, with the 3.4°C
633 contour of simulated temperatures extending down to the ~1600-m depth in 2015 but just to the
634 ~1000-m depth in 2014; 2) temperatures below 3°C occurring from the surface to the ~200-m
635 depth from late 2015 to early 2016; and 3) temperatures above 6°C extending to a maximum of
636 ~100 m below the surface during the summer. Given that: 1) our model does not directly
637 simulate or parameterize deep convection and 2) we are comparing the temporal evolution of
638 simulated temperatures at one location against a composite of observations over an area with a
639 diameter of $O(100\text{ km})$ in Y24, we find these similarities encouraging.

Deleted: ¶

Deleted: deep convection

640 It should be noted that the horizontal grid size of our model is $O(1\text{ km})$, which is much coarser
641 than the typical horizontal scale of $O(100\text{ m})$ for the convective plumes (e.g., The Lab Sea
642 Group, 1998). Furthermore, our circulation model does not use an explicit winter advection
643 scheme, instead it uses large vertical mixing coefficients produced by the modified "2.5-level"
644 scheme of Mellor and Yamada (1982) to mimic the intense convective mixing associated with
645 DWC. A fine-resolution model with a horizontal grid size of $O(100\text{ m})$ nested within
646 DALROMS-NWA12 v1.0 will be used in our future research to develop better parameterizations
647 of DWC over the NWA and to examine how the model simulates deep ocean ventilation and
648 near-surface carbon removal due to DWC.

676 4 Sensitivity studies

677 The ocean circulation and sea ice modules of DalROMS-NWA12 v1.0 are used in this section to
 678 examine the roles of tides and sea ice in the hydrodynamics of the NWA. This is done by
 679 comparing the model results from Prog to those from two additional simulations that are
 680 identical to Prog but with the tidal forcing absent from one (NoTides) and sea ice absent from the
 681 other (NoIce). In NoIce, the net surface heat flux is set to zero if it would cool the ocean and the
 682 sea surface temperature is already at or below the local freezing temperature. The difference

683 between surface temperatures simulated in Prog and in NoTides (Prog minus NoTides) will be
 684 denoted ΔT_{sfc}^{P-NT} and the difference in bottom temperatures will be denoted ΔT_{btm}^{P-NT} . Similar
 685 notations will be used for differences in salinity (e.g., ΔS_{sfc}^{P-NT}) and current speed (e.g.,
 686 $\Delta |V|_{sfc}^{P-NT}$) and for differences between model results from Prog and NoIce (e.g., ΔT_{sfc}^{P-NI}).

687 4.1 The effect of tides

688 Differences between Prog and NoTides (Prog minus NoTides) in sea surface salinity, currents,
 689 and temperature over Baffin Bay and the Labrador Sea, averaged over the winters (December–
 690 February) and summers (June–August) of December 2014–August 2018, are shown in Fig. 17. In
 691 winter (Fig. 17a–b), differences between the simulations of temperature and salinity over this
 692 area are relatively small – generally within ± 1 for salinity, and up to $\sim +1.5^\circ\text{C}$ for temperature. In
 693 summer (Fig. 17c–d), ΔS_{sfc}^{P-NT} is positive along most of the Baffin Island coast, in Ungava Bay,
 694 and on the northern Labrador Shelf (up to ~ 7 in Ungava Bay) while ΔT_{sfc}^{P-NT} is mostly negative
 695 throughout the area but especially over shelves ($\sim -1.0^\circ\text{C}$). These differences between Prog and
 696 NoTides are consistent with the presence of sea ice over large portions of this area during winter,
 697 given that sea ice can modulate tidal mixing and thus tend to reduce the differences between the
 698 ocean states simulated with and without tides. In summer, the presence of tidal mixing in Prog
 699 contributes to vertical mixing over shelf areas, resulting in surface waters that are saltier and
 700 colder than if there were no tides and the water column were more highly stratified. There are,
 701 however, areas in which the inclusion of tides results in positive ΔT_{sfc}^{P-NT} during the summer,
 702 notably along the coast of Ungava Bay. Given that ΔS_{sfc}^{P-NT} is positive throughout the Bay, the
 703 contrast between positive ΔT_{sfc}^{P-NT} along the coast and negative ΔT_{sfc}^{P-NT} near the Bay’s mouth
 704 suggests air-sea fluxes might differ between the two parts of the Bay.

