15 **Abstract**

16 Accurate representation of the hourly variation of the NO₂ column-to-surface relationship is needed to
17 interpret geostationary constellation observations of tropospheric NO₂ columns. Prior work has revealed
18 inconsistency in the hourly variation in NO₂ columns and surface concentrations. In this study, we use the
19 high-performance configuration of the GEOS-Chem model (GCHP) to interpret the daytime hourly
20 variation in NO₂ total columns and surface concentrations during summer. We use summer-time Pandora
21 sun photometers and aircraft measurements during the Deriving Information on Surface Conditions from
22 Column and Vertically Resolved Observations Relevant to Air Quality (DISCOVER-AQ) field campaigns
23 over Maryland, Texas, and Colorado as well as 50 sites (31: contiguous USA, 10: Europe, 9: Asia) from
24 the Pandora Global Network (PGN). We correct the Pandora total NO₂ vertical columns for 1) hourly
25 variation in the column effective temperature driven by the fractional contribution of atmospheric layers to
26 the total NO₂ column, and 2) change in local solar time along the line-of-sight of the Pandora instrument.
27 The corrected Pandora total NO₂ vertical columns are increased by about $5\text{-}6 \times 10^{14}$ molecules cm⁻² at 9
28 AM and 6 PM across all Pandora sites. We conduct fine resolution (~12 km) simulations over the
29 contiguous US, Europe, and East Asia using the stretched grid capability of GCHP. We also examine the
30 effect of planetary boundary layer height (PBLH) corrections on the total columns. We first evaluate the
31 GCHP simulated absolute NO₂ concentration with Pandora and aircraft observations. We find that fine
32 resolution simulations at 12 km compared with moderate resolution of ~55 km reduce the Normalized Bias
33 (NB) against Pandora total columns (19% to 10%) and aircraft measurements (25% to 13%) over Maryland,
34 Texas, and Colorado. 12 km simulations also reduce the NB versus Pandora total columns over the eastern
35 US (17% to 9%), western US (22% to 14%), Europe (24% to 15%), and Asia (29% to 21%) as compared
36 to the 55 km simulations. We next use the 12 km simulations to examine the hourly variation in the NO₂
37 columns and surface concentrations. We explain the weaker hourly variation in NO₂ columns than NO₂
38 surface concentrations as a function of 1) hourly variation in the column effective temperature, 2) hourly
39 variation in the local solar time along the Pandora line-of-sight, and 3) the differences in hourly variation
40 of atmospheric layers; with the lowest 500 m exhibiting greater NO₂ concentrations in morning and evening
41 than midday, while the residual column above 500 m dominates the total column with weaker variability.

42

43

44 **1 Introduction**

45 Nitrogen oxides ($\text{NO}_x \equiv \text{NO} + \text{NO}_2$) affect air quality and human health directly by
46 contributing to premature mortality (Burnett et al., 2004; Tao et al., 2012) and asthma for children
47 and adults (Anenberg et al., 2018), and indirectly by acting as precursors for tropospheric ozone
48 (O_3) formation (Jacob et al., 1996), and nitrate aerosols (Bauer et al., 2007). Significant spatial
49 gaps in ground-based monitoring of surface NO_2 concentrations and pronounced NO_2
50 heterogeneity inhibit exposure assessment. To fill in the knowledge of NO_2 exposures across a
51 greater fraction of the human population, satellite remote sensing offers the potential for spatially
52 comprehensive measurements. Major advances in satellite remote sensing from sun-synchronous
53 low earth orbit (LEO) has achieved global characterization of tropospheric NO_2 columns at
54 specific times of the day (Duncan et al., 2013; Veefkind et al., 2012) that have been applied to
55 infer ground level NO_2 concentrations (Anenberg et al., 2022; Lamsal et al., 2011; Geddes and
56 Martin, 2017; Cooper et al., 2022). The emerging geostationary constellation (Al-Saadi et al.,
57 2017) including the Geostationary Environmental Monitoring Spectrophotometer (GEMS) over
58 Asia, Tropospheric Emissions: Monitoring Pollution (TEMPO) over North America, and Sentinel-
59 4 over Europe offers the prospect of inferring spatially comprehensive maps of hourly ground-
60 level NO_2 concentrations. Toward this goal, there is a need to develop an accurate representation
61 of the hourly NO_2 column to surface relationship.

62 Understanding the hourly variation of the relationship of NO_2 columns with surface
63 concentrations is of particular interest due to its role in the inference of hourly surface NO_2 from
64 satellite remote sensing. Numerous studies have separately examined the role of processes such as
65 surface emissions, boundary layer mixing, chemistry, deposition, and advection (Yang et al.,
66 2023b; Herman et al., 2009; Ghude et al., 2020; Zhang et al., 2016) upon the hourly variation of
67 NO_2 columns and upon surface NO_2 concentrations in the United States (Day et al., 2009), Spain

68 (Van Stratum et al., 2012), India (David and Nair, 2011), South Korea (Yang et al., 2023a, b) and
69 China (Tong et al., 2017). Differences have been identified in the daytime hourly variation of NO₂
70 tropospheric columns and surface concentrations during the DISCOVER-AQ and KORUS-AQ
71 (Korea US -Air Quality) campaigns with pronounced variation in surface concentrations that is
72 not evident in the columns (Choi et al., 2020; Crawford et al., 2021). Differences have also been
73 noted in hourly variation of NO₂ measured by aircraft and ground-based Pandora instruments (Li
74 et al., 2021). There is a need to understand the factors that can affect the relationship of hourly
75 NO₂ columns with surface concentrations.

76 Major challenges in the interpretation of satellite NO₂ observations include the short
77 lifetime of NO_x (Laughner and Cohen, 2019), and localized emissions (Crippa et al., 2018) that
78 affect its spatial heterogeneity. Coarse resolution inputs to satellite retrieval algorithms (e.g.,
79 terrain height, albedo, and a priori NO₂ profiles) can lead to biases (Laughner et al., 2019;
80 Laughner et al., 2018; Russell et al., 2011). Complications with ground-based measurements of
81 the NO₂ columns as part of Pandora include uncertainties at steeper solar zenith angles during
82 morning and evening hours (Herman et al., 2009; Reed et al., 2015) and the changing Pandora
83 field of view (FOV) during morning and late evening (Li et al., 2021). Non-linearities in the
84 relationship between NO₂ concentrations and NO_x sources or sinks can lead to biases in coarse-
85 resolution chemical transport models (CTMs) (Valin et al., 2011) that necessitate CTMs with a
86 finer resolution (Li et al., 2021, 2023a). Recent advances in the simulation of global atmospheric
87 composition at fine resolution (Eastham et al., 2018; Hu et al., 2018; Martin et al., 2022) offer the
88 opportunity to address the resolution need at the global scales of the geostationary constellation.

