Abstract

Remote sensing radars from air- and spaceborne platforms provide critical observations of clouds to estimate precipitation rates across the globe. Capability of these radars to detect changes in precipitation properties is advanced by Doppler measurements of particle fall speed. Within mixed-phase clouds, precipitation mass and its fall characteristics are especially sensitive to the effects of riming. In this study, we quantified these effects and investigated the distinction of riming from aggregation in Doppler radar vertical profiles using quasi-idealized particle-based model simulations. Observational constraints of a control simulation were determined from airborne in situ and remote sensing measurements collected during the Investigation of Microphysics and Precipitation for Atlantic Coast-Threatening Snowstorms (IMPACTS) for a wintry-mixed precipitation event over the northeast United States on 04 February 2022. From the upper boundary of a one-dimensional column, particle evolution was simulated through vapor deposition, aggregation, and riming processes, producing realistic Doppler radar profiles. Despite a modest observed amount of supercooled liquid water (0.05 g m^{-3}), riming accounted for 55% of the ice-phase precipitation mass, cumulatively increasing reflectivity by 44% and Doppler velocity by 68%. Independent evaluation of process-based sensitivities showed that while radar reflectivity is comparably sensitive to either riming- or aggregation-based particle morphology, the Doppler velocity profile is uniquely sensitive to particle density changes during riming. Thus, Doppler velocity profiles advance the diagnosis of riming as a dominant microphysical process in stratiform clouds from single-wavelength radars, which has implications for quantitative constraints of particle properties in remote sensing applications.

63 1. Introduction

64 Ice crystals within precipitating winter storms evolve through an inherently stochastic
65 sequence of microphysical processes which uniquely affect their physical properties and fall
66 characteristics. This continuous and process-based evolution of ice-phase particles remains
67 poorly represented by many numerical models and remote sensing retrieval algorithms. A
68 fundamental limitation is that cloud and precipitation processes occur on physical scales that are
69 several orders of magnitude smaller than typical cloud-scale model grids or the remote sensing
70 instrument sampling volume. Nevertheless, realistic representation of varied particle populations
71 within clouds is necessary to accurately estimate precipitation rates.

72 Commonly, a population of particles within some volume is expressed by a particle size
73 distribution (PSD), and weighted integrals (i.e., moments) of the PSD are sensitive to the
74 microphysical evolution of ice-phase particles (Morrison et al. 2020). Ice-phase precipitation
75 mass is proportional to the second moment of the PSD. Because radar reflectivity, Z , is
76 proportional to the square of the mass (i.e., the fourth moment of the PSD), the precipitation
77 mass directly affects power returned to a radar. However, because of the physical complexity
78 arising from diversity in initial ice crystal habits and their unique process-based morphologies
79 with time, assumptions about the particle properties and the PSD are often necessary to derive
80 remote sensing precipitation rate estimates. For example, ice crystals are commonly assumed to
81 be spherical (e.g., Iguchi et al. 2018) and the population may be constrained to a prescriptive
82 PSD shape or snow density (e.g., Grecu et al. 2016). A consequence of such a priori assumptions
83 is that process-based variations cannot be expressed and retrieved precipitation rate estimates are
84 inherently constrained, leading to snowfall rate underestimation and increased error compared to
85 liquid phase (e.g., Speirs et al. 2017). To advance the utility of radar remote sensing
86 measurements of ice-phase precipitation, it is important to understand the quantitative effects of
87 process-based evolution on the intrinsic physical properties of precipitation in natural clouds and
88 their implications for the radar measurements.

89 A remarkable property of precipitating clouds is that liquid water droplets are frequently
90 present at sub-freezing temperatures alongside ice crystals. A region of cloud containing both ice
91 and sub-freezing (i.e., supercooled) liquid water (SLW) is described as a mixed-phase layer. One
92 implication of the mixed phase particle population is that depositional ice growth occurs at the
93 expense of liquid water due to differences in saturation vapor pressures over ice and liquid

94 surfaces, a process commonly referred to as the Wegener-Bergeron-Findeisen process
95 (Pruppacher and Klett 1997). Additionally, upon contact with falling ice crystals, the SLW
96 droplets freeze and are accreted by the crystal (i.e., riming), initiating a physical morphology of
97 the particle. Natural ice crystals demonstrate tremendous variability in shape and complexity
98 depending on growth habits (e.g., Magono and Lee 1966; Pruppacher and Klett 1997; Bailey and
99 Hallet 2009). Because of this diversity, it is often convenient to define the crystal size along
100 major and minor axes while the major axis is assumed to be along the maximum dimension of
101 the crystal and the minor axis is along an orthogonal orientation. The aspect ratio defines the
102 ratio between the crystal dimensions along the minor and major axes (Jensen and Harrington
103 2015). One commonly adopted conceptual description for the change in particle properties
104 during riming is the “fill-in” model (Heymsfield 1982) whereby the liquid water will initially fill
105 open voids, while largely maintaining the initial dimensions of the crystal axes. During later
106 stages of the “fill-in” riming model, rime accumulates on the underside of the falling crystal,
107 increasing the minor dimension of the crystal while the major dimension remains unchanged.
108 With increasing riming, aspect ratio approaches unity, which is expected for heavily rimed
109 graupel particles. Consequently, riming results in increasing particle density and, therefore, fall
110 velocity. The adjustments in particle geometry and fall characteristics with rime accumulation
111 are relative to, and dependent on, the initial ice crystal geometry and accreted rime but further
112 dependent on prior and concurrent processes including vapor depositional growth and
113 aggregation (e.g., Jensen and Harrington 2015).

114 Ice-phase particle growth by deposition of vapor-phase water directly increases the ice water
115 content (IWC) and therefore, yields direct increases in Z (Field et al. 2005, 2007). However,
116 depositional mass accumulation occurs at a relatively slow rate, thus, gradual increases in Z are
117 expected from depositional growth alone. Aggregation of two or more particles does not
118 explicitly alter the IWC of the particles, but rather redistributes the mass to a larger size particle.
119 Despite unchanging IWC, increased particle diameters, D , during aggregation enhances radar
120 scattering at a rate proportional to D^4 and consequently, Z may be significantly increased by
121 effects of aggregation. Through accumulation of liquid-phase water which yields increases in
122 IWC, similar, rapid adjustments in Z are also possible during riming. Evaluation of process-
123 based effects on the evolution of the PSD moments and their implications for precipitation
124 fallout from natural clouds is challenging because specific processes cannot be readily isolated,

125 even if observations are collected in situ. In general, observationally-consistent numerical
126 modeling simulations are necessary to determine such effects.

127 The physical scales of processes that govern the formation and evolution of falling ice
128 crystals are not resolved by most numerical models. In bulk- and bin-microphysics schemes, ice-
129 phase processes are commonly expressed implicitly through conversion processes whereby
130 precipitation is exchanged among predefined categories (e.g., ice, snow, graupel, hail; Thompson
131 et al. 2004; Morrison et al. 2005). However, prior studies (e.g., Colle et al. 2005; Morrison and
132 Milbrandt 2011; van Weverberg et al. 2012) have demonstrated that the precipitation evolution
133 and fallout is sensitive to a priori thresholds that define category conversions (e.g., snow to
134 graupel during riming). For rimed growth, Lagrangian particle-based model simulations indicate
135 that bulk particle density can undergo rapid evolution in response to small variations in the
136 background SLW concentration, significantly modulating the particle fall velocity and surface
137 precipitation rate (DeLaFrance et al. 2024). For remote sensing retrievals of mixed-phase
138 precipitation, the effects of rime accumulation are constrained by the a priori assumptions about
139 the particle's mass, geometry, or fall characteristics. Recently, diverse methodologies leveraging
140 multi-frequency, dual-polarization, and Doppler radar measurements have been proposed for
141 retrieving some properties of ice-phase particles that would otherwise be prescribed (e.g.,
142 Leinonen and Szyrmer 2015; Kneifel et al. 2016; Moisseev et al. 2017; Oue et al. 2018;
143 Leinonen et al. 2018; Mason et al. 2019, Chase et al. 2021). Among these methods, leveraging
144 radar Doppler data has shown promise in inferring the onset of riming and, subsequently, the
145 riming-based modulations of retrieved particle property estimates. Mason et al. (2018)
146 demonstrated that the addition of Doppler radar measurements provides constraint on the bulk
147 ice density parameter in retrievals of snowfall. Furthermore, as shown by Kalesse et al. (2016),
148 rimed snow occupies a unique region of Doppler spectra distinct from unrimed snow. One-
149 dimensional (1D) spectral bin microphysics modeling simulations have shown promise in
150 reproducing the Doppler spectra moments of riming but demonstrate sensitivity to particle
151 property assumptions (Kalesse et al. 2016).

152 The 1D columnar modeling approach offers a framework for simulating explicit
153 microphysical processes and detailed particle properties that are computationally prohibitive in a
154 three-dimensional (3D) dynamic model. The 1D construction is therefore well suited to advanced
155 bin and Lagrangian particle-based microphysics schemes. One challenge for such simulation

156 designs, however, is constraining the model in a way that minimizes assumptions and, as a result,
157 ambiguity in the attributing physical process for adjustments in the cloud's radar and
158 precipitation characteristics (e.g., Kalesse et al. 2016; Bringi et al. 2020). Some assumptions can
159 be constrained by coincident in situ and remote sensing radar measurements.