705 The effect of tides on water temperature within Ungava Bay is explored in Figs. 18 and 19. In
 706 winter, the models results from Prog and NoTides are similar not only in terms of the surface
 707 temperature (Fig. 18a), but also in terms of bottom temperature ($|\Delta T_{btm}^{P-NT}| < \sim 1.0^\circ\text{C}$, Fig. 18b)
 708 and current speeds at both the surface and bottom ($\Delta |V|_{sfc}^{P-NT}$ and $\Delta |V|_{btm}^{P-NT} < \sim 0.1 \text{ m s}^{-1}$, Fig.
 709 18a–b). In summer at the sea surface (Fig. 18c), both $\Delta |V|_{sfc}^{P-NT}$ and ΔT_{sfc}^{P-NT} are positive along

Deleted: 6

Deleted: 6

Deleted: 7

Deleted: 8

Deleted: 7

Deleted: 7

Deleted: 7

Deleted: 7

719 the coast but generally negative in the outer bay. Along the bottom in summer (Fig. 18d),
720 ΔT_{btm}^{P-NT} is positive and as large as $\sim+4^{\circ}\text{C}$ along the coast, while in the outer bay ΔT_{btm}^{P-NT} is small
721 ($|\Delta T_{btm}^{P-NT}| < \sim 1.0^{\circ}\text{C}$) and the currents are generally weak in both simulations. The patterns of
722 mean summer sea ice concentration are also different between the two simulations, with the ice
723 cover produced in Prog (Fig. 19a) being highest over the outer bay (up to $\sim 40\%$) and low near
724 the coast, while NoTides (Fig. 19b) produces a wide area of high ice cover along the coast (up to
725 $\sim 90\%$). The patterns of mean summer sea surface temperature from the two simulations (Fig.
726 19c-d) correspond to those of the sea ice cover, with areas of higher (lower) ice cover
727 corresponding to lower (higher) temperatures. Given that the only difference between the Prog
728 and NoTides simulations is the inclusion of tides in the former, these results suggest that tides
729 along the coast of Ungava Bay promotes an earlier disappearance of ice there during the summer,
730 and this in turn leads to a larger flux of solar radiation into the ocean and a less impeded flow.

731 The effect of tides is also evident in the region surrounding two other areas with large tidal
732 ranges, the St. Lawrence Estuary and the Bay of Fundy. In both winter and summer, ΔS_{sfc}^{P-NT} in
733 the St. Lawrence Estuary (Fig. 20a,c) is positive (up to ~ 6.0 in most of the Estuary but > 10 in
734 parts of the Upper Estuary during the summer), suggesting that tidal mixing brings higher-
735 salinity subsurface water towards the surface. In summer (Fig. 20c), the influence of this higher
736 salinity due to tidal mixing spreads into the northwest Gulf of St. Lawrence due to the
737 propagation of the estuarine plume. In the Bay of Fundy, the salinity difference is also positive in
738 both seasons. In winter, ΔS_{sfc}^{P-NT} ranges from ~ 0.4 in most of the Bay to ~ 2.4 near the Saint John
739 River's mouth and in summer, it ranges from ~ 1.2 in the upper Bay to ~ 3.6 near the Saint John
740 River's mouth. The role of tidal mixing is also evident in the patterns of sea surface temperatures
741 (Fig. 20b,d), with ΔT_{sfc}^{P-NT} positive in winter (up to $\sim 1.5^{\circ}\text{C}$ in both the St. Lawrence Estuary and
742 the Bay of Fundy) and negative in summer (as low as $\sim -4.5^{\circ}\text{C}$ in both areas). Differences
743 between the simulations are also visible over the open ocean for all three fields. As Wang et al.
744 (2020) have suggested, this may be caused by internal tides that are generated near the shelf
745 break and propagate offshore.

778 **4.2 The effect of sea ice**

779 The effect of sea ice is examined next by comparing simulated surface fields from Prog to those
 780 from the simulation in which ROMS is run without coupling to CICE (NoIce). A prominent
 781 feature in winter is the horizontal gradient in ΔS_{sfc}^{P-NI} , approximately aligned with the 1000-m
 782 isobath, in western Baffin Bay (Fig. 21a). ΔS_{sfc}^{P-NI} is positive on the shelf (~ 0.2) but negative
 783 offshore of the shelf break (~ -0.3). In the zone where ΔS_{sfc}^{P-NI} changes signs, $\Delta |V|_{sfc}^{P-NI}$ is positive
 784 (up to $\sim 0.3 \text{ m s}^{-1}$). The area on the shelf where ΔS_{sfc}^{P-NI} is positive coincides with the highest
 785 average sea ice thickness in the domain (Fig. 10d), which makes the higher salinity in Prog
 786 consistent with brine rejection at the time of sea ice formation. Values of $|\Delta T_{sfc}^{P-NI}|$ in winter (Fig.
 787 21b) tend to be largest over the parts of Baffin Bay and the northern Labrador Shelf where the

Deleted: 0

Deleted: 0

792 ice edge occurs in Prog (Fig. 10c). ΔT_{sfc}^{P-NI} in these areas are negative (as low as $\sim -1.9^\circ$). Surface
793 heat flux is expected to result in positive ΔT_{sfc}^{P-NI} , given that in winter it is expected to cool the
794 ocean surface while sea ice can insulate the ocean surface below from cold air. Another possible
795 factor in ΔT_{sfc}^{P-NI} is vertical mixing, which is examined later.