89 An important consideration in the inference of surface NO₂ concentrations with columnar
90 satellite observations is the vertical profile of NO₂ concentrations. Aircraft observations from the

91 NASA Deriving Information on Surface Conditions from Column and Vertically Resolved
92 Observations Relevant to Air Quality (DISCOVER-AQ) campaign offers measurements of the
93 NO₂ vertical profile in the lower troposphere for evaluation of modeled vertical profiles (Flynn et
94 al., 2014; Reed et al., 2015). The Pandora Global Network (PGN) is a global sun photometer
95 network that offers hourly measurements of total NO₂ columns (Verhoelst et al., 2021), useful for
96 interpretation of the daytime variation of NO₂ columns and evaluation of simulated columns. In
97 this study, we interpret the summertime NO₂ measurements from the NASA P-3B aircraft using
98 the high-performance GEOS-Chem (GCHP) simulations along aircraft flight tracks and account
99 for line-of-sight of the Pandora sun photometers over Maryland, Texas, and Colorado during the
100 DISCOVER-AQ campaign. We also explore the effect of vertical changes in the hourly variation
101 of temperature on the NO₂ cross-section and the raw Pandora columns. We further investigate the
102 hourly variation of NO₂ columns and surface concentrations from 50 PGN sites across the northern
103 hemisphere. Section 2 describes the datasets and methods used in this study to interpret the
104 variation of NO₂ columns, surface concentrations, and vertical distribution over DISCOVER-AQ
105 and PGN sites. Section 3 examines the consistency between the NO₂ vertical columns and surface
106 concentrations across DISCOVER-AQ sites, and PGN sites across the contiguous United States
107 (CONUS), Europe, and Asia. We explore the effects of model resolution and boundary layer height
108 adjustments on the hourly variation of NO₂ total columns and surface concentrations as a function
109 of hourly variation in mixed layer depth and photochemistry, and measurement characteristics of
110 Pandora sun photometers over PGN sites across the CONUS, Europe, and Asia.

111 **2 Materials and Methods**

112 **2.1 Aircraft measurements of NO₂ vertical profiles**

113 The DISCOVER-AQ campaign offers comprehensive datasets of airborne and surface

114 observations relevant for accessing air quality. One of the main objectives of the campaign was to
115 examine the hourly variation of the relationship between the column and surface concentrations.
116 In this study, we use aircraft, Pandora, and surface measurements over Maryland (July 2011),
117 Texas (September 2013) and Colorado (July-August 2014) to investigate the hourly variation of
118 NO₂ vertical profiles during summer when a long duration of daylight exists for analysis. Figure
119 A1 shows the flight tracks, altitude variation, roadways, and Pandora instrument locations over
120 Maryland, Texas, and Colorado during the DISCOVER-AQ campaign. We focus on the aircraft
121 spirals since they are designed to sample the vertical profile. We use NO₂ concentrations measured
122 by the thermal dissociation laser-induced fluorescence (TD-LIF) technique (Thornton et al., 2000;
123 Day et al., 2002) during the campaign. The laser-induced fluorescence method is highly sensitive
124 for directly measuring NO₂, with a measurement uncertainty of 5 % and a detection limit of 30
125 pptv (Thornton et al., 2000). It also attempts to correct for positive interferences (Nault et al., 2015;
126 Yang et al., 2023b). We use aircraft measurements from a height of about 300 m above ground
127 level (AGL) up to 4 km AGL where high measurement frequency facilitates regional
128 representation.

129 **2.2 Pandonia Global Network NO₂ Total Column Densities**

130 PGN is a global network of ground-based sun photometers that measure sun and sky
131 radiance from 270 to 530 nm that allow retrievals of various trace gases including NO₂. Retrieval
132 precision for total vertical NO₂ columns (“NO₂ columns” hereafter) is 5.4×10^{14} molecules/cm²
133 with a nominal accuracy of 2.7×10^{15} molecules/cm² under clear-sky conditions (Herman et al.,
134 2009; Cede 2021). We obtained the level 2 data product from the version rrvs3p1-8 for PGN and
135 DISCOVER-AQ (data source listed in the code and data availability section). We also include
136 surface NO₂ observations from co-located DISCOVER-AQ and PGN sites. We use NO₂ columns

137 and surface concentrations employed during the DISCOVER-AQ campaign from 18 sites over
138 Maryland, Texas and Colorado. We also include NO₂ columns and surface concentrations from 50
139 PGN sites (the US: 31, Europe: 10, Asia: 9) for June-July-August (JJA) 2019. We focus on the
140 NO₂ observations between 9 AM - 6 PM local solar time, for consistency in observation frequency
141 across all PGN sites. Tables A1 and A2 contain the names and locations of the DISCOVER-AQ
142 and PGN sites respectively. We exclude Pandora measurements with SZA>80°. We use total NO₂
143 columns including the stratosphere because the use of external information sources to remove the
144 stratospheric NO₂ columns from PGN can introduce errors in the residual tropospheric columns
145 (Choi et al., 2020).

146 **2.3 GEOS-Chem simulations**

147 We use GCHP, the high-performance configuration of the GEOS-Chem model that
148 operates with a distributed-memory framework for massive parallelization (Eastham et al., 2018),
149 to interpret the NO₂ column, vertical distribution and surface observations. GCHP offers the ability
150 to simulate the entire atmospheric column needed to interpret Pandora measurements and the fine
151 spatial resolution needed to interpret aircraft measurements. GEOS-Chem is driven by assimilated
152 meteorological data from the NASA Goddard Earth Observation System (GEOS). GEOS-Chem
153 includes a comprehensive O_x-NO_x-VOC-halogen-aerosol chemical mechanism in the troposphere,
154 in addition to the unified tropospheric-stratospheric chemistry extension in the stratosphere
155 (Eastham et al., 2014). We use GEOS-Chem 14.1.1 which includes recent updates to GCHP
156 (Martin et al., 2022), NO_x heterogenous and cloud chemistry (Holmes et al., 2019), isoprene
157 chemistry (Bates and Jacob, 2019), and aromatic chemistry (Bates et al., 2021). The ISORROPIA
158 II module simulates the thermodynamic partitioning between the gas and condensed phase
159 (Fountoukis and Nenes, 2007). Natural emissions include biogenic volatile organic compounds

160 (VOCs) (Weng et al., 2020), lightning NO_x (Murray et al., 2012), and soil NO_x (Weng et al., 2020).
161 GEOS-Chem includes an updated aircraft NO_x emissions inventory for 2019, developed with the
162 Aircraft Emissions Inventory Code (Simone et al., 2013). Figure A2 shows the hourly variation of
163 NO_x emissions across the PGN sites. For the interpretation of PGN measurements in 2019, we
164 conduct the simulations for the year 2019 using GEOS-FP meteorology and the stretched grid
165 capability (Bindle et al., 2021) at a cubed sphere resolution of C180 (~55 km) and stretch factor
166 of 4.0 yielding a regional refinement of ~12 km. All simulations were conducted with a two-week
167 spin-up. We interpolate hourly GCHP outputs of simulated NO₂ columns and surface
168 concentrations to the local solar time at the PGN observation sites.