160 Data collected during winters of 2020, 2022, and 2023 from the Investigation of
161 Microphysics and Precipitation for Atlantic Coast Threatening Snowstorms (IMPACTS)
162 campaign (McMurdie et al. 2022) provide those constraints. Midlatitude cyclones over the
163 United States East Coast and Midwest regions were comprehensively sampled by coordinated
164 aircraft- and ground-based platforms to better understand the precipitation microphysics within
165 regions of snowfall that organize into elongated regions commonly recognized as snowbands
166 (e.g., Novak et al. 2004). Consistent with IMPACTS's goal to support improved numerical
167 modeling and remote sensing retrievals of winter precipitation, in the present study we
168 investigate the process-based effects of riming in a sampled storm that produced moderate rates
169 of wintry-mixed precipitation for a prolonged period over the Northeast. Our overarching
170 approach is to combine these observations with numerical modeling simulations to describe the
171 process-based particle evolution and contributions of riming to the observed radar properties and
172 precipitation rates. Here, we use an observationally-constrained, sophisticated Lagrangian
173 particle-based model within a 1D columnar framework to address the following questions:

- 174 1. Can primary ice processes (i.e., deposition, aggregation, riming) within a simplified
175 1D simulation reasonably reproduce the observed evolution of particles within the
176 natural cloud?
- 177 2. What were the quantitative contributions of riming to the observed Doppler radar
178 vertical profiles and to the surface precipitation rate?
- 179 3. Do simulated Doppler radar vertical profiles yield characteristic responses to the
180 onset or degree of riming that is distinct from other ice-phase processes (e.g.,
181 aggregation)?

182

183 **2. Winter Storm Observations**

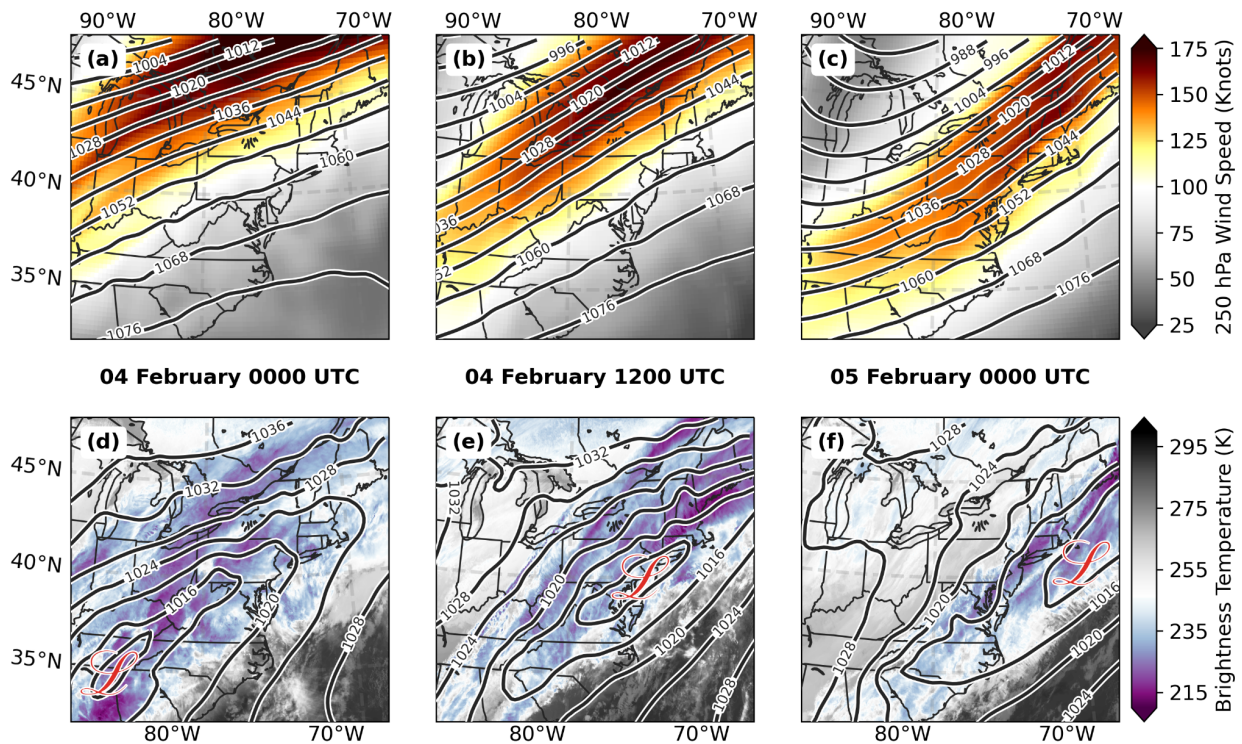

184 **2.1. 04 February 2022 Case Study**

185 For this analysis, we will use IMPACTS observations collected during the 04 February 2022
186 event that delivered wintry-mixed precipitation across a broad region of the northeast US.

187 IMPACTS deployed an in situ (P-3) and remote sensing (ER-2) aircraft. The P-3 aircraft was
188 equipped with instrumentation to measure the in situ cloud microphysical properties and the
189 high-altitude ER-2 aircraft was equipped with nadir-viewing remote sensing instrumentation
190 analogous to those onboard satellite-based platforms (e.g., Skofronick-Jackson et al. 2017). The
191 two aircraft targeted the storm over the coastal New England area where, as an example of the
192 surface precipitation characteristics during this event, the Boston, MA (KBOS) Automated
193 Surface Observing System (ASOS; Brodzik 2022a) reported nearly 32 mm of precipitation in 24
194 hours. Precipitation initially accumulated in the form of light to heavy rain before transitioning to
195 freezing rain at about 1300 UTC, ice pellets by 1600 UTC, and back to freezing rain at about
196 1930 UTC. A transition to snow and continued accumulation occurred on 05 February at KBOS
197 and over most of the New England area.

198 Winter storms that impact the northeast US are commonly described according to the track of
199 the low-pressure center, with implications for their precipitation characteristics. From these
200 tracks, Zaremba et al. (2024) classified twenty-six IMPACTS events in one of six categories,
201 which varied in, for example, rates and regions of cyclogenesis, frontal forcing, and precipitation
202 intensity and distribution. Six of the events were classified as cold fronts and had relatively weak
203 and expansive low-pressure areas which yielded widespread rain and snow along, and extending
204 to the cold side of, the front. As one of these cold front events, the 04 February case had a broad
205 frontal boundary that extended from the Gulf of Mexico to Maine. The prolonged period of
206 wintry-mixed precipitation over the northeast US was sustained by isentropic lifting of moisture-
207 rich low-level flow along this front and overrunning a surface layer which, for many areas,
208 remained subfreezing. Over the eastern US, a mean southwesterly flow developed ahead of an
209 initially positively tilted 250-hPa trough at 0000 UTC 04 February that developed to nearly
210 neutral tilt by 0000 UTC 05 February (Fig. 1a-c). An associated jet streak exceeding 150 kts was
211 situated over northern New England such that between about 1200 UTC 04 and 0000 UTC 05
212 February, upper-level divergence in the right entrance region further supported lifting within the
213 atmospheric column (Bjerknes 1951; Uccellini and Kocin 1987; Holton and Hakim 2012).
214 During this time period, a modest elongated southwest-northeast oriented low-pressure minimum
215 of approximately 1010 hPa was maintained over a broad region of coastal New England (Fig. 1d-
216 f).

217

218

219 **Figure 1:** Synoptic evolution of the winter storm that impacted the northeast US: (a-c) 250 hPa
 220 geopotential heights (dam) and wind speeds (knots) and (d-f) mean sea level pressure (MSLP,
 221 hPa) and cloud brightness temperature (K) for the times 0000 UTC 4 February (a, c); 1200 UTC
 222 4 February (b, e) and 0000 UTC 5 February 2022 (c, f) . The 250-hPa and MSLP data are from
 223 the European Center for Medium-Range Weather Forecast Reanalysis v5 (ERA5; Hersbach et
 224 al. 2020) and the brightness temperature data are from the Geostationary Operational
 225 Environmental Satellites (GOES) 10.3 μm channel (Brodzik 2022b).

