22

23

24 **Abstract.** George VI Ice Shelf (GVIIS), on the western side of the Antarctic Peninsula, is
25 currently losing mass. Paleo observations suggest that atmospheric and oceanic warming in the
26 early Holocene caused complete loss of the ice shelf, leading to the possibility that modern
27 observed warming can initiate a similar loss. Ice shelf loss is assumed to be, primarily, a direct
28 response to atmospheric and ocean warming through increased hydrofracture and basal melting.
29 Here, however, we consider the hypothesis that increased lubrication of grounded ice is a further
30 contributor to destabilizing the ice shelf, where the lubrication may come from processes such as
31 increased surface meltwater percolating to the base of glaciers or changes in liquid water fluxes
32 across the grounding line. Motivated by the differences in our observation-based strain-induced
33 dynamic thickness change between 2013–2018 along the northern and southern sectors GVIIS
34 which also experiences variable surface melt, we use an ice sheet model to investigate this
35 hypothesis. We find that, as expected, reduced bed friction increases the flow of grounded ice.
36 However, because of the unique ice flow and buttressing features of GVIIS, the increased ice
37 flux across the grounding line also increases compression of the northern GVIIS, which makes it
38 resistant to rifting and hydrofracture. In contrast, the southern GVIIS, which is fed by ice streams
39 sitting on submarine beds, experiences continued divergence. We suggest that the associated
40 strain thinning reduces buttressing of grounded ice, creating a positive feedback of accelerated
41 ice inflow to the southern GVIIS and likely making it more vulnerable to future retreats than the
42 northern sector.

43

44 **Plain language summary.** George VI Ice Shelf (GVIIS) on the western Antarctic Peninsula is
45 currently thinning and the glaciers feeding the ice shelf are accelerating. Geologic evidence
46 indicates that GVIIS had previously disappeared several thousand years ago as regional air and

47 ocean temperatures increased, similar to what the region is experiencing now. In this work, we
48 use remote sensing and numerical modeling to show that the southern side is likely more
49 vulnerable because of ice dynamics and thinning triggered by increased ice velocity and ice flux,
50 in contrast to paleo observations that proposed that the past retreat proceeded from the north.

51

52 **1. Introduction**

53 The glaciers draining the Antarctic Peninsula (AP) have undergone widespread retreat and
54 acceleration during recent decades (Pritchard et al., 2009; Scambos et al., 2009; Rignot et al.,
55 2019; Smith et al., 2020; Boxall et al., 2022; Wallis et al., 2023). The retreat has been linked
56 primarily to increased ocean-induced bottom melting (Hogg and Gudmundsson, 2017;
57 Adusumilli et al., 2018, 2020). Along the western AP, as with major parts of the West Antarctic
58 Ice Sheet, a significant number of the outlet glaciers flow on retrograde bed slopes below sea
59 level, where mass loss due to increased atmospheric (Cook and Vaughan, 2010) and oceanic
60 warming (Pritchard et al., 2012) may be conditionally exacerbated by marine ice sheet instability
61 (MISI) (Weertman, 1974; Schoof, 2007; Gudmundsson et al., 2012; Schannwell et al., 2018).
62 Previous studies have also shown overall acceleration of western AP glaciers either for an earlier
63 epoch (Hogg and Gudmundsson, 2017) or for glaciers north of GVIIS (Wallis et al., 2023).

64

65 The largest ice shelf on the western AP, George VI Ice Shelf (GVIIS, Fig. 1), appears to be
66 thinning by excessive ocean-induced basal melting (Pritchard et al., 2012; Shepherd et al., 2012;
67 Adusumilli et al., 2018, 2020). GVIIS also experiences significant surface melt ponding in the
68 summer, primarily on the northern sector (red box in Fig. 1; Banwell et al., 2021). Previous
69 studies have identified increases in ice velocity of the glaciers and ice streams flowing into the

70 ice shelf (Hogg and Gudmundsson, 2017; Boxall et al., 2022). Rignot et al. (2019) calculated an
71 ice discharge of $\sim 79 \text{ Gt a}^{-1}$ between 2009 and 2017 over an area of $\sim 80 \text{ M km}^2$ of GVIIS. This
72 was an increase from their reported discharge of $\sim 78.5 \text{ Gt a}^{-1}$ between 1999 and 2010. Modeling
73 studies suggest that the complete loss of GVIIS would trigger MISI, with a total contribution of
74 $\sim 8 \text{ mm}$ global sea level rise (Schannwell et al., 2018). Increased freshwater influx from basal
75 melting and changing coastal geometry from a thinned ice shelf will also alter ocean circulation
76 pathways in this biologically active region, and affect the Antarctic Coastal Current (Moffat et
77 al., 2008) that delivers freshwater southward to the Amundsen Sea to modify ice shelf melting
78 there (Flexas et al., 2022).