169 For interpretation of the DISCOVER-AQ aircraft campaigns, we conduct stretched grid
170 simulations over Maryland (July 2011), Texas (September 2013) and Colorado (July-August 2014)
171 with identical stretched grid configurations, with sampling along the aircraft flight tracks. We use
172 MERRA-2 meteorology for these simulations as GEOS-FP meteorology datasets are not available
173 prior to 2014. A sensitivity test for the year 2019 using either GEOS-FP and MERRA-2 affects
174 the local simulated NO₂ columns and surface concentrations by less than 5% for both 12 km and
175 55 km resolutions.

176 Hourly variation of the planetary boundary layer height (PBLH) can influence the vertical
177 distribution and hence the surface concentration of aerosols and trace gases (Lin and McElroy,
178 2010). Millet et al., (2015) found that GEOS-FP reanalysis over-estimates daytime PBLH as
179 compared to observations; correcting for PBLH estimations can lead to a better agreement of ozone
180 (Oak et al., 2019) and PM_{2.5} (Li et al., 2023b) with measurements. Our base case simulation uses
181 the PBLH derived from the Aircraft Meteorological Data Reports (AMDAR) at 54 sites across the
182 CONUS to adjust the PBLH estimates as described in Li et al., (2023). We examine the effect of

183 using the adjusted PBLH for simulations over the CONUS, Europe and East Asia. Table 1 shows
 184 the 3 simulation cases conducted over Maryland, Texas, Colorado, the CONUS, Europe and East
 185 Asia.

186 Table 1. Summary of GCHP Simulations

	Name	Description
188	Base_12	12 km base
189	No Δ BL_12	12 km without PBLH modification
190	No Δ BL_55	55 km without PBLH modification

191 **2.5 Effective temperature of Pandora measurements**

192 The NO₂ cross section is temperature dependent with the magnitude of spectral features in a 294
 193 K NO₂ spectrum about 80% of those in 220 K NO₂ spectrum (Vandaele et al., 2002). Thus, the
 194 NO₂ columns fitted with a 220 K NO₂ spectrum are about 80% of those fitted with the 294 K NO₂
 195 spectrum. Prior studies have identified biases in the Pandora total ozone column effective
 196 temperature driven by variations in seasonal temperature (Zhao et al., 2016; Herman et al., 2015).
 197 To account for the hourly changes in vertical variation of column temperature, we calculate
 198 simulated NO₂ effective temperatures T_{eff} using the site-specific hourly GEOS-FP temperature
 199 profiles $(T)_i$, NO₂ cross section $\sigma(NO_2)_i$, and GCHP NO₂ vertical profiles $VC(NO_2)_i$ following
 200 equation (1) of Herman et al. (2009):
 201

$$202 \quad T_{eff} = \frac{\sum_i^N (\sigma(NO_2)_i \cdot VC(NO_2)_i \cdot (T)_i)}{\sum_i^N (\sigma(NO_2)_i \cdot VC(NO_2)_i)} \quad (1)$$

203 The comparison between GCHP simulated and Pandora observed effective temperature is
 204 discussed in sec 3.2.

205 **2.6 Local solar time along Pandora line-of-sight**

206 At observing scenarios with large solar zenith angles, the Pandora sun photometer observes
207 air masses with varying local solar time at different altitudes along the line-of-sight. This feature
208 is particularly noteworthy for comparing hourly Pandora observations with other measurements or
209 simulations. Figure 1 shows the sampling process of GCHP simulations along the line-of-sight of
210 the Pandora sun photometer. GCHP grid boxes are integrated along the viewing geometry of the
211 Pandora instrument to create a “staircase column” that accounts for the effects of local solar time
212 on the horizontal and vertical variation in NO₂ concentrations. The variation in local solar time is
213 most relevant near sunrise and sunset when the NO₂/NO_x ratios change rapidly as discussed in
214 section 3.2. We correct the vertical columns reported by PGN to the local solar time of the
215 instrument by applying the ratio of integrated staircase columns to vertical columns.

216
217 Figure 1. Configuration of integrating the GCHP grid boxes along the line-of-sight of the Pandora
218 instrument. The shaded grid boxes represent the line-of-sight for the Pandora sun photometer at an inclined
219 solar zenith angle. Clock faces indicate a change in local solar time.

220 **2.7 Ground based surface NO₂ measurements**

221 We use hourly NO₂ surface concentrations from the catalytic converter measurements over

222 DISCOVER-AQ and PGN sites. Based on the approach of Lamsal et al., (2008) and Shah et al.,
223 (2020), we correct the interference of organic nitrates and HNO₃ in the NO₂ measurements, using
224 a correction factor derived from GCHP simulated site-specific NO₂, organic nitrates, and HNO₃
225 mixing ratios. The correction for HNO₃ and organic nitrates reduced the summertime mean NO₂
226 surface concentrations by 18% over DISCOVER-AQ sites and 23% over PGN sites.

227 **2.8 Normalized Bias**

228 We use normalized absolute bias or normalized bias (NB) to evaluate the simulations. The NB is
229 calculated using the following equation-

$$230 \quad NB = \frac{\sum_{i=1}^N |S_i - O_i|}{\sum_{i=1}^N O_i} \times 100\% \quad (2)$$

231 where, O_i is the observation and S_i is the corresponding simulated value, i refers to the index of
232 the observation and N refers to the total number of observations.