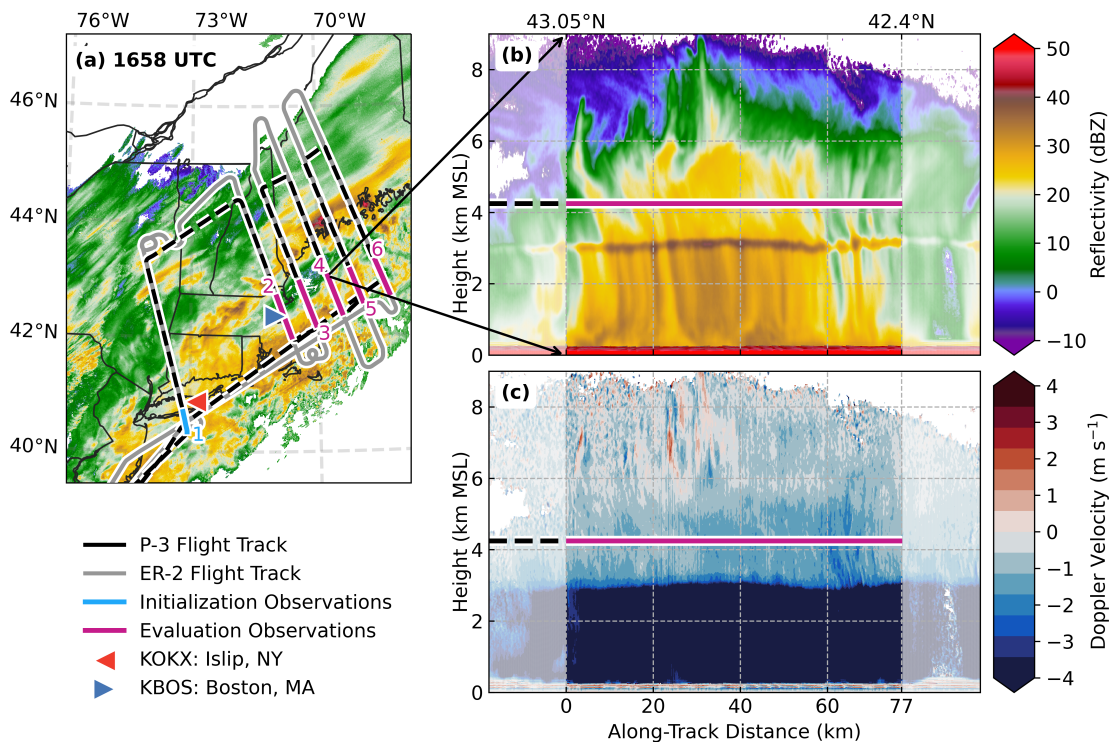

226

227

228 Between about 1300 and 1800 UTC, the P-3 and ER-2 aircrafts flew a “lawnmower-style”
 229 pattern orthogonal to the long axis of an enhanced region of reflectivity while translating
 230 subsequent flight legs to the northeast, such that the storm was sampled in an approximately
 231 Lagrangian manner (Fig. 2a). The P-3 flew its initial flight leg south to north beginning at about
 232 1340 UTC briefly at 6.5 km MSL before descending to a constant altitude of about 6.2 km MSL.
 233 At the southern end, this initial flight leg was near the NWS rawinsonde launch site at Islip, NY
 234 (KOKX). The P-3 descended on each subsequent flight leg to sample different layers of the
 235 cloud reaching an altitude of 3.0 km MSL on the final north-to-south flight leg, which transected
 236 the 0°C melting level. The two enhanced regions of reflectivity, on either side of the surface

237 frontal boundary, exhibited differing cloud and precipitation properties. At the surface, the
 238 northern region of enhanced reflectivity was dominated by snowfall whereas the southern region
 239 was dominated by rain during the period of aircraft sampling then transitioning to wintry-mixed
 240 precipitation. As we describe in Section 2.2, in situ measurements are used to indicate riming,
 241 which was commonly observed over the southern region of enhanced reflectivity but absent over
 242 the northern region. Therefore, to address our science questions, our present analysis is
 243 constrained to measurements of the southern portions of flight legs (Fig. 2a).

244

245

246 **Figure 2:** IMPACTS operations on 04 February 2022 over the northeast US targeting regions of
 247 enhanced reflectivity that persisted for several hours in the operational National Weather
 248 Service (NWS) Multi-Radar Multi-Sensor (MRMS; Zhang et al. 2011) product. Shown are (a) the
 249 coordinated P-3 and ER-2 flight tracks and MRMS composite reflectivity at approximately mid-
 250 flight (1658 UTC) with subsets for each numbered flight leg at the southern enhanced region of
 251 reflectivity indicating data used for this study. Also indicated in (a) are the NWS rawinsonde
 252 launch site at Islip, NY (KOKX) and ground verification site at Boston, MA (KBOS). Ku-band
 253 reflectivity (b) and Doppler velocity (c) vertical profiles as measured by the ER-2 aircraft from
 254 1628 (north) to 1634 UTC (south) depict the vertical cloud profile across the region of enhanced
 255 reflectivity (between transparent regions) for the fourth flight leg while the P-3 aircraft sampled
 256 in situ at ~4.3 km MSL altitude (magenta line in b, c), ending the flight leg at ~42.4°N.

257

258

2.2. Observations: Surface Based, Remote Sensing, and In Situ

The initial ER-2 and P-3 flight leg approximately overflew the NWS operational Islip, NY (KOKX) rawinsonde launch site (Fig. 2a). Because of the relatively steady-state nature of the storm during the aircraft sampling period, the KOKX 1200 UTC rawinsonde (Waldstreicher and Brodzik 2022) is used to estimate the atmospheric properties in the southern portion of the flight legs. Because these southern portions of the flight legs were mostly offshore, we use the nearest ASOS measurements at KBOS between 1300 and 1800 UTC to estimate the mean surface precipitation rate for model comparison. The ER-2 aircraft flew well above the storm at approximately 20 km MSL and operated two nadir-viewing radars on 04 February: the dual-band 13.9 GHz (Ku-band) and 35.6 GHz (Ka-band) High-Altitude Wind and Rain Airborne Profiler (HIWRAP; Li et al. 2016; Mclinden et al. 2022a) and the 94 GHz (W-band) Cloud Radar System (CRS; McLinden et al. 2022b). For radar reflectivity and Doppler velocity measurements of the precipitation, we use HIWRAP measurements, which have a vertical resolution of 150 m and a surface footprint of 1 km. At Ku-band, HIWRAP has a minimum sensitivity of approximately -10 dB at an altitude of 10 km MSL (Li et al. 2016).

Of the numerous instruments onboard the P-3 aircraft, those of relevance to this study include cloud Optical Array Probes (OAPs) and those that measure Liquid Water Content (LWC) and vertical air motion. The OAPs provide measurements of the two-dimensional projected sizes, shapes, and concentrations of particles. Data from a Two-Dimensional Stereo (2D-S; Lawson et al. 2006), which is commonly used for measurements of particles smaller than about 1 mm in diameter, are unavailable for the 04 February flight. However, a vertically oriented High-Volume Precipitation Spectrometer (HVPS; Lawson et al. 1993) provided particle measurements at sizes greater than 0.5 mm which were used to construct PSDs. Measurements of LWC were obtained from a Fast Cloud Droplet Probe (FCDP; Lawson et al. 2017) which operated as part of the Hawkeye combination probe. The FCDP uses Mie light scattering principles to size and count liquid water droplets from 2 to 50 μm in diameter, from which number and mass concentrations can be derived. Processing of the OAP and FCDP data was performed by the National Center for Atmospheric Research (NCAR; Bansemmer et al. 2022) and is used at a 1 Hz frequency. Vertical air motion measurements were provided by the Turbulent Air Motion Measurement System (TAMMS), which uses several sensors at different locations on the aircraft to estimate the 3D components of the ambient wind (Thornhill et al. 2003). For

290 TAMMS configured to the P-3, the accuracy of vertical winds measurements is estimated to be
291 0.2 m s^{-1} (Thornhill 2022).

292

293 **3. Simulation Design and Validation**

294 **3.1. Model Description**

295 Several bulk microphysics schemes have been developed to more realistically represent the
296 observed continuous evolution of ice-phase particle populations during riming (e.g., Morrison
297 and Milbrandt 2015; Jensen et al. 2017; Cholette et al. 2023). Recently, this modeling approach
298 has been extended to a Lagrangian particle-based scheme in the novel McSnow model (Brdar
299 and Seifert 2018). The particle-based approach affords some advantages over the bulk approach,
300 namely that evolution of a population of particles occurs independent of an Eulerian grid cell
301 structure and is not constrained by assumptions about the PSD. The McSnow model was
302 developed in a 1D columnar configuration and was expressly designed to simulate the evolution
303 of an initial particle population during sedimentation through the column (Brdar and Seifert
304 2018). The notion of a particle in McSnow follows the super-droplet principle (Shima et al.
305 2009) whereby a multiplicity of real particles having commonality among physical properties
306 and location are represented by a single super-particle. These super-particles are continuously
307 introduced in the upper boundary of the model such that initially prescribed PSD characteristics
308 are maintained and then evolve by vapor deposition and aggregation, with an option for riming to
309 occur within a user-defined mixed-phase layer. From 2D simulations using McSnow,
310 DeLaFrance et al. (2024) demonstrated that mixed-phase layer depth significantly modulates
311 surface precipitation rates, varying up to 50% in response to a depth change of 750 m and that in
312 situ measurements of SLW content provide a constraint on the layer's vertical extent. Following
313 riming, melting of the particles occurs as its surface temperature exceeds 0°C , and collision-
314 coalescence processes may then occur, but no additional precipitation mass is generated by
315 warm-rain processes. The thermodynamic profile is prescribed and there are no mechanisms of
316 feedback on the ambient environment based on the microphysical processes.

317 At any point in the column, detailed information about individual particle properties are
318 directly accessible. In general, however, there is greater utility in the description of a population
319 of particles in the form of a binned PSD expressed as the number concentration, N , of particles
320 with diameter, D . We use a construction of 200 bins linearly spaced from $2 \mu\text{m}$ to 10 cm . From

321 the PSD, radar quantities associated with moments of the PSD are computed by using a forward
 322 operator to estimate the radar scattering properties. Several scattering models have previously
 323 been adopted to radar scattering from ice crystals, principally differing in the complexity of the
 324 scattering particle's geometry. A population of ice crystals may be treated as spheres and
 325 scattering computed directly from Mie theory (Bohren and Huffman 1983); however, this
 326 approach vastly simplifies the irregular geometry of natural ice crystals. Scattering estimates
 327 based on the T-matrix method (Mishchenko et al. 1996) support nonsphericity of particles using
 328 a spheroidal shape. Furthermore, the orientation of the spheroids relative to the radar beam may
 329 be specified or randomized (Mishchenko and Travis 1998). A more sophisticated approach
 330 termed discrete-dipole approximation (DDA) accounts for the complex scattering interactions of
 331 irregular crystal geometry (Purcell and Pennypacker 1973) and is therefore a compelling method
 332 to estimate scattering of natural crystals. However, for our simulations, crystal habits or detailed
 333 properties of particle geometry are not predicted and thus, T-matrix is an apt method of
 334 estimating radar scattering. Specifically, we use the PyTMatrix software (Leinonen 2014) to
 335 estimate the radar backscattering cross section, σ , and compute Z , defined as:

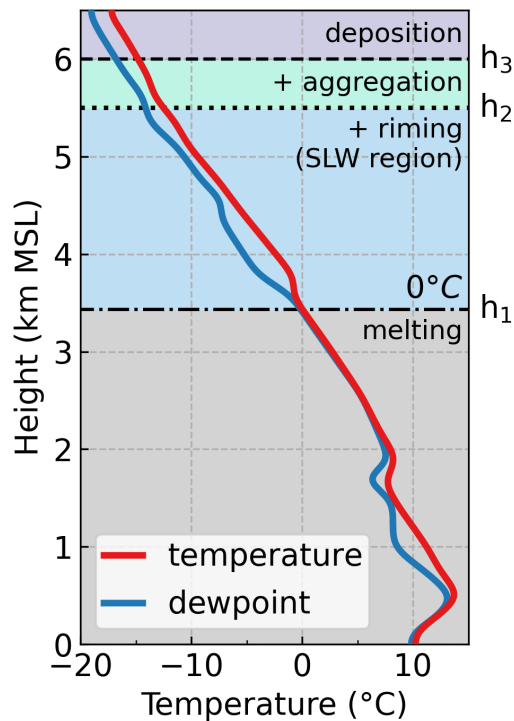

$$336 \quad Z = \frac{\lambda^4}{\pi^5 |K|^2} 10^{18} \int_0^\infty \sigma(D)N(D)dD, \quad (1)$$

337 where λ is the radar wavelength and K is the dielectric factor. From the simulations, we also
 338 estimate Doppler velocity, V_D , which is the reflectivity-weighted fall velocity, v , of the particles,
 339 defined as:

$$340 \quad V_D = \frac{\int_0^\infty v(D)\sigma(D)N(D)dD}{\int_0^\infty \sigma(D)N(D)dD}. \quad (2)$$

341 For a mixed-phase cloud, Tridon et al. (2019) demonstrated a degradation of skill in T-matrix Z
 342 estimates at higher radar frequencies (i.e., Ka- and W-band). To minimize uncertainties
 343 associated with non-Rayleigh radar scattering effects (e.g., Matrosov 2007; Liu 2004, 2008), we
 344 specify $\lambda = 25$ mm for all calculations, which is comparable to the Ku channel on the HIWRAP
 345 radar. Additionally, for consistency with the HIWRAP measurements, a two-way correction for
 346 attenuation due to precipitation particles was applied following methodology described in
 347 Williams (2022).

348

349

350 **Figure 3:** Schematic of the one-dimensional columnar configuration of the McSnow model with
 351 prescriptive process-based layers for evolution of new particles initiated at the column's upper
 352 boundary. Static temperature and dew point vertical profiles are derived from the 04 February
 353 1200 UTC KOKX rawinsonde.
 354

355

356 3.2. Control Simulation Design

357 We use the in situ measurements combined with rawinsonde data to construct a quasi-
 358 idealized cloud profile that is representative of the mean state of the 04 February storm which we
 359 apply prescriptively in the 1D columnar McSnow model. The process-based model design is
 360 illustrated by the schematic in Fig. 3. Introduction of new particles from a prescribed PSD occurs
 361 at 6.5 km MSL, which approximately corresponds to the uppermost height of in situ
 362 observations. Dominant particle types observed at this height were side planes and bullet
 363 rosettes. As newly introduced particles undergo sedimentation, growth occurs initially by vapor
 364 deposition only. Aggregation is introduced at 6 km MSL (-15°C) since aggregate particles,
 365 mostly side planes and other planar crystals, were present in observations below 6 km MSL.
 366 Riming is introduced at 5.5 km MSL, which we approximate as an upper extent of the mixed-
 367 phase layer based on the presence of SLW droplets and rimed particles beginning at flight leg 3

368 (4.9 km MSL) and, subsequently, on legs 4 and 5 (4.3 and 3.6 km MSL). The onset of melting is
369 determined by the thermodynamic profile which is obtained from the 1200 UTC KOKX
370 rawinsonde. Although model processes are largely independent of an Eulerian grid (see
371 discussion in Brdar and Seifert 2018, Section 2), model output and analysis occurs on a gridded
372 column with 500 vertical levels, which yields a vertical resolution of 13 m. Additionally, we
373 specify a time step of 5 s and total run duration of ten hours; results are analyzed as averages
374 over the final five hours, after the system has reached a steady state.

375 As a constraint on the observational data used for simulation construction, we approximate
376 the horizontal extent of the southern region of enhanced reflectivity by visually assessing its
377 lateral edges during each flight leg using the Ku-band radar vertical profiles. An example of this
378 approach is provided in Fig. 2b, c for the fourth flight leg in which data used is from the center
379 portion of the figure. The boundaries (opaque regions) varied for each flight leg, adapting to the
380 northeastward progression of the storm and translation of each flight leg. The initial PSD
381 characteristics are derived from an average of the measurements on the uppermost height flight
382 leg at ~6.5 km MSL between the southern end point of the leg and 40.7°N latitude (see Fig. 2a).
383 Because measurements are unavailable for particles smaller than 0.5 mm, we fit a Gamma
384 distribution to the mean PSD from HVPS measurements and then extend the fitted distribution to
385 a lower size limit of 112.5 μm to estimate an IWC of 0.14 g m^{-3} and total number concentration,
386 N , of $23 \times 10^3 \text{ m}^{-3}$. For all simulations, an initial super-particle multiplicity of 10^5 in the upper
387 boundary is specified. We assume that newly initialized particles at 6.5 km MSL have a mass-
388 dimension relationship of $m = 0.00294D^{1.94}$ (cgs units) following Brown and Francis (1995), for
389 unrimed aggregate ice crystals in a stratiform cloud. From analysis of four IMPACTS events
390 during the preceding 2020 deployment, Heymsfield et al. (2023) showed that Z calculated from a
391 PSD using the Brown and Francis (1995) mass-dimension relationship and a T-matrix approach
392 yielded an agreement with observations at Ku band within 1.15 dB.

393

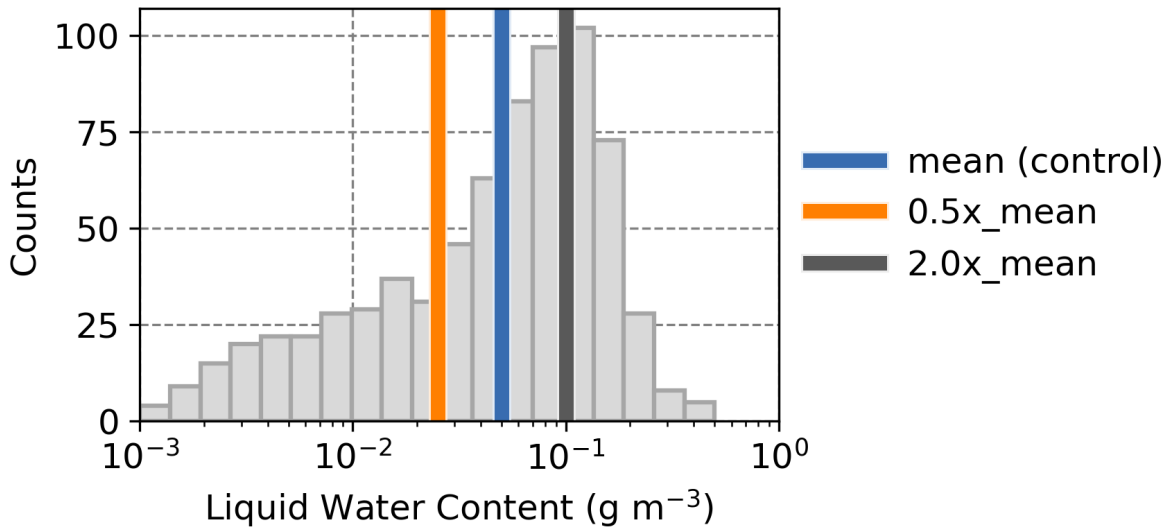

394

395 **Figure 4:** Vertical wind velocity measurements from the Turbulent Air Motion Measurement
 396 System (TAMMS) during P-3 flight legs indicating lower to upper quartiles in the boxed regions,
 397 10th and 90th percentiles at the whiskers, and medians at the vertical lines. A mean profile is
 398 fitted to the flight-level mean values (white markers).
 399

400

401 Falling particles are subject to an updraft. We estimate a mean-state vertical wind profile by
 402 fitting a third-degree polynomial curve to the mean measurements from each flight leg and
 403 extending the upper- and lower-most measurements as a constant value to heights beyond the
 404 observation altitudes (violet curve in Fig. 4). Within the mixed-phase layer (h_2 to h_1 in Fig. 3),
 405 SLW properties are derived collectively using FCDP measurements on flight legs 3, 4, and 5. We
 406 uniformly prescribe the mean values for SLW concentration of 0.05 g m^{-3} (Fig. 5) and a
 407 characteristic droplet diameter of $22 \text{ }\mu\text{m}$ within the mixed-phase layer.
 408

409
 410 **Figure 5:** Histogram of liquid water content (LWC) measurements from the Fast Cloud Droplet
 411 Probe (FCDP) during P-3 flight legs through mixed phase cloud (4.9 to 3.6 km MSL). Vertical
 412 bars indicate mean (0.05 g m^{-3}) and perturbed-state values used for sensitivity simulations scaled
 413 from the mean by factors of 0.5 and 2.0.
 414

415
 416 Although we prioritize the use of observations for model constraint, several decisions are
 417 necessary regarding the parameterizations of modeled processes. With two exceptions, these
 418 parameterization decisions follow those discussed in DeLaFrance et al. (2024, see Section 2.3
 419 and Appendix A). The first difference regards the aggregation process. Upon collision of two or
 420 more particles, a sticking efficiency parameter which scales from 0 to 1 is used to describe the
 421 probability of the particles merging, where an efficiency of 1 will always yield a union. The
 422 sticking efficiency parameterization follows Connolly et al. (2012), which is dependent on
 423 temperature and maximizes at -15°C . In testing, however, we found that the maximum likelihood
 424 estimate (MLE) values of Connolly et al. (2012; see Fig. 14b) yielded lower concentrations of
 425 large particles than were observed. Alternatively, use of a higher efficiency value inspired by the
 426 upper extent of their confidence interval yielded a more observationally-consistent PSD
 427 evolution and maximum particle sizes. Therefore, aggregation is introduced at 6 km MSL (Fig.
 428 3) with a sticking efficiency of 0.9 at -15°C and linearly decreases to 0.5 at -10°C , remaining
 429 constant at 0.5 between -10° and 0°C . The second parameterization decision which differs from
 430 DeLaFrance et al. (2024) regards riming where a continuous approach was used in favor of a

431 stochastic approach, although they describe only minor differences between the two approaches.
432 In the present analysis, we find a slightly reduced collection of rime mass using the continuous
433 parameterization when compared to the stochastic parameterization. Applying the continuous
434 parameterization approach, particles accumulate a mean rime fractional mass of 0.49 by the time
435 they reach 3.6 km MSL (flight leg 5, immediately above the melting level), whereas applying the
436 stochastic parameterization, a rime fractional mass of 0.55 is accumulated. Visual assessment of
437 the in situ particle imagery indicated that the stochastic method produces a more observationally
438 consistent riming evolution. Therefore, the stochastic riming parameterization is used in all
439 simulations.