796 In summer, ΔS_{sfc}^{P-NI} and ΔT_{sfc}^{P-NI} (Fig. 21c and 21d respectively) are lowest in western Baffin Bay,
797 with the former as low as ~ -4.0 psu (reflecting the input of freshwater due to melting sea ice) and
798 the latter as low as $\sim -4.7^\circ\text{C}$ (reflecting the blocking of shortwave radiation by the sea ice that
799 remains in summer). These results suggest that, as sea ice in areas such as Baffin Bay and the
800 Labrador Shelf decline in a warming climate, areas downstream from them such as the Scotian
801 Shelf and the Gulf of Maine will experience changes in the temperature and salinity of the water
802 that is brought there by the Labrador Current. The effect of changes in water masses advected
803 into a given area, in combination with changes that occur in situ due to climate change, is
804 another possible topic of future research.

805 Differences in the wintertime vertical stratification and vertical mixing between Prog and NoIce
806 are examined further using vertical profiles of four-year mean wintertime temperature, salinity,
807 and vertical eddy viscosity produced by the two runs, as well as the squared buoyancy frequency
808 (N^2) calculated from the mean wintertime temperature and salinity using the Gibbs-SeaWater
809 Oceanographic Toolbox (McDougall and Barker, 2011). The profiles represent temporal averages
810 over the same period as in Figs. 21a–b (winters of 2015–2018) and are calculated at 1-m depth
811 intervals for two locations: location A (62.56°W , 67.60°N), indicated by the square in Fig. 21b,
812 where ΔT_{sfc}^{P-NI} is small and the 2015–2018 mean of the February-mean sea ice cover is $\sim 95\%$
813 (Fig. 10c), and location B (57.64°W , 67.60°N), indicated by the circle in Fig. 21b, where
814 ΔT_{sfc}^{P-NI} has a large magnitude ($\sim -1.9^\circ\text{C}$) and the four-year mean of the February-mean sea ice
815 cover is $\sim 84\%$. The model's water depths at the two locations are similar (231 m and 218 m).

816 The vertical profiles of mean wintertime temperature (Fig. 22a) and salinity (Fig. 22b) at location
817 A are similar between runs Prog and NoIce, with a vertical range of $< 1.4^\circ\text{C}$ for temperature and
818 < 0.8 for salinity in both runs. The profiles of N^2 (Fig. 22c) are thus also similar between the runs,
819 with maximum values of $\sim 6 \times 10^{-5} \text{ s}^{-2}$ about 40 m below the sea surface. Negative values of N^2 ,
820 indicating instability, are limited to the top few metres of the water column. Values of the

Deleted: 0

Deleted: 0

Deleted: 0

Deleted: 0

Deleted:

Deleted: 1

Deleted: 1

Deleted: 1

Deleted: 1

831 Richardson number (not shown) below 0.25, including negative values, are limited to the top 5 m
832 of the water column, again indicating a mostly stable water column and weak convection in both
833 Prog and NoIce. The mean wintertime vertical mixing below the surface is very weak in both
834 runs (Fig. 22d), with the vertical eddy diffusivity from both runs having maximum values of
835 $\sim 0.02 \text{ m}^2 \text{ s}^{-1}$ about 10 m below the surface and having values $< 0.002 \text{ m}^2 \text{ s}^{-1}$ in $\sim 80\%$ of the water
836 column. It should be noted that the mean wintertime stress exerted on the sea surface (by winds
837 and/or sea ice in Prog and by winds in NoIce) differs significantly between the two runs (Fig.
838 22d). The surface stress has a much smaller magnitude in Prog (0.02 N m^{-2}) than in NoIce (1.0 N
839 m^{-2}), which can be explained by the buffering effect of sea ice on the wind stress in Prog. Due to
840 this buffering effect of sea ice, the wind-induced vertical mixing in the surface layer (Fig. 22d) is
841 weaker in Prog than in NoIce, as expected.

842 In contrast to location A, the vertical profiles of mean wintertime model results at location B
843 differ significantly between runs Prog and NoIce. The mean wintertime temperature (Fig. 23a)
844 has a vertical range of $> 3^\circ\text{C}$ in Prog (about -0.9°C near the surface and 2.4°C near the bottom)
845 but $< 1.0^\circ\text{C}$ in NoIce (about 1.1°C near the surface and 1.7°C near the bottom). The mean
846 wintertime salinity (Fig. 23b) has a vertical range of ~ 0.5 in Prog (about 34.0 near the surface
847 and 34.5 near the bottom) but just ~ 0.1 in NoIce (about 34.5 near the surface and 34.6 near the
848 bottom). Values of N^2 (Fig. 23c) from both runs are lower than at location A; with a maximum of
849 $\sim 1.9 \times 10^{-5} \text{ s}^{-2}$ in Prog and $\sim 2.1 \times 10^{-6} \text{ s}^{-2}$ in NoIce. In addition, the N^2 in NoIce is negative in the
850 top ~ 20 m of the water column and between depths of ~ 40 and ~ 50 m, indicating unstable
851 stratification and unrealistically strong convection. The Richardson number is < 0.25 in the top ~ 5
852 m of the water column in Prog, and at approximately the same depths as the negative values of
853 N^2 in NoIce. The maximum vertical eddy diffusivity coefficient is $\sim 0.3 \text{ m}^2 \text{ s}^{-1}$ in NoIce, which is
854 much larger than the maximum values of $\sim 0.06 \text{ m}^2 \text{ s}^{-1}$ in Prog, while the surface stress is similar
855 at $\sim 0.1 \text{ N m}^{-2}$ in both runs.