233 **3 Results and Discussion**

234 **3.1 Hourly variation of observed and simulated NO₂ vertical profiles**

235 Figure 2 shows the hourly variation in the airborne TD-LIF measurements and simulated NO₂
236 vertical profiles at 12 km resolution (Base_12) over Maryland, Texas and Colorado during the
237 DISCOVER-AQ campaign. The measurements exhibit a pronounced maximum at 500 m at 10
238 AM (squares) that diminishes by a factor of 2 in the afternoon as concentrations become more
239 uniform below 1.5 km (triangles and diamonds), driven by the hourly variation in PBLH mixing
240 from early morning to late afternoon. For all three DISCOVER-AQ campaigns, the 12 km
241 simulated NO₂ mixing ratios represent the vertical profile well with normalized bias (NB) below
242 16% at local times: 10 AM, 2 PM, and 5 PM. Differences tend to be larger within 1-2 km above
243 ground level in the afternoon (2 PM and 5 PM local time), which integrates to a lower simulated

244 partial column of 6×10^{14} molecules cm^{-2} . The simulated NO_2 vertical profiles at 12 km without
 245 PBLH modifications (No ΔBL_{12}) are similar to those with the PBLH modification (Figure A3).
 246 Figure A4 shows the 55 km simulated NO_2 vertical profiles (No ΔBL_{55}). The 55 km GCHP
 247 simulations have increased NB by a factor of 2, as compared to 12 km. Overall, the NO_2 vertical
 248 profile exhibits greater consistency with observations at 12 km than at 55 km by better resolving

249
 250 Figure 2: NO_2 vertical profiles from TD-LIF instrument aboard P-3B during the DISCOVER-AQ campaign
 251 over Maryland, Texas, and Colorado. The colored solid lines with pentagram markers represent
 252 observations. The dotted colored lines with square markers represent 12 km GCHP simulated mixing ratios.
 253 The inset values in the boxes show the normalized biases (NBs) at 10 AM, 2 PM, and 5 PM. The numbers
 254 on the right of each panel represent the number the observations associated with the corresponding altitude
 255 level. Error bars indicate standard errors in measurements.

256 the heterogeneous conditions along the aircraft flight tracks.

257 3.2 Corrections to Pandora Effective Temperature

258 The left panel in Figure 3 shows the Pandora and simulated mean hourly effective temperature of
 259 the NO_2 columns over all PGN sites during June-August as inferred using hourly GEOS-FP
 260 temperature profiles and GCHP NO_2 vertical profiles. The Pandora effective temperatures exhibit

261 weak hourly variation with a warmer temperature at the Asian sites where boundary layer NO₂
 262 concentrations are typically higher than in the US and Europe. The GCHP simulated effective
 263 temperature is also warmer for Asian sites, however, the effective temperature is lower during the
 264 early afternoon when near-surface NO₂ concentrations tend to be minimum such that the
 265 stratospheric NO₂ that makes a larger fractional contribution to the total column. The simulated
 266 effective temperature further deviates from the Pandora effective temperature with an increase
 267 toward sunrise and sunset with increasing near-surface NO₂ fraction. The corresponding correction

268
 269 Figure 3. Hourly variation of the total NO₂ column mean effective temperature across all PGN sites (left
 270 panel) and the corresponding correction factors (right panel).

271 factor (CF) for hourly variation in the effective temperature is calculated as:

$$272 \quad CF = 1 + \left(\frac{1}{0.8} - 1 \right) \times \frac{(T_{eff}(GCHP(hour)) - T_{eff}(Pandora(hour)))}{294 - 220} \quad (3)$$

273 The factor of $\left(\frac{1}{0.8} - 1 \right)$ reflects the difference between the NO₂ columns fitted with a 220 K NO₂
 274 spectrum that are about 80% of those fitted with a 294 K NO₂ spectrum. The CF for the Pandora
 275 NO₂ columns increases toward sunrise and sunset due to the increased effective temperature,
 276 reflecting the greater abundance of NO₂ molecules observed per unit absorption. We apply site-

277 specific CFs across all Pandora observations.

278 3.3 Hourly variation of observed and simulated NO₂ VCDs

279 Figure 4 (left) shows the mean hourly daytime Pandora vertical NO₂ columns summarized
280 from the summertime DISCOVER-AQ campaign measurements. The raw Pandora NO₂ columns
281 exhibit weak hourly variation of 8×10^{14} molecules cm⁻² (within 10% of the daytime mean) that
282 is inconsistent with the aircraft measurements that indicate total columns in the morning and