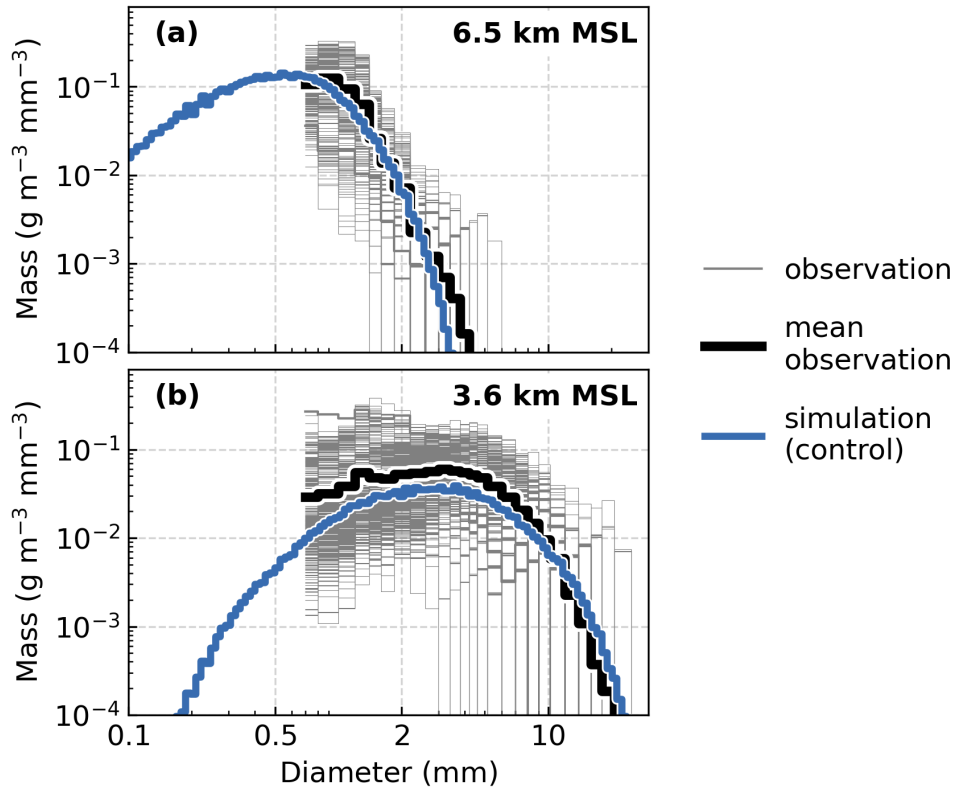

440

441 **3.3. Control Simulation Assessment**

442 The objective for a control simulation is to produce an evolution of a population of particles
443 within a vertical column that is physically consistent with the observed cloud profile. In Fig. 6,
444 we compare the control simulation PSD to the mean observed PSD ($D \geq 0.7$ mm). Although PSD
445 measurements at smaller particle sizes are unavailable for this flight, the approximately
446 Lagrangian aircraft sampling yielded a temporally consistent evolution of the PSD at larger sizes.
447 Measurements from flight leg 1 are used to assess the simulation during the particle initialization
448 stages within the uppermost region of the model, whereas measurements collected downstream
449 on flight legs 2 through 6 are used to assess simulation performance during the later stages of
450 particle evolution. The model produces an initial particle population at 6.5 km MSL (Fig. 6a) that
451 is consistent with the mean observations at large particle sizes and follows the assumed Gamma
452 distribution form at small sizes. Flight leg 5 (Fig. 2a), at approximately 3.6 km MSL, was the
453 lowest altitude flown before reaching the melting level. At this altitude, evaluation of the
454 simulation shows skill in evolving this initial particle population by deposition, aggregation, and
455 riming processes throughout a nearly 3 km-deep cloud layer.

456 Particle growth between 6.5 km (Fig. 6a) and 3.6 km MSL (Fig. 6b) through aggregation and
457 to a lesser extent, depositional growth, is expressed in the shift of the observed PSD to larger
458 particle sizes. This evolutionary characteristic is reproduced by the control simulation although
459 slightly larger maximum particle sizes are generated, and the ice mass may be underrepresented
460 among particles smaller than about 2 mm in diameter. We note, however, that sizing uncertainty
461 in the observed measurements is greater at these small sizes owing to the relatively coarse pixel

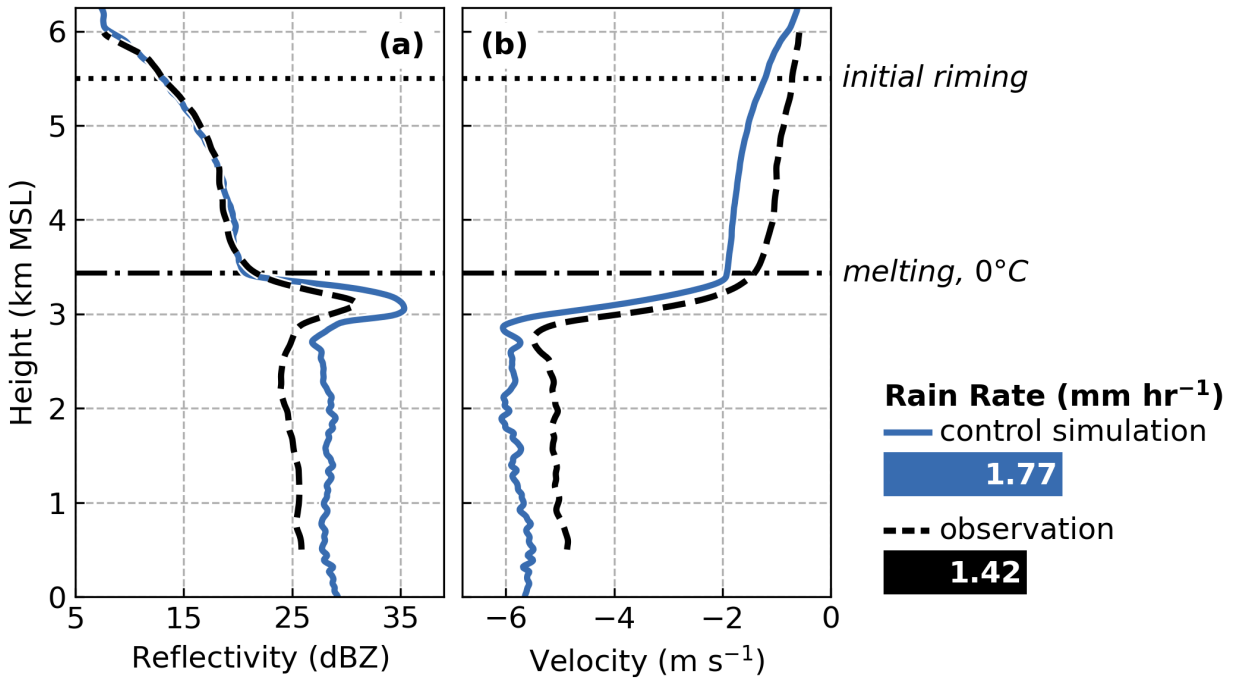

462 resolution of $150\ \mu\text{m}$ for the HVPS probe (Bansemer et al. 2022). To further validate the control
 463 simulation and to assess the continuous particle evolution throughout the vertical profile, Z is
 464 estimated from the simulated PSD and compared to the HIWRAP Ku-band measurements.
 465

466
 467 **Figure 6:** Particle size distributions (PSDs) of ice mass for observed 1 Hz and mean values
 468 derived from (a) P-3 flight leg 1 at 6.5 km MSL and (b) flight leg 5 at 3.6 km MSL (see Fig. 2)
 469 and for the control simulation at equivalent altitudes.
 470

471
 472 Figure 7 shows the median observed vertical profile of Z and V_D computed from the
 473 downstream flight legs 2 through 6, as indicated in Fig. 2a. Data from the lowest 500 m were
 474 removed due to noise from ground clutter. From the observed vertical profiles, several inferences
 475 are made about the microphysical processes. Beginning at 6 km MSL, Z rapidly increases with
 476 descent, which is expected with an onset of aggregation. The rate of increase in Z with
 477 descending height reaches a relative maximum near 5.5 km MSL (Fig. 7a), coincident with an
 478 apparent acceleration of V_D . Within the subsequent 1 km (5.5 km to 4.5 km MSL), V_D becomes