856 A possible explanation for the relatively warm ($> 2.0^\circ\text{C}$) and salty ($> 34.0 \text{ psu}$) subsurface water
857 in the lower water column at location B in Prog (solid blue lines in Fig. 23a,b) is the horizontal
858 advection of relatively warm and salty waters from the south to this location. In Prog, the ocean-
859 to-air heat flux in winter results in cooling of the near-surface water as well as sea ice formation,
860 and subsurface ablation of the sea ice can be a source of fresh water that contributes to vertical

 893 change from Fig. 22 in the x-axis limits for the squared buoyancy frequency (c) and the vertical eddy diffusivity (d).

894 stability. The advection of relatively warm, salty subsurface waters from the south would also
 895 occur in Nolce, but in this case the near-surface water would be cooled to the freezing point
 896 without an accompanying reduction in salinity, which may explain the very large vertical mixing
 897 and nearly uniform vertical profiles of temperature and salinity in this run.

898 5 Conclusions

899 In this study, a newly-developed, fully-coupled modelling system for simulating the ocean
 900 circulation, sea ice, and biogeochemistry of the northwest North Atlantic Ocean (DalROMS-

Deleted: 2

Deleted: 1

Formatted: Tab stops: Not at 5 cm

Deleted: ¶

906 NWA12 v1.0) was described. The model domain covers the area from Cape Hatteras to Baffin
907 Bay with a horizontal resolution of ~2 to ~8 km, making this modelling system highly suitable
908 for a range of research topics, including study of the biological carbon pump and quantification
909 of the major physical and biogeochemical (BGC) processes influencing the ocean carbon cycle
910 over the region. The results of two simulations using this modelling system, with and without
911 nudging of the simulated temperature and salinity towards a blend of observations and
912 reanalysis, were compared to observations and reanalysis. We found that results of the control
913 run, which included the nudging, are more realistic than results of the prognostic (un-nudged)
914 simulation for several important physical features observed in this region, such as separation of
915 the Gulf Stream and the West Greenland Current from their respective coasts, as well as
916 propagation of low-salinity waters from the St. Lawrence Estuary. These results demonstrate the
917 utility of simple data assimilation in reducing the systematic model errors that can be attributed
918 to model configuration (such as horizontal grid resolution in the case of currents' separation from
919 coasts and the choice of tracer advection scheme in the case of estuarine plume propagation) and
920 unresolved or parameterized physical and BGC processes. The prognostic simulation, while
921 having difficulties with the above-mentioned features, was able to reproduce the general
922 spatiotemporal patterns of the physical fields and outperformed the control run in terms of the
923 sea ice concentration. The major differences between the simulations in the sea ice extent
924 highlight the complex nature of interactions among the atmosphere, ocean, and sea ice.

925 The modelling system was able to reproduce the general patterns of BGC variables over the
926 northwest Atlantic shelves and in the Labrador Sea. Further validation will include comparisons
927 with observations made by BGC Argo floats (Johnson and Claustre, 2016). Future work will use
928 this modelling system to investigate the biological carbon pump in the Labrador Sea including
929 vertical flux estimates derived from BGC Argo (Wang and Fennel, 2022 and 2023). The addition
930 of silicate as a state variable will also be tested.

931 As an example of application of this modelling system, sensitivity studies were made in which
932 results of the prognostic simulation were compared to those from similar simulations from which
933 either the tides or simulation of sea ice were excluded. The comparisons suggest that tides and
934 sea ice strongly affect the physical oceanography of the NWA in several ways. These include the

935 combined effects of tides and sea ice (in Ungava Bay) as well as individual effects (e.g., higher
936 surface salinity in summer when sea ice is not simulated).

937 In addition to studies of the biological carbon pump and of the downstream effects of changes in
938 the water transported by the Labrador Current, another possible direction of future research is to
939 [explore further the effects of model configuration, such as parameterization of deep convection](#)
940 [or the choice of advection schemes \(including the use of non-zero horizontal eddy diffusivity and](#)
941 [viscosity with the third-order upstream scheme\). In addition, we can](#) use the ocean state
942 simulated by this model as input for numerical particle-tracking experiments to investigate
943 connectivity among different areas of the NWA. The resulting metrics of connectivity under
944 current and projected future climate conditions can support decision-making processes
945 concerning conservation measures. The model will also be used to compare approaches to
946 reducing bias in long-term simulations (Renkl et al., in prep.).