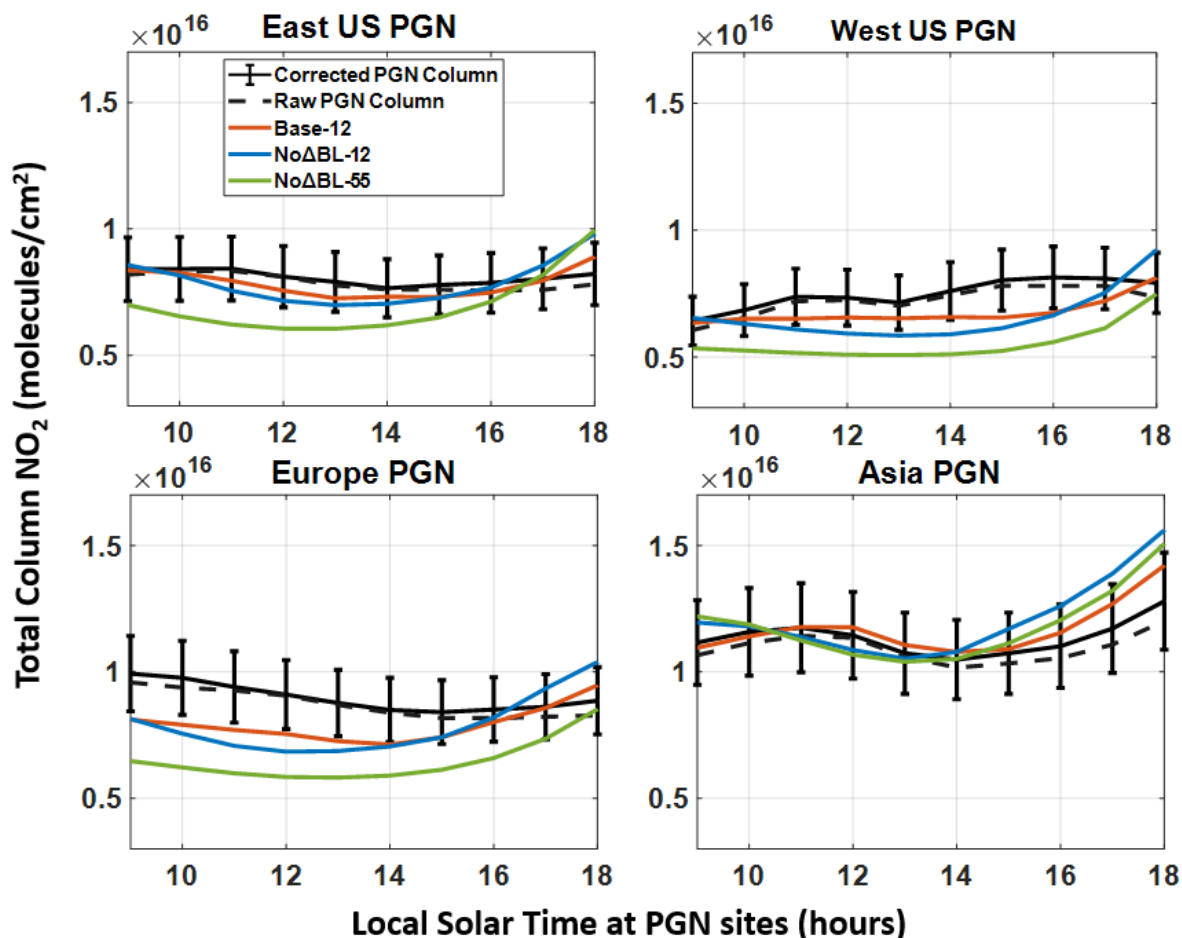

283
284 Figure 4. The left panel shows the total NO₂ vertical columns from corrected DISCOVER-AQ Pandora
285 columns (black), raw DISCOVER-AQ Pandora columns (black dotted), the 12 km base case simulation
286 (red), 12 km without modified PBLH (blue) and 55 km without modified PBLH (green), during the
287 DISCOVER-AQ campaigns over Maryland (2011), Texas (2013) and Colorado (2014). The corrected
288 Pandora columns account for the hourly variation in the effective temperature and the local solar time along
289 the line-of-sight. The right panel shows sampled aircraft and simulated partial columns (300 m A.G.L - 4
290 km A.G.L). Error bars indicate standard error.

291
292 evening of about 1.5×10^{15} molecules cm⁻² greater than afternoon. The corrected Pandora
293 measurements that account for hourly variation in effective temperature and local solar time along
294 line-of-sight exhibit greater NO₂ columns in morning and evening by about 1.3×10^{15} molecules
295 cm⁻², similar to the aircraft measurements. Since the Pandora instruments track the sun, viewing
296 stratospheric air masses 100 - 200 km away from the measurement station to the East in the
297 morning and to the West in the evening, the local solar time of stratospheric NO₂ observed by

308 Pandora instruments near sunrise and sunset is systematically shifted by about 5-10 mins towards
309 noon. This shift can be particularly important during sunrise and sunset when NO₂ columns in the
300 stratosphere undergo a pronounced increase driven by an increasing NO₂/NO_x ratio (Figure A5).
301 The 12 km simulated vertical columns generally represent the corrected Pandora observed columns
302 with an NB of 10%. Excluding the PBLH modification would have increased the NB to 13%.
303 Using a coarser 55 km simulation would have further degraded the agreement with an NB of 19%.
304 We sample the GCHP simulated NO₂ columns between 300 m and 4 km to compare with the
305 aircraft columns (right panel). The hourly variation of partial NO₂ columns over 300 m to 4 km
306 AGL from aircraft observations exhibits a distinct increase in morning and evening and are well
307 represented by the 12 km base case simulation (NB = 13%). Similar to our analysis for Pandora
308 sites, excluding the PBLH modification and coarsening the simulation to 55 km degrades the
309 performance (NB = 15% and 25%) versus aircraft columns.

310 Figure 5 extends our analysis to all PGN sites across the CONUS, Europe and East Asia. Raw
311 measurements across all regions exhibit weak hourly variation. The correction for effective
312 temperature and local solar time along the Pandora line-of-site increases the mean NO₂ columns
313 in the morning and evening by about 6×10^{14} molecules cm⁻² across all regions. The base case
314 simulation generally reproduces measurements with NB of 9% for the eastern US, 14% for the
315 western US, 15% for Europe and 21% for east Asia sites. Excluding the PBLH correction would
316 have increased the NB (eastern US: 12%, western US: 18%, Europe: 18%, and eastern Asia: 26%)
317 with the largest change in Asia. Excluding the PBLH correction yields a higher daytime PBLH
318 resulting in increased chemical lifetime of NO_x, reduced NO₂ dry deposition rates and increased
319 NO₂/NO_x ratio during afternoon and evening (Figure A6), thus leading to an hourly variation that
320 deviates from the Pandora observations. Coarser resolution generally further increases the bias,

321 reflecting resolution effects discussed in the next section. The increase of the simulated total NO₂
 322 columns between 3-6 PM across all PGN sites reflects an increase in the NO₂/NO_x ratio throughout
 323 the column, driven by a reduction in HO_x (Figure A7).