479 increasingly negative (-0.72 m s^{-1} to -1.00 m s^{-1}) as particle fall speeds increase (Fig. 7b). This
 480 effect is assumed to be associated with the onset of riming, and subsequently, changes in particle
 481 densities. Particle melting begins near 3.4 km MSL, at which point a bright band signature is
 482 apparent and V_D rapidly accelerates. Below the bright band, Z remains nearly constant at about
 483 25 dBZ and V_D is about -5 m s^{-1} .
 484

485
 486 **Figure 7:** Vertical profiles of (a) radar reflectivity and (b) Doppler velocity at Ku band for the
 487 control simulation (blue lines) and observed (dashed black lines) median from ER-2 HIWRAP
 488 radar during flight legs 2-6 (see Fig. 2a, magenta segments). Data for the observed profile below
 489 500 m MSL are omitted due to ground clutter. A dotted line at 5.5 km MSL indicates the onset of
 490 riming and a dash-dotted line indicates the 0°C height. Also shown at the right are the surface
 491 rain rate values from the control simulation (blue) and observed at KBOS (black) between 1300
 492 and 1800 UTC on 04 February 2022; horizontal bar lengths illustrate magnitude differences.
 493

494
 495 The vertical profile of Z is well reproduced by the control simulation, particularly above the
 496 melting level (Fig. 7a), which suggests confidence in its prescriptive configuration. Upon
 497 melting, Z is overestimated by the control simulation and maintains a bias of about 2 to 5 dB
 498 throughout the warm layer. While an evaluation of warm-rain processes is beyond the scope of
 499 the present study, it is possible that this overestimate in Z results from an incomplete

500 representation of warm-rain processes by the model, such as droplet breakup and shedding, or
501 from uncertainties in the scattering estimates. Confirmation of an attributable mechanism would
502 be challenging without in situ observations below the melting level. Rain rates at the surface are
503 one common model validation metric. Because the aircraft sampling occurred primarily offshore
504 (see Fig. 2a), an ideally situated ground site is unavailable. However, we find comparison with a
505 nearby ground site useful towards determining whether the control simulation produces
506 physically realistic estimates that are representative of the rainfall across the broader region. At
507 the surface, during aircraft sampling (1300 to 1800 UTC), the nearest ground site, KBOS,
508 reported a rain rate of 1.42 mm hr^{-1} . The control simulation produces about 25% more surface
509 rain with an average rain rate of 1.77 mm hr^{-1} .

510 Despite the confidence in Z aloft, we find that V_D is underestimated by about 0.5 to 1 m s^{-1} in
511 the control simulation but within an uncertainty range of $\pm 1 \text{ m s}^{-1}$ (Matthew McLinden, personal
512 communication, 25 April 2024) for the HIWRAP Ku-band V_D measurements. Some of the
513 uncertainty in the V_D measurements is due to corrections necessary for the aircraft motion,
514 which, although unlikely to significantly affect the relative evolution of V_D with height, may
515 yield an absolute magnitude bias. This bias between the observed and simulated V_D is consistent
516 throughout the column, suggesting that this consistent bias may be explained, to a large extent,
517 by those uncertainties in the observations. More importantly for this analysis, the relative
518 changes in V_D with height, which have process-based implications, are similar between the
519 observed and simulated profiles.

520

521 **4. Process-Based Contributions and Sensitivities on Doppler Radar Vertical Profiles**

522 A principal advantage of the particle-based design of the McSnow model is that information
523 about microphysical properties is retained by the model at the scale of the individual particles.
524 For particles in the control simulation, the onset of riming at 5.5 km MSL (h_2 in Fig. 3) initiates a
525 change in the physical evolution of the particle with subsequent sedimentation. At 3.6 km MSL ,
526 the particles have accumulated a mean rime fractional mass of 0.55 , increasing the total
527 precipitation mass and accelerating its fallout rate. Radar scattering by the particle, expressed
528 through Z , is also modified by rime accumulation, yet these effects are difficult to distinguish
529 from concurrent processes, including deposition and aggregation. To investigate these scattering
530 implications, we estimate the vertical profile of Z with and without contributions of rime mass.

532

533 **Figure 8:** *As in Fig. 7a but with an added vertical profile (in green) for estimated reflectivity (Z)*
 534 *with particle rime mass removed. Shown at the right are simulated and observed Z values*
 535 *computed at 3.6 km MSL; horizontal bar lengths illustrate magnitude differences.*
 536

537

538 Figure 8 compares Z from the control simulation (as in Fig. 7a) to an unrimed estimate of Z
 539 obtained by subtracting the rime mass from the particles and recomputing their scattering
 540 properties. Removal of rime mass appears to significantly impede further increases in Z with
 541 descending height below 5.5. km MSL. Near the melting level, Z is reduced from 20.07 to 13.03
 542 dBZ between the control and simulation and the unrimed estimate, suggesting that the
 543 accumulated rime mass contributes to about 35% of the total Z (in dB units). This calculation,
 544 however, only considers the implications of riming on radar scattering; the complex interactions
 545 of concurrent processes are neglected by solely removing the rime mass from evolved particles
 546 in the control simulation. Additionally, the effects on V_D , which manifest cumulatively during
 547 riming, cannot be investigated in the same manner. To explicitly investigate the effects of riming
 548 on the radar profiles, and to distinguish these effects from concurrent processes, we introduce
 549 several sensitivity simulations which independently perturb the riming or aggregation processes.

Simulation	Description	Perturbation Assignment
control	Observation-based mean-state simulation	none
high_SLW	Increase SLW by 2.0 from control	0.100 g m ⁻³ LWC
low_SLW	Reduce SLW by 0.5 from control	0.025 g m ⁻³ LWC
no_riming	Remove riming to distinguish effects from aggregation	Riming process turned off
MLE_C12_agg	Reduce aggregation from control to moderate efficiency	MLE sticking efficiency; see Fig. 14, Connolly et al. (2012)
low_C12_agg	Reduce aggregation from control to low efficiency	0.5 x MLE sticking efficiency; see Fig. 14, Connolly et al. (2012)

551

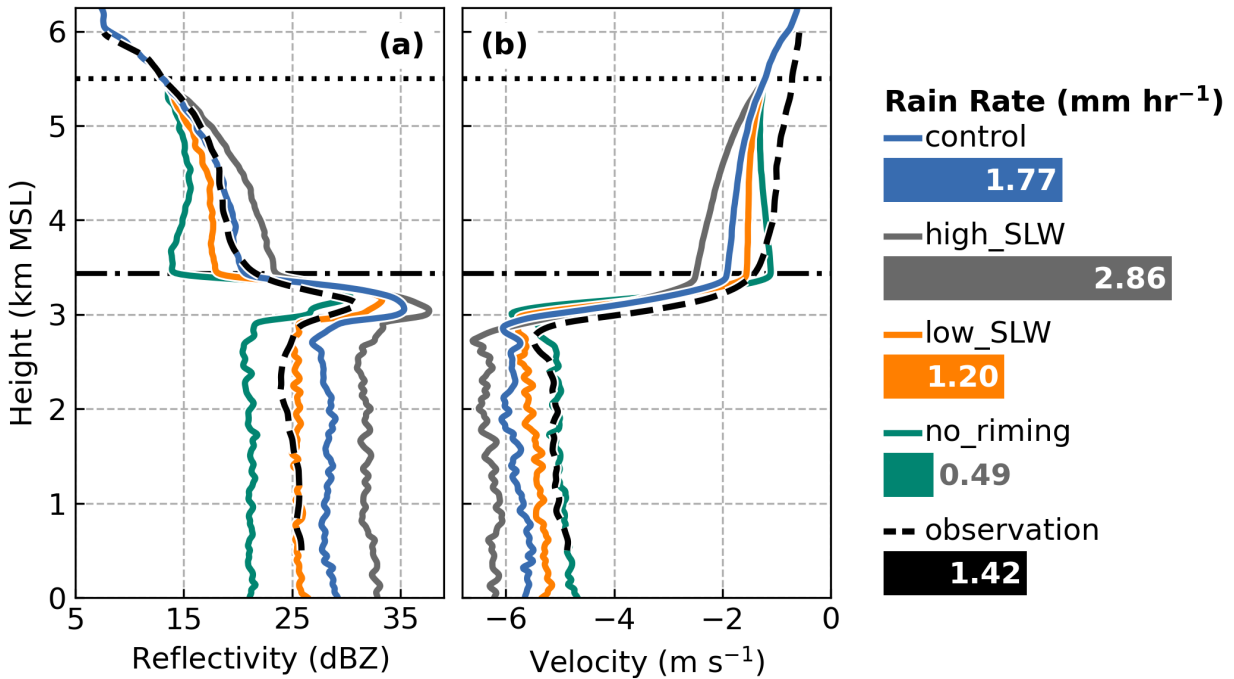

552 **Table 1:** *Descriptions and perturbations relative to the control simulation applied for each*
553 *simulation.*

554

555

556 Although the southern regions of the 04 February 2024 event were predominantly stratiform,
557 variations in the mixed-phase layer LWC were observed (Fig. 5). Within sufficiently deep
558 mixed-phase layers, prior model simulations have demonstrated that small (e.g., < 0.05 g m⁻³)
559 perturbations in LWC alter particle fallout characteristics which can yield substantial increases or
560 decreases in the surface precipitation rate (DeLaFrance et al. 2024). Here, we similarly introduce
561 two sensitivity simulations perturbing LWC within the mixed-phase layer (h_1 to h_2 in Fig. 3),
562 within the range of observed LWC (Fig. 5). In the control simulation, we prescribed the mean
563 observed LWC value of 0.05 g m⁻³. A scaling factor of two relative to the control is used to
564 prescribe a high concentration (0.1 g m⁻³) for the “high_SLW” simulation and low concentration
565 (0.025 g m⁻³) for “low_SLW” concentration. As a limiting case which is analogous to the
566 removal of rime mass (Fig. 8), we construct a “no_riming” simulation with the riming process
567 inactive. A brief summary of these riming sensitivity simulations is provided in Table 1.