947 The high air-to-sea flux of CO₂ and the subsequent downward export of fixed carbon make the
948 NWA a key component in the global climate system, but it is a remote region where seasonal
949 transitions can take place in just a few weeks (e.g., in terms of pCO₂; Körtzinger et al., 2008) and
950 details of the interactions between physical and biogeochemical processes are still unknown or
951 remain poorly integrated into models (e.g., the sea-ice carbon pump; Richaud et al., 2023). The
952 four-dimensional ocean states produced by numerical models can aid in the interpretation of
953 observations as well as enable experiments that elucidate the roles of various processes in the
954 ocean and how those processes might change under future climate scenarios. [As part of our](#)
955 [future studies, this advanced coupled modelling system will be run for longer simulation periods](#)
956 [to examine the effects of climate change on the marine conditions over the NWA. The modelling](#)
957 [system will also be used to predict the temporal and spatial variability of future marine](#)
958 [conditions over the region under different climate scenarios.](#)

959 **Appendix A: The vertical coordinate system in ROMS**

960 ROMS uses a generalized terrain-following vertical coordinate system with several options
961 for vertical transformation equations and vertical stretching functions. In this study the default
962 configuration is used, with the vertical coordinate S defined as (Hedstrom, 2018):

$$963 \quad z(x, y, \sigma, t) = \zeta(x, y, t) + [\zeta(x, y, t) + h(x, y)]S(x, y, \sigma) \quad (\text{A1})$$

964
$$S(x, y, \sigma) = \frac{h_c + h(x, y)C(\sigma)}{h_c + h(x, y)} \quad (\text{A2})$$

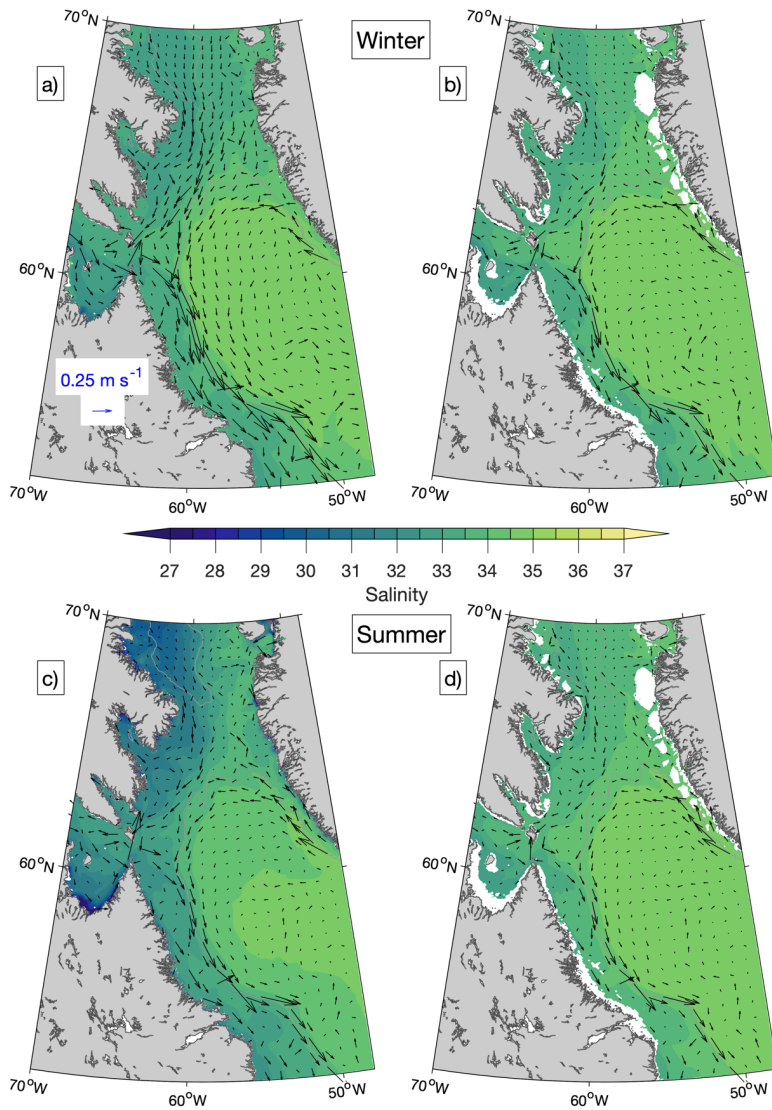

965
$$C(\sigma) = \frac{\exp(\theta_b C'(\sigma)) - 1}{1 - \exp(-\theta_b)} \quad (\text{A3})$$

966
$$C'(\sigma) = \frac{1 - \cosh(\theta_s \sigma)}{\cosh(\theta_s) - 1} \quad (\text{A4})$$