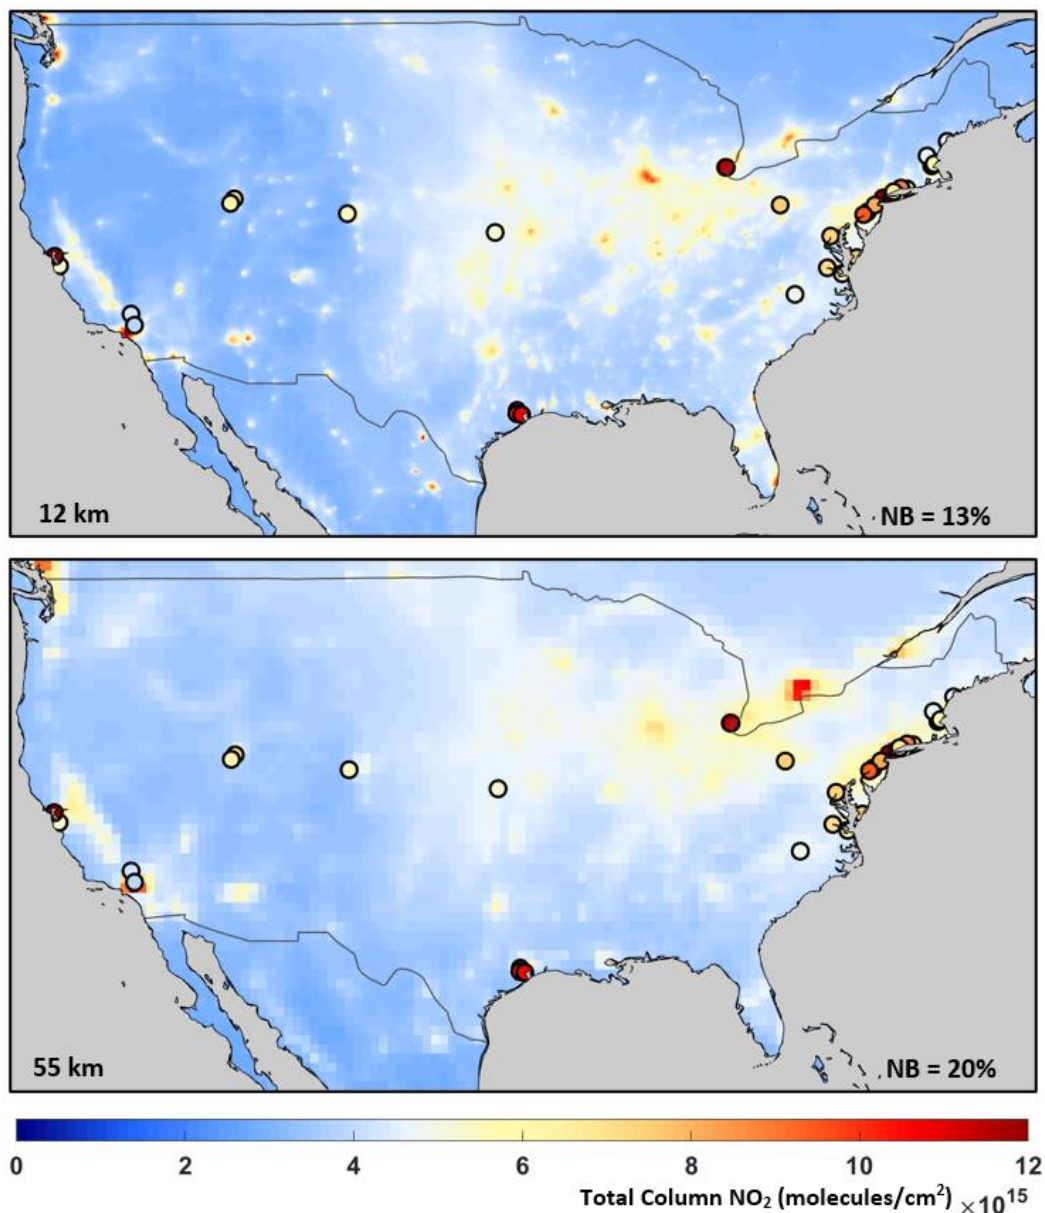

324
 325 Figure 5. The total NO₂ vertical columns from corrected Pandora columns (black), raw Pandora columns
 326 (black dotted), the 12 km base case simulation (red), 12 km without modified PBLH (blue) and 55 km
 327 without modified PBLH (green) sampled over PGN sites for the summer months of June-July-August in
 328 2019. Error bars indicate standard error.

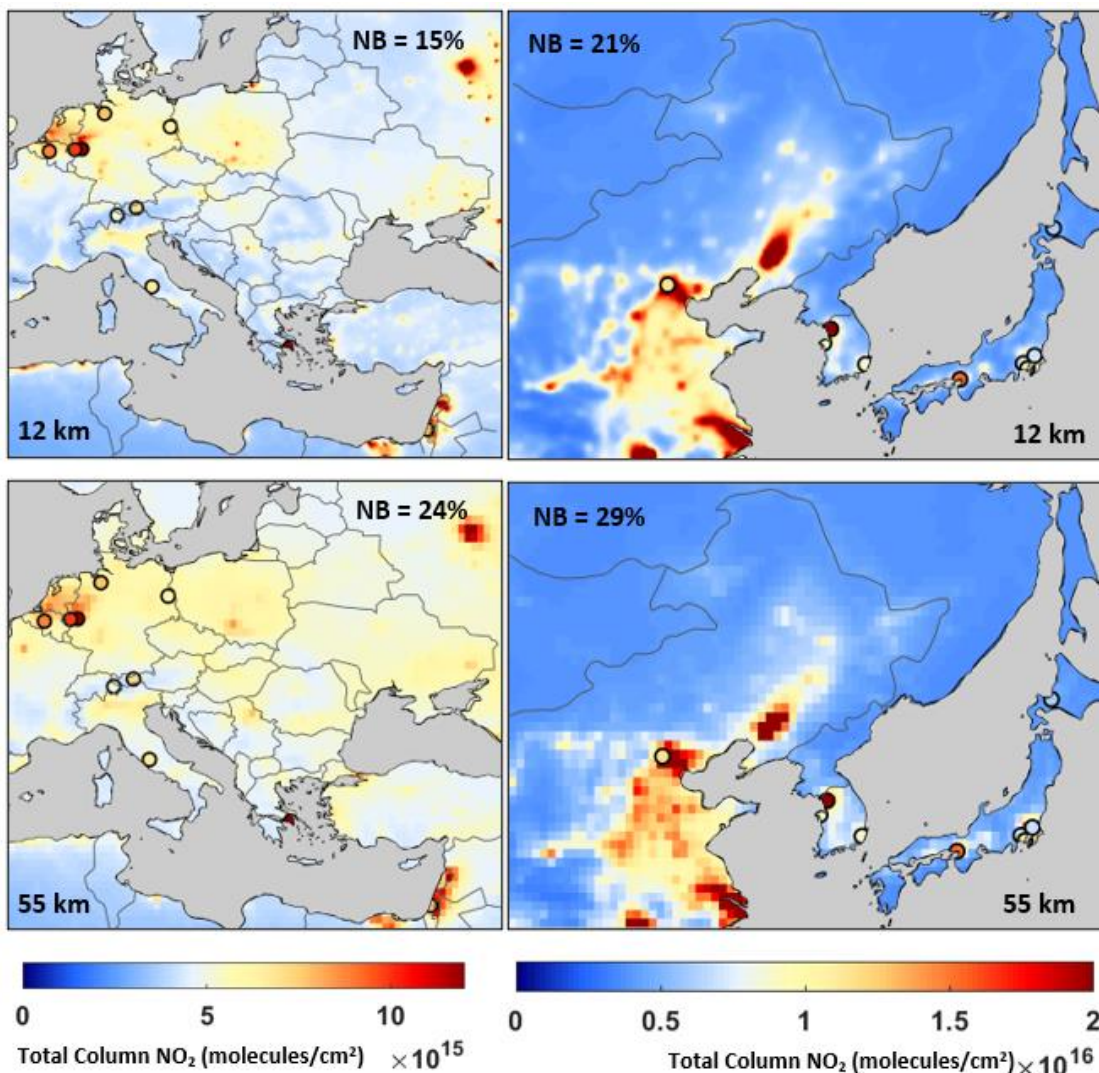

329 3.4 Simulated total NO₂ columns

330 Figure 6 shows the 12 km and 55 km simulated total NO₂ columns, for the summer months of
 331 June-July-August in 2019, between 9 AM and 6 PM (local solar time) over the CONUS. The
 332 overlaid circles show the PGN mean total NO₂ columns. The 12 km simulated NO₂ columns
 333 exhibit greater heterogeneity and better consistency with PGN observed columns (NB = 13%) as