568

569

570 **Figure 9:** As in Fig. 7 but for the control and riming-based sensitivity simulations: *high_SLW*,
 571 *low_SLW*, and *no_riming*. At the right are surface simulated and observed surface rain rate
 572 values; horizontal bar lengths illustrate magnitude differences.
 573

574

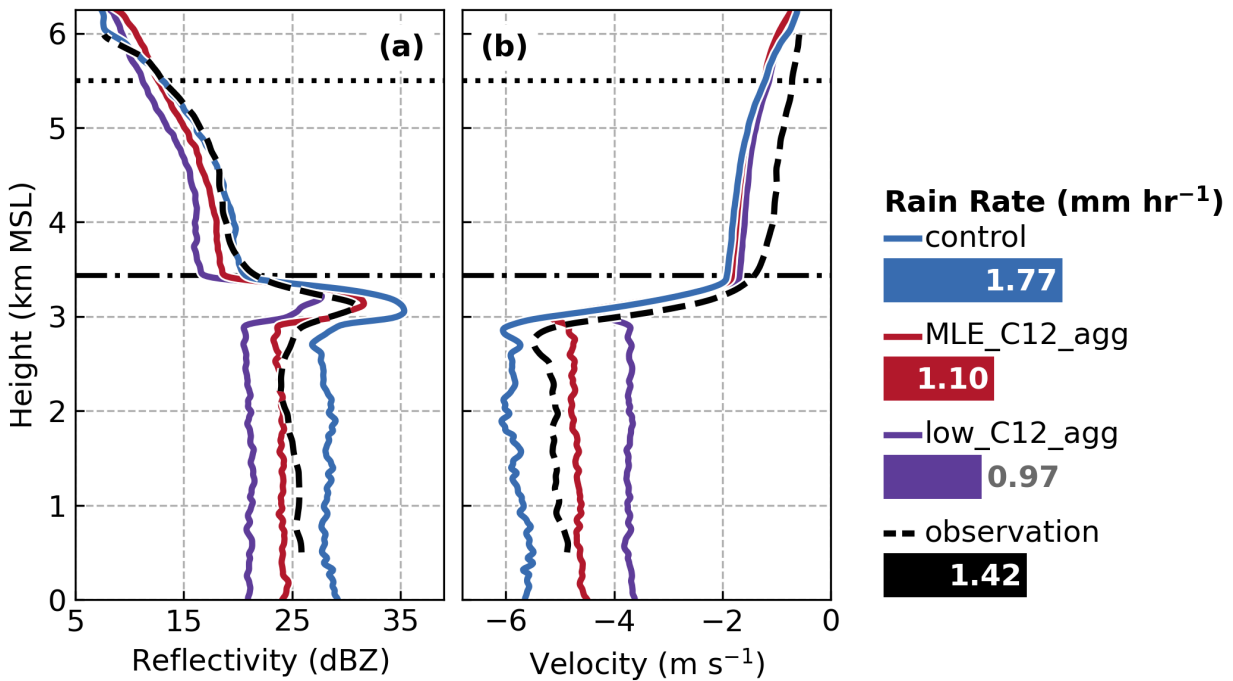

575 Vertical profiles of Z and V_D for the *high_SLW*, *low_SLW*, and *no_riming* sensitivity
 576 simulations relative to the control are shown in Fig. 9. Complete removal of the riming process
 577 in the no riming simulation (Fig. 9a) produces a similar Z profile as found by computing Z for
 578 equivalent unrimed particles from the control simulation (Fig. 8). This result underscores the
 579 significant sensitivity of Z to changes in particle mass during riming, despite concurrent
 580 microphysical processes. Perturbing LWC by a factor of 2 in the *high_SLW* or 0.5 in the
 581 *low_SLW* simulations relative to the control produces opposing, but similar in magnitude,
 582 changes in Z (Fig. 9a), indicating a regularity in the response of Z to SLW variability. Similarly,
 583 the effects of SLW variability on V_D demonstrate a regular response (Fig. 9b). We note that these
 584 simulation responses in Z and V_D to SLW variability assume that the particles are well mixed
 585 such that probabilistic collision of ice crystals and SLW droplets is the same throughout the
 586 layer.

587 As discussed in Section 3.3, remote sensing measurements of V_D , including those from the
 588 HIWRAP radar used throughout this study, are subject to magnitude biases. Nonetheless, as with

589 Z , the relative magnitude changes in V_D with height demonstrate a sensitivity to the riming
590 process. In the high_SLW simulation, the rate of further V_D acceleration with descent below 5.5
591 km MSL is nearly doubled relative to the control. Conversely, below about 5 km MSL, further
592 increases in V_D cease in the low_SLW simulation and decrease in V_D occurs in the no_riming
593 simulation. As a result of rime accumulation in the control simulation, V_D immediately above the
594 melting level (3.6 km MSL) increased by about 68% relative to the no_riming simulation.
595 Similarly, Z increased by about 44%. The competing effects of riming and aggregation processes
596 on V_D manifest in the low_SLW and no_riming simulations; riming accelerates the V_D with mass
597 accumulation whereas in the absence of riming, further aggregation yields larger, lower density
598 particles with reduced fall speeds. Consequently, vertical profiles of V_D may provide an insight
599 into dominant microphysical processes, which is consistent with the notion that rimed particles
600 occupy a distinct region of the Doppler spectra (Kalesse et al. 2016). To advance the
601 differentiation of particles evolved by riming, it is necessary to first consider relative effects of
602 variability in the aggregation process.

603 In our development of the control simulation for the 04 February 2022 event, the aggregation
604 process was initially assumed to follow a temperature dependent sticking efficiency identified as
605 the MLE by Connolly et al. (2012; see Fig. 14b). Comparison with in situ PSDs indicated that
606 the MLE sticking efficiency parameter was insufficient to generate observed concentrations of
607 large particles, motivating the use of an increased sticking efficiency in the control simulation.
608 However, to elucidate the effects of aggregation efficiency on radar profiles, we now consider a
609 sensitivity simulation, “MLE_C12_agg”, which follows the MLE sticking efficiency of Connolly
610 et al (2012). Additionally, analogous to the design of the riming sensitivity simulations, we
611 introduce a “low_C12_agg” simulation for which the sticking efficiency is further reduced from
612 the MLE estimate by a factor of 0.5. Relative to the control simulation, the reduction in sticking
613 efficiency in the MLE_C12_agg and low_C12_agg sensitivity simulations lack observational
614 consistency with the presently analyzed 04 February 2022 event. However, it is useful to
615 consider the implications of a realistic range of variability in the aggregation process efficiency
616 to inform general distinctions from the effects of riming within vertical profiles of Z and V_D .

617

618

619 **Figure 10:** As in Fig. 7 but for the control and aggregation-based sensitivity simulations:
 620 MLE_C12_agg, and low_C12_agg. At the right are surface simulated and observed surface rain
 621 rate values; horizontal bar lengths illustrate magnitude differences.
 622

623

624 Figure 10 shows the vertical profiles of Z and V_D for the aggregation efficiency sensitivity
 625 simulations, MLE_C12_agg and low_C12_agg. Reducing aggregation efficiency suppresses the
 626 generation of large particles and because of the strong dependency of radar backscatter on
 627 particle size, Z decreases relative to the control (Fig. 10a). Additionally, smaller aggregate
 628 particles become smaller targets for collision with SLW droplets to accumulate rime mass, which
 629 also reduces Z . The latter effect manifests in the reduced surface rain rates, decreasing by 38% in
 630 the MLE_C12_agg (1.10 mm hr⁻¹) and 45% in the low_C12_agg (0.97 mm hr⁻¹) simulations
 631 relative to the control (1.77 mm hr⁻¹). Conversely, a reduction in aggregation efficiency has a
 632 minimal effect on V_D for ice-phase particles (Fig. 10b). Above the melting level, at 3.6 km MSL,
 633 V_D in the MLE_C12_agg simulation is reduced from the control simulation by about 4% and in
 634 the low_C12_agg, reduced by about 13%. This relative insensitivity of V_D to aggregation arises
 635 despite these sensitivity simulations assessing a broad range of possible sticking efficiencies. For
 636 example, at -15°C, the sticking efficiency is reduced from 0.9 in the control to 0.32 in the

637 low_C12_agg simulation and at -10°C , from 0.5 in the control to 0.12 in the low_C12_agg
638 simulation.

639 Below the melting layer, however, the effects of aggregation on V_D become significant,
640 decreasing by approximately 2 m s^{-1} between the control and low_C12_agg simulations.
641 Similarly, the surface rain rate decreases by about 45% between the control and low_C12_agg
642 simulations. Thus, despite the significant implications of the aggregation process on precipitation
643 production and its fallout, its variations are not readily perceived in vertical profiles of V_D . This
644 finding significantly differs from the robust sensitivity of V_D to variations in the riming process.
645 While variations in the aggregation and riming processes may manifest similarly in vertical
646 profiles of Z , we find that V_D is uniquely sensitive to riming. Thus, vertical profiles of V_D show
647 promise in identification of riming as a dominant ice-phase microphysical process, which is
648 ambiguous in profiles of Z , only.