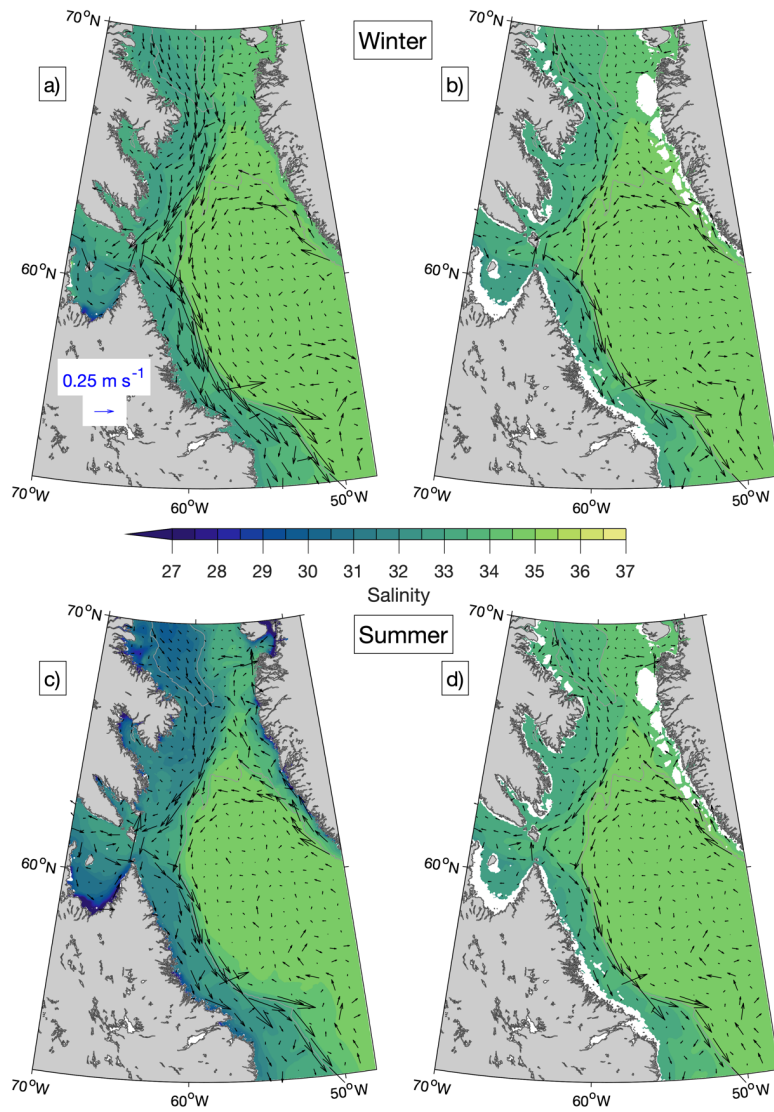

967 where σ ranges from 0 at the free surface to -1 at the ocean bottom, ζ is the free surface, h is the
 968 undisturbed water column thickness, h_c is the value of h below which the vertical layers are more
 969 uniformly spaced, and θ_s and θ_b are parameters that control the vertical resolution near the
 970 surface and the bottom respectively. In this study ROMS has 40 layers and the parameters h_c , θ_s ,
 971 and θ_b are set to 100 m, 5.0, and 0.5 respectively.

972 **Appendix B: Seasonal-mean simulated fields**

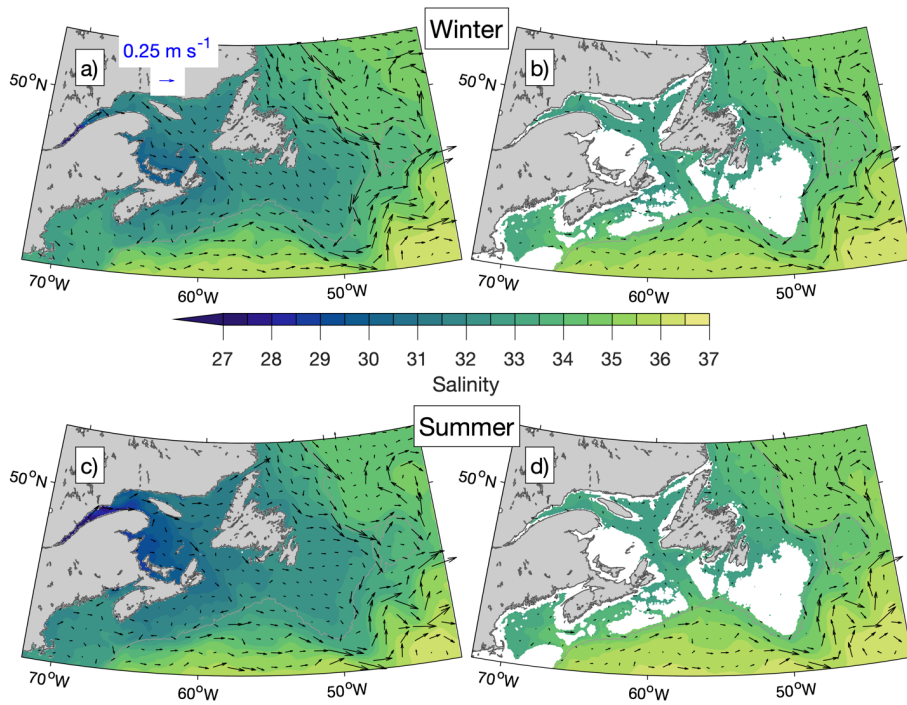

973 Seasonal means of salinity and currents in Baffin Bay and the northern Labrador Sea
 974 simulated in Ctrl and Prog, averaged over [the period](#) December 2014–December 2018, are
 975 shown in Figs. B1 and B2. Differences between the simulations are more evident in summer
 976 (June–August; Figs. B1c–d and B2c–d) than in winter (December–February; Figs. B1a–b and
 977 B2a–b). The northward branch of the West Greenland Current and the Baffin Island Current are
 978 stronger in Prog by up to $\sim 0.25 \text{ m s}^{-1}$ at the surface and $\sim 0.15 \text{ m s}^{-1}$ for model results interpolated
 979 to the 100-m depth. In the area between the southern Labrador Sea and the Gulf of Maine (Figs.
 980 B3 and B4), the difference in salinity between the simulations is more prominent in summer,
 981 following the annual peak in freshwater discharges from the St. Lawrence and other rivers. In the
 982 St. Lawrence Estuary, the 2015–2018 mean of summer surface salinity simulated in Prog is
 983 lower than that from Ctrl by up to ~ 3.5 , but further downstream in the Gulf of St. Lawrence, the
 984 salinity from Prog is higher by ~ 2 .