334 compared to the 55 km simulated NO₂ columns (NB = 20%). This is primarily driven by better
335 representation of emission and chemical processes at fine resolution (Zhang et al., 2023; Li et al.,
336 2023a). Emissions at these sites are dominated by the transportation sector (Table A3). Figure 7

337
338 Figure 6. Simulated NO₂ total columns at 12 km (panel A) and 55 km (panel B) horizontal resolutions for
339 the three-month average of June-July-August 2019 over domains where PGN monitors were available
340 between 9 AM – 6 PM local solar time. The solid circles represent the PGN mean total columns between
341 9 AM – 6 PM local solar time for PGN sites in CONUS (31)

342

343 Figure 7. Simulated NO₂ total columns at 12 km (panel C and D) and 55 km (panel E and F) horizontal
 344 resolutions for the three-month average of June-July-August 2019 over domains where PGN monitors were
 345 available between 9 AM – 6 PM local solar time. The solid circles represent the PGN mean total columns
 346 between 9 AM – 6 PM local solar time for the PGN sites in Europe (10) and Asia (9).

347 shows the total NO₂ columns from PGN, 12 km simulation and 55 km simulation for the summer
 348 months of June-July- August in 2019, between 9 AM and 6 PM local solar time over Europe and
 349 East Asia. We find enhanced NO₂ vertical columns over urban areas in western Europe, eastern
 350 China, Japan and the Korean peninsula. The 12 km simulated NO₂ columns exhibit more resolved
 351 combustion features and better agreement with Pandora observed columns for Europe (NB = 15%)
 352 and east Asia (NB = 17%) as compared to the 55 km simulated NO₂ columns for Europe (NB =

353 24%) and east Asia (NB = 29%).

354 3.5 Hourly variation of observed and simulated surface NO₂ concentrations

355 Figure 8 shows the hourly variation in surface NO₂ mixing ratios from the corrected in situ
356 measurements and 12 km simulations over Maryland, Texas and Colorado. Measured NO₂ mixing
357 ratios are greater in morning and evening than in afternoon as expected from the mixed layer
358 growth and shorter NO_x lifetime in afternoon. Observed NO₂ surface concentrations over PGN
359 sites in Asia show enhancement at evening hours (5-6 PM) as compared to PGN sites elsewhere.

361 Figure 8. The left panel shows the hourly variation of corrected surface NO₂ mixing ratios from
362 observations during the DISCOVER-AQ campaign. The middle and right panels show the hourly variation
363 of observed and 12 km simulated surface NO₂ mixing ratios averaged over the PGN sites with and without
364 PBLH modification respectively. Error bars indicate standard error.

365 The measurements are better represented at 12 km (NB = 21%) than at 55 km (NB = 63%) by
366 better resolving high NO_x emissions near measurement sites. Both Base_12 and NoΔBL_12
367 simulated NO₂ concentrations generally represent the observations well with NB = 18% (Base_12)
368 and NB = 20% (NoΔBL_12), across all PGN sites.

369 3.6 Hourly variation of layer contributions to simulated total NO₂ columns

370 Given the overall skill of the 12 km simulations in representing the Pandora, aircraft, and surface
371 NO₂ we proceed to apply the 12 km simulations to understand how the simulated NO₂ vertical
372 profile affects the simulated NO₂ column to surface relationship. Figure 9 shows the hourly

373 variation of simulated contributions to the NO₂ total columns (Base_12) from different vertical
 374 layers for multiple regions. In all four regions, within the troposphere, the layer below 0.5 km is
 375 the largest contributor at 9 AM with a diminishing contribution into the afternoon associated with
 376 mixed layer growth followed by an increasing contribution towards evening. The contribution

377
 378 Figure 9. The simulated absolute contribution of NO₂ columns at different hours of the day averaged over
 379 the summer months of June-July-August for 2019 for PGN sites over the eastern US, western US, Europe,
 380 and eastern Asia. The colored lines resemble the absolute concentrations from different sections of the
 381 column. The black line (hexagon) represents the total NO₂ column. The right y-axis (specifically for the
 382 total NO₂ column representing the black marked line) shows the total columns of NO₂.

383 from layers between 0.5 km and the tropopause has weaker variation contributing to the overall
 384 weaker variation in total columns. Fractional layer contributions are shown in Figure A8.
 385 Fractional hourly variation of the layers above 0.5 km exhibits a compensating inverse behavior,
 386 with a pronounced variation in the stratospheric fraction. Contributions from the free troposphere
 387 are relatively high for the eastern US reflecting the lightning contribution (Shah et al., 2023; Dang

388 et al., 2023). Over Asia the fractional contribution below 0.5 km is the highest (26% - 42%)
389 reflecting major surface contributions. Overall, we find that for all four regions, the hourly
390 variation in the total column reflects hourly variation below 500 m, dampened by greater column
391 contributions above 500 m that dominate the total column.

392 **Conclusion**

393 We applied GCHP to investigate the hourly variation of summertime NO₂ columns and surface
394 concentrations by interpreting DISCOVER-AQ aircraft and ground-based measurements over
395 Maryland, Texas, Colorado and PGN measurements over the CONUS, Europe, and eastern Asia.
396 We corrected the hourly variation in Pandora observations for the effects of temperature on the
397 NO₂ cross section and the local solar time along the Pandora line-of-sight. The site-specific
398 effective temperature correction factors typically increase the hourly variation of the Pandora
399 observed columns over DISCOVER_AQ sites (3.5% from the daytime mean) and PGN sites (4%
400 from the daytime mean). Near sunrise and sunset, differences in local solar time observed by
401 Pandora in the stratosphere versus the measurement site reflect displacement of 5-10 mins in local
402 solar time toward noon which is relevant in the stratosphere near sunrise and sunset when the
403 NO₂/NO_x ratio is varying rapidly. These corrections to the Pandora measurements improve their
404 consistency with the hourly variation in the NO₂ columns inferred from DISCOVER-AQ aircraft
405 measurements. We find that fine scale simulations at 12 km better represent the NO₂ vertical
406 profile measured by aircraft, reducing the NB from 23% to 16% as compared to simulations at a
407 moderate resolution of 55 km. Simulations at fine resolution (~12 km) of vertical columns along
408 the line-of-sight of Pandora instruments have lower NB with Pandora sun photometers at
409 DISCOVER-AQ sites (10%), and across the eastern US (9%), western US (14%), Europe (15%)
410 and Asia (21%) as compared to moderate resolution (55 km). Fine resolution represents