649

650 5. Discussion

651 Sensitivity in vertical profiles of both Z and V_D owing to rime accumulation rates were
652 previously shown by Kalesse et al. (2016) from bin model simulations by prescribing a fixed
653 vertical profile of LWC then testing two different riming efficiency parameterizations. Their two
654 simulations yielded similar vertical gradients in Z and V_D profiles but with differences in
655 magnitude. They attributed these differences to assumptions about the physical morphology of
656 the ice crystals with accretion of rime mass that had implications for their scattering properties.
657 In our study, we uniquely provided an observational constraint to establish a control state
658 simulation and modeling framework for assessing impacts of riming and aggregation
659 independently. By selecting a fixed riming parameterization for all simulations using this
660 framework, we were able to assess Z and V_D sensitivities attributable to LWC perturbations
661 within the range of observed variability. We found that a small ($\leq 0.05\text{ g m}^{-3}$) range of
662 perturbations in the LWC produced substantial changes in the surface precipitation rate and a
663 corresponding sensitivity in vertical profiles of Z and V_D .

664 The sensitivities expressed in Doppler radar profiles to LWC perturbations is tied to the
665 impact on bulk microphysical properties, especially particle density, ρ_e . In the deposition- and
666 aggregation-prescribed region above 5.5 km MSL (Fig. 11), ρ_e rapidly decreases with
667 descending height due to the efficient aggregation of increasingly open particle geometry. At 5.5

668 km MSL, riming is introduced and ρ_e approaches 0.02 g cm^{-3} , remaining nearly constant until the
 669 melting level as a result of the competing effects of aggregation and riming. In the high_SLW
 670 simulation, the effects of riming dominate whereby the gradient in ρ_e abruptly increases with
 671 descending height. Conversely, in the low_SLW and no_riming simulations, the effects of
 672 aggregation continue to dominate and ρ_e further decreases.
 673

674
 675 **Figure 11:** Vertical profiles of bulk effective density, ρ_e , for the evolved particle population for
 676 the control simulation and three riming-based sensitivity simulations described in Section 4:
 677 high_SLW, low_SLW, and no_riming. Calculations of ρ_e assume equivalent spherical volumes of
 678 the particles following Heymsfield et al. (2004).
 679

680
 681 Despite the opposing process-based effects on the evolution of ρ_e with height, our
 682 simulations suggest that the effects of aggregation and riming are not readily distinguished by Z
 683 from a Ku-band radar band alone. Riming may be detectable, however, from three-wavelength
 684 (Ku-, Ka-, and W-band) radar by leveraging differential attenuation effects. In prior idealized
 685 modeling simulations for rimed particle growth scenarios, Leinonen and Szyrmer (2015)
 686 identified unique signatures of riming by comparing dual-wavelength ratios (DWR) between Ka
 687 and W bands with DWR at Ku and Ka bands. However, they found the magnitude of this
 688 signature to be modest and proposed that it would likely be difficult to accurately distinguish in

689 observational data. Mason et al. (2019) later investigated the use of triple-frequency Doppler
690 radar measurements from mixed-phase clouds during wintertime snow events to constrain the
691 retrievals of bulk microphysical properties, including the PSD shape factor and ρ_e . They found
692 that triple-wavelength Z measurements effectively constrained the PSD shape parameter, but did
693 not constrain ρ_e . Rather, V_D measurements were necessary to identify transitions to rimed growth
694 cloud regions and provide constraint on ρ_e . Our findings demonstrate that this constraint on ρ_e is
695 attributable to the unique density-dependent response in V_D expressly owing to variations in the
696 riming process within mixed-phase cloud layers with concurrent riming and aggregational
697 growth. Further, our findings suggest that, when combined with Z , coincident vertical profiling
698 measurements of V_D have utility towards diagnosing riming as a dominant process within
699 stratiform clouds from a single-wavelength radar.

700

701 **6. Conclusions**

702 The evolution of ice-phase precipitating particles within a mixed-phase stratiform cloud was
703 simulated to evaluate the effects of riming on the PSD moments and assess the process-based
704 implications on Doppler radar vertical profiles. In situ and remote sensing airborne observations
705 collected during the IMPACTS field campaign for a prolonged wintry-mixed precipitation event
706 over the northeast US on 04 February 2022 were used to design and constrain a quasi-idealized
707 1D mean-state control simulation. Using the Lagrangian particle-based McSnow model, we
708 defined an initial population of ice particles based on in situ measurements in the upper portion
709 of the cloud. As those particles fell, initial evolution occurred by vapor deposition followed by
710 subsequent additions of aggregation and then riming within prescriptive observation-based
711 layered regions. Radar scattering properties were estimated using a T-matrix forward operator
712 and vertical profiles of Z and V_D were computed from the evolved PSD, then evaluated through
713 comparisons with the airborne radar data. The effects of riming on PSD moments expressed
714 through Z and V_D were assessed from simulations which introduce small perturbations in cloud
715 LWC within a range of observed variability. To distinguish effects of riming and aggregation,
716 two additional sensitivity simulations were introduced to determine the unique implications of
717 aggregational growth efficiency on Z and V_D . Through these approaches, we found:

718

- 719 ● Ice-phase precipitation particle evolution in a mixed-phase wintertime storm cloud is well
720 constrained by the 1D quasi-idealized McSnow model.
- 721 ● Despite modest supercooled liquid water concentrations, rime accumulation is estimated
722 to account for 55% of particle mass generated above the melting level, dominating ice-
723 phase contribution to precipitation rates.
- 724 ● Riming cumulatively increased radar reflectivity above the melting level by an estimated
725 44% and Doppler velocity by 68% and demonstrated significant sensitivity to small
726 perturbations in supercooled liquid water concentrations.
- 727 ● Vertical profiles of radar reflectivity demonstrate similar sensitivities to riming and
728 aggregation, but Doppler velocity is uniquely sensitive to riming-based perturbations
729 through changes in particle density.

730

731 Constraining parameterized treatments of rimed particle evolution in numerical models is a
732 known source of uncertainty in simulations of precipitation from bulk-, bin- and Lagrangian
733 particle-based models (e.g., Lin and Colle 2011; Jensen and Harrington 2015; Jensen et al. 2017;
734 Brdar and Seifert 2018). One objective of our analysis was to address this constraining need
735 through quantifying precipitation sensitivities to riming in model simulations based on an
736 observed range of variability in LWC. We found a difference of about 6% in rime fractional
737 mass accumulation in our control simulation whether using a continuous or a stochastic
738 representation of riming with the McSnow model. This effect was expressed within a modeling
739 framework using a quasi-idealized and steady-state 1D column with a homogeneous mixed-
740 phase layer. This approach was appropriate for our intentionally selected region of the observed
741 storm because of its idealistic layered vertical structure apparent in radar observations (Fig. 2b,
742 c), along with its known presence of SLW based on in situ observations. However, in reality,
743 processes are not neatly initiated at distinct levels (e.g., in convective areas). It is expected that
744 increasing ambiguity exists in distinguishing concurrent microphysical processes in these
745 scenarios and, thus, our analysis did not assess the full natural range of complexity in mixed-
746 phase precipitation processes.

747 While model schemes have become increasingly sophisticated, it is not clear that uncertainty
748 in ice-based precipitation estimates have necessarily reduced, highlighting the need for judicious
749 use of observations to advance constraints on modeled processes (e.g., Morrison et al. 2020).

750 Because of the capacity for explicit process representation at the scale of individual particles,
751 Lagrangian models (e.g., McSnow) may be ideally suited to addressing these challenges,
752 especially when combined with datasets which prioritize observations that are consistent with the
753 evolution of particles. This observational consideration was favored during the 04 February 2022
754 event, which was sampled by IMPACTS in an approximately Lagrangian manner. In this study,
755 we focused on riming as a primary ice-phase process, but the northern region of the sampled
756 storm observed significantly less SLW and rime accumulation, presenting a unique natural
757 laboratory for evaluation of modeled aggregation. Sticking efficiencies during aggregation are
758 highly uncertain and difficult to constrain from laboratory experiments (e.g., Connolly et al.
759 2012) yet, as we demonstrated in our study, have significant implications for the accuracy of
760 simulated Z and rain rates. Ongoing work involves curating the in situ measurements of particle
761 evolution within this northern storm region to constrain Lagrangian particle-based simulations
762 and assess the ambient environmental dependencies (i.e., temperature, water supersaturation) and
763 ranges of sensitivities associated with modeled aggregation.

764

765

766 **7. Data Availability Statement**

767 All field observation data from IMPACTS used in this study are accessible through the
768 NASA Distributed Active Archive Center (McMurdie et al. 2019). Readers can find a complete
769 description of the McSnow model and its availability in Brdar and Seifert (2018).

770

771 **8. Author Contributions**

772 All authors contributed to the study design and methodology decisions. Andrew DeLaFrance
773 conducted the data curation and performed the simulations and computations from model output.
774 All authors contributed to the evaluation and interpretation of the results. Andrew DeLaFrance
775 prepared the manuscript with contributions from all co-authors.

776

777 **9. Competing Interests**

778 The authors declare that they have no conflict of interest.

779

780

781 **10. Acknowledgments**

782 The authors acknowledge the entire IMPACTS team for their excellence in the collection and
783 distribution of the robust IMPACTS dataset. The authors thank Axel Seifert and Christoph
784 Siewert for their support and feedback regarding application of the McSnow model. The authors
785 also expressly thank Aaron Bansemer for processing of the microphysics probe data and helpful
786 discussions regarding its application and limitations. Funding was provided by NASA Future
787 Investigators in NASA Earth and Space Science Technology Grant # 80NSSC21K1589 and
788 NASA Grant # 80NSSC19K0338. NCAR provided resources for Andrew DeLaFrance to visit its
789 Mesoscale and Microscale Meteorology Laboratory (host Andrew Heymsfield), which benefited
790 the design and data curation for this analysis. Andrew Heymsfield is supported by the IMPACTS
791 field program under NASA Grant # 80NSSC19K0397 and by the National Science Foundation.
792 We are grateful for the feedback received from two anonymous reviewers, which greatly
793 improved this manuscript.