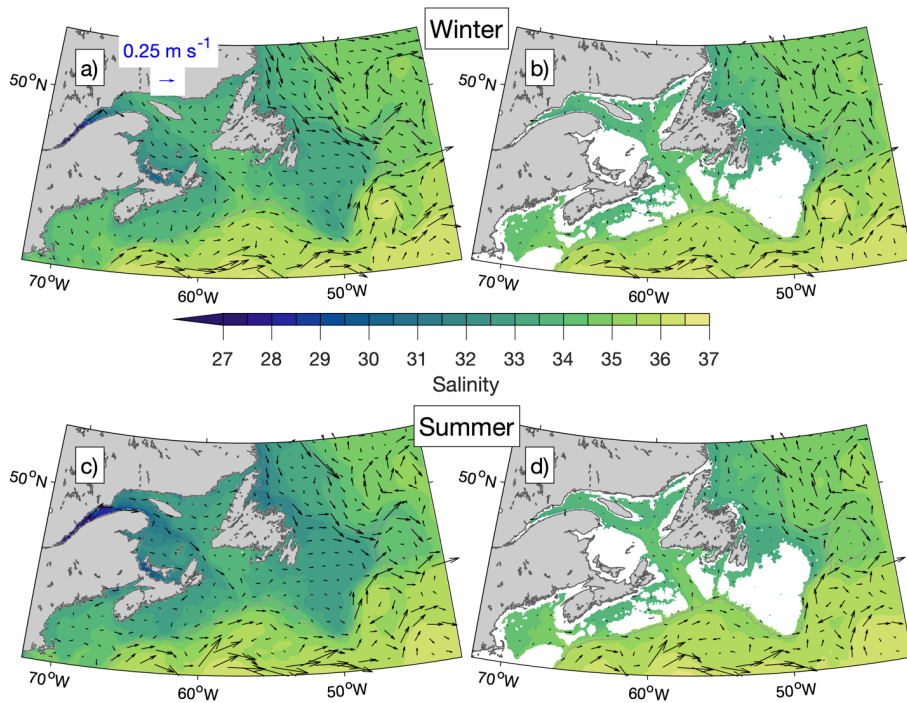

985
 986
 987 **Figure B1.** Seasonal-mean simulated salinity and currents at the sea surface (a, c) and interpolated to the 100-m
 988 depth (b, d) from Ctrl averaged over the winters (a, b) and summers (c, d) of 2015–2018 in Baffin Bay and the
 989 Labrador Sea. Winters are defined as December of the previous year to February of that year. Summers are defined
 990 as June to August. Current vectors are shown at every 12th grid point. The 1000-m depth contour is shown in gray.

991
 992
 993 **Figure B2.** Similar to Figure B1 but for Prog.

994
 995 **Figure B3.** Seasonal-mean simulated salinity and currents at the sea surface (a, c) and interpolated to the 100-m
 996 depth (b, d) from Ctrl averaged over the winters (a, b) and summers (c, d) of 2015–2018 over the area between the
 997 Gulf of Maine and the southern Labrador Sea. Current vectors are shown at every 12th grid point. The 1000-m depth
 998 contour is shown in gray.

999
1000
1001 **Figure B4.** Similar to Fig. B3 but for Prog.

1002 **Appendix C: Datasets used in model performance assessment**

1003 Online sources of the datasets used to assess the model performance are listed below in the order
1004 they are discussed in Section 3.

- 1005 1. Sea surface temperature: OISST v2.1 (Huang et al., 2021), a daily dataset on a $1/4^\circ$ grid that
1006 incorporates satellite and in situ observations. A combination of v2.0 and v2.1 was used in this
1007 study; v2.0 is now retired. <https://www.ncei.noaa.gov/products/optimum-interpolation-sst>
1008 2. Sea surface salinity: MULTI-OBS_GLO_PHY_S_SURFACE_MYNRT_015_013 (Buongiorno
1009 Nardelli et al., 2016), a dataset that incorporates satellite and in situ observations. At the time
1010 of this study, it was a weekly dataset on a $1/4^\circ$ grid; now it is a daily dataset on a $1/8^\circ$ grid.
1011 [https://data.marine.copernicus.eu/product/MULTI-OBS_GLO_PHY_S_SURFACE_MYNRT_](https://data.marine.copernicus.eu/product/MULTI-OBS_GLO_PHY_S_SURFACE_MYNRT_015_013/description)
1012 [015_013/description](https://data.marine.copernicus.eu/product/MULTI-OBS_GLO_PHY_S_SURFACE_MYNRT_015_013/description)