411 atmospheric physical and chemical processes with greater accuracy. Excluding the effects of
412 model resolution and the PBLH modification increases the NB to 21% across DISCOVER-AQ
413 sites (over Maryland, Texas and Colorado) and increases the NB at PGN sites over the eastern US
414 (17%), western US (24%), Europe (24%) and east Asia (29%). Adjusting the PBLH to represent
415 observations improves the daytime variation in NO_2/NO_x ratios by increasing the NO_2/NO_x ratio
416 in midday and decreasing the NO_2/NO_x ratio in the afternoon and evening.

417 Given the overall skill of the 12 km GCHP simulations in representing the corrected Pandora,
418 aircraft, and surface NO_2 measurements, we apply them to derive the hourly contribution of
419 vertical layers to the total tropospheric columns. We find weaker hourly variation in total NO_2
420 columns than in the lowest 500 m where NO_2 concentrations are greater in morning and evening
421 than midday, while the residual tropospheric column above 500 m dominates the total column with
422 weaker variability. Thus, the weak hourly variation in the column reflects fractional contributions
423 from NO_2 below and above 500 m. Despite the skill of the 12 km simulations in representing the
424 Pandora column measurements, there appears to be greater hourly variation in the simulation, the
425 aircraft measurements, and the surface measurements than in the Pandora observations. Future
426 work should continue to understand this relationship. Future work should also leverage the
427 information developed here to test the performance of surface NO_2 concentrations inferred from
428 the geostationary constellation against ground-based measurements.

429 **Code and Data Availability**

430 GEOS-Chem 14.1.1 along with GCHP code is available for download at
431 <https://github.com/geoschem/GCHP.git>. The PGN data is available at [https://data.pandonia-](https://data.pandonia-global-network.org/)
432 [global-network.org/](https://data.pandonia-global-network.org/). The DISCOVER-AQ aircraft and Pandora data are available here:

433 <https://asdc.larc.nasa.gov/project/DISCOVER-AQ>. For hourly simulated NO₂ datasets please
434 contact the author (deepangsuchatterjee@wustl.edu; deepangsuchatterjee@gmail.com)

435 **Author contributions**

436 The manuscript was written using contributions from all authors. The conceptualization was
437 initialized by DC and RVM. The methodology was developed by DC and RVM .DC conducted
438 the model simulations. DC conducted the data analysis with help from CL,DZ,HZ,LL,DH,RC. JC
439 conducted the DISCOVER-AQ campaign. AC manages the PGN datasets. DC and RVM wrote
440 the original draft. All authors have reviewed, edited and given approval to the final version of the
441 manuscript.

442 **Competing interests**

443 The contact author has declared that neither they nor their co-authors have any competing interests.

444 445 **Acknowledgments**

446 This work has been supported by the NASA Grant 80NSSC21K1343 and 80NSSC21K0508 and
447 NSF Grant 2244984. We thank the GEOS-Chem support team for maintaining the model used in
448 this work.

Appendix

711
712
713

714 Figure A1. Flight tracks showing the path and altitude of the P-3B aircraft during the DISCOVER-AQ
715 campaign over Maryland during July 2011 (left), over Texas during September 2013 (center) and over
716 Colorado during July-August 2014 (right). The green triangles show the locations of the Pandora sun
717 photometers that have been used in this study. The Sites names and coordinates are listed in Table A1. Grey
718 indicates land, white indicates water. The black bold lines indicate roads.

719

720 Figure A2. Hourly variation of NO_x emissions including all sectors across 50 PGN sites over the CONUS,
 721 Europe, and east Asia.

722

723

724 Figure A3: NO₂ Vertical profiles from TD-LIF instrument aboard during the DISCOVER-AQ campaign
 725 over Maryland, Texas and Colorado. NO₂ vertical profiles from TD-LIF instrument aboard P-3B during the
 726 DISCOVER-AQ campaign over Maryland, Texas and Colorado. The colored solid lines with pentagram
 727 markers represent observations. The dotted colored lines with square markers represent 12 km GCHP
 728 simulated mixing ratios. The inset values in the boxes show the NB at 10 AM, 2 PM, and 5 PM. The

729 numbers in the middle represent the number the observations associated with the corresponding altitude
 730 level. Error bars indicate standard errors in measurements.

731

732 Figure A4: NO₂ Vertical profiles from TD-LIF instrument aboard during the DISCOVER-AQ campaign
 733 over Maryland, Texas and Colorado. NO₂ vertical profiles from TD-LIF instrument aboard P-3B during the
 734 DISCOVER-AQ campaign over Maryland, Texas and Colorado. The colored solid lines with pentagram
 735 markers represent observations. The dotted colored lines with square markers represent 12 km GCHP
 736 simulated mixing ratios. The inset values in the boxes show the NB at 10 AM, 2 PM, and 5 PM. The
 737 numbers in the middle represent the number the observations associated with the corresponding altitude
 738 level. Error bars indicate standard errors in measurements.

739

31

740 Figure A5. GCHP NO₂ stratospheric columns for the three-month average of June-July-August at
 741 DISCOVER-AQ sites (red) and PGN sites (blue).

742

743 Figure A6. Hourly variation of 12 km simulated column NO₂/NO_x ratios across 50 PGN sites over the
 744 CONUS (red), Europe (blue), and east Asia (green). The dotted lines show the 12 km simulated NO₂/NO_x
 745 ratios without modified PBLH.

746

747

748 Figure A7. Simulated NO₂/NO_x ratios (left panel) and simulated partial and total OH columns (right panel)
 749 at different hours of the day averaged over the summer months of June-July-August for 2019 for PGN sites
 750 over the eastern US, western US, Europe, and eastern Asia.

751

752 Figure A8. The simulated fractional contribution of NO₂ columns at different hours of the day averaged
 753 over the summer months of June-July-August for 2019 for PGN sites over the eastern US, western US,
 754 Europe, and eastern Asia. The right Y-axis shows the total columns of NO₂.

755 Table A1. Site name, latitude and longitude for 18 sites in Texas, Maryland, and Colorado that has
 756 concurrent pandora and aircraft measurements.