- 1013 3. CURRENTS: GLOBAL_MULTIYEAR_PHY_001_030, also known as GLORYS12V1
1014 (Lellouche et al., 2021), a daily reanalysis dataset on a 1/12° grid.
1015 https://data.marine.copernicus.eu/product/GLOBAL_MULTIYEAR_PHY_001_030/description
1016 [on](#)
- 1017 4. SHIPBOARD OBSERVATIONS OF PHYSICAL AND BIOGEOCHEMICAL VARIABLES: Atlantic Zone Monitoring
1018 Program (Pepin et al., 2005) cruises take place seasonally and Atlantic Zone Off-Shelf
1019 Monitoring Program (e.g., Yashayaev and Loder, 2017) cruises take place annually.
1020 https://catalogue.cioosatlantic.ca/dataset/ca-cioos_9a4bd73f-12a2-40ff-a7c7-b961a1d11311
1021 https://catalogue.cioosatlantic.ca/dataset/ca-cioos_15f90eab-21ed-447d-aca7-8fe98ea27fe5
- 1022 5. SEA ICE: AMSR2 ASI sea ice concentration data for the Arctic, v5.4 (Melsheimer and Spreen,
1023 2019), a daily dataset on a 6.5-km grid derived from satellite observations.
1024 <https://doi.pangaea.de/10.1594/PANGAEA.898399>

1025 **Code and Data Availability**

1026 The model codes, scripts for compiling the model, and sample CPP header and runtime
1027 parameter files for physics-only simulations are available at
1028 <https://doi.org/10.5281/zenodo.12752091> (Ohashi et al., 2024a). Input files used by the ocean
1029 circulation and sea ice modules in a simulation of September – December 2013 are available at
1030 <https://doi.org/10.5281/zenodo.12752190> (Ohashi et al., 2024b),
1031 <https://doi.org/10.5281/zenodo.12734049> (Ohashi et al., 2024c), and
1032 <https://doi.org/10.5281/zenodo.12735153> (Ohashi et al., 2024d). Daily-mean output files from
1033 the ocean circulation, sea ice, and biogeochemistry modules are available for September 2013
1034 (beginning of simulation period) at <https://doi.org/10.5281/zenodo.12744506> (Ohashi et al.,
1035 2024e) and for January 2015 (beginning of model validation period) at
1036 <https://doi.org/10.5281/zenodo.12746262> (Ohashi et al., 2024f). Input and output files for the
1037 remainder of the simulation period, as well as CPP header, runtime parameter, and input files for
1038 the biogeochemistry module, are available from the corresponding author KO upon request.

1039 **Author contributions**

1040 KO configured the ocean circulation model; prepared the model bathymetry, freshwater input
1041 files, atmospheric forcing files, and some of the lateral boundary input files; and carried out the
1042 Prog, NoTides, and NoIce runs. AL prepared input files for and configured the biogeochemical
1043 module; and carried out the Ctrl run. CR configured the sea ice model and its coupling to the
1044 ocean circulation model; prepared some of the lateral boundary input files and the pseudo-mean
1045 versions of freshwater input files; configured the regions used to evaluate model performance;
1046 processed the observations used in model evaluation; and calculated the model errors with
1047 respect to AZMP observations. AL carried out the analyses for and prepared Figs. 13–15; and
1048 wrote the text describing the biogeochemical module, the Ctrl run, and Figs.13–15. KO prepared
1049 the rest of the manuscript with advice from JS. JS, KF, and EO provided advice throughout
1050 development and evaluation of the model and provided funding to KO, AL, and CR respectively.

1051 **Competing interests**

1052 The authors declare that they have no conflicts of interest.

1053 **Acknowledgements**

1054 This study is part of the Ocean Frontier Institute’s research project “The Northwest Atlantic
1055 Biological Carbon Pump”. Simulations were carried out on computing resources maintained by
1056 the Digital Research Alliance of Canada. JS, KF, and EO acknowledge support from the National
1057 Science and Engineering Research Council of Canada’s Discovery Grant program. JS and KO
1058 were supported by funding from Fisheries and Oceans Canada (for the project “Modelling
1059 ecological connectivity among Canada’s Atlantic Marine Protected Areas during the
1060 Anthropocene”) during preparation of this manuscript. CR was supported by a postdoctoral
1061 fellowship from the Marine Environmental Observation, Prediction and Response network
1062 (MEOPAR). The authors thank Fehmi Dilmahamod, Xianmin Hu, Bin Wang, and Shengmu Yang
1063 for their suggestions and assistance during development of the model. [We are also grateful for](#)
1064 [the constructive comments provided by two anonymous reviewers, which led to the addition of](#)
1065 [section 3.5 and many other enhancements to the manuscript. Maps in this study were generated](#)

1066 [using the package M_Map \(Pawlowicz, 2020\)](#). The colour maps used in this study are by Thyng
1067 et al. (2016) and Crameri (2018).