79

80 The southern and northern sections of GVIIS, which we denote as GVIIS-S and GVIIS-N
81 respectively, have distinct structure, topographic settings and connectivity to the Bellingshausen
82 Sea (see Fig. 1, and Schannwell et al. (2018), their Fig. 1), and exhibit distinct behaviors over the
83 period of satellite observations. Notably, much of GVIIS-N is fed by Palmer Land glaciers sitting
84 on a bed above sea level, whereas GVIIS-S is fed by comparatively larger glaciers from a marine
85 base (bed below sea level). The different pathways of warm Circumpolar Deep Water (CDW)
86 along troughs leading to the two calving fronts result in distinct properties of the water masses
87 driving basal melting under GVIIS-S and GVIIS-N (Jenkins and Jacobs, 2008). Strong gradients
88 of atmospheric conditions, coupling between the ocean and atmospheric forcing, and the region's
89 sensitivity to large-scale climate variability associated with the El Nino Southern Oscillation
90 (ENSO) and the Southern Annular Mode (SAM) add complexity to the drivers of mass losses for
91 each section of the ice shelf.

92

93 This complexity has led to uncertainty in the greatest risks to GVIIS. Holt et al. (2013) noted an
94 increased frequency of calving along the southern calving front and postulated that GVIIS,
95 although regarded as in no imminent danger of collapse, is more susceptible to breakup along its
96 southern margin. Nine years later, Holt and Glasser (2022) concluded that GVIIS should be
97 regarded as being on the brink of instability, with recently observed glaciological changes
98 focused on GVIIS-N.

99

100 Paleo records suggest that GVIIS previously disappeared when regional ocean and air
101 temperatures were similar to the present day (Bentley et al., 2005; Smith et al., 2007). Together
102 with marine geological data from the western AP shelf (e.g., Heroy and Anderson, 2007; Ó
103 Cofaigh et al., 2014), which demonstrates deglaciation occurred earlier in the north and
104 progressed southward, Smith et al. (2007) argued that the GVIIS retreated gradually from north
105 to south. Geological data from Moutonnée Lake, a large epishelf lake on Alexander Island (~70°
106 51'S, 68° 20'W), indicate that GVIIS disappeared in the Early Holocene (~9.6-7.7 ka before
107 present (B.P.), where present is 1950), with the onset of retreat occurring at ~9.6 ka B.P., and
108 was completely or partially reformed at this site by ~7.7 ka B.P. (Bentley et al., 2005; Smith et
109 al., 2007). Additional evidence ~120 km to the south of Moutonnée Lake (Two Step Cliffs, Fig.
110 1), suggest that the ice shelf was absent ~1.0 ka later at this site (~7.0-6.6 ka BP; Sugden and
111 Clapperton, 1981). However, limited paleo proxies exist south of GVIIS.

112

113 Several possible mechanisms leading to GVIIS collapse exist, including the well-known ones of
114 hydrofracture, and increased rifting as the ice shelf thins and shear margins weaken. Here,
115 however, we explore a new hypothesis: “Acceleration of grounded glaciers flowing into GVIIS

116 from Palmer Land is weakening GVIIS-S by increased strain-induced dynamic thinning”. This
117 hypothesis reflects the possibility that grounded glaciers might accelerate due to processes
118 occurring upstream of the grounding line rather than loss of buttressing by mass reduction of the
119 ice shelf. Upstream processes include enhanced lubrication from surface melt water penetration
120 to the bed, and seawater incursions along existing subglacial channels (e.g., Chen et al., 2023).
121 We use a numerical model to show that the ice shelf will respond by generation of regions of
122 enhanced dynamic thinning, and hypothesize that this will create a positive feedback as reduced
123 buttressing from the ice shelf allows the grounded glaciers to accelerate further.

124

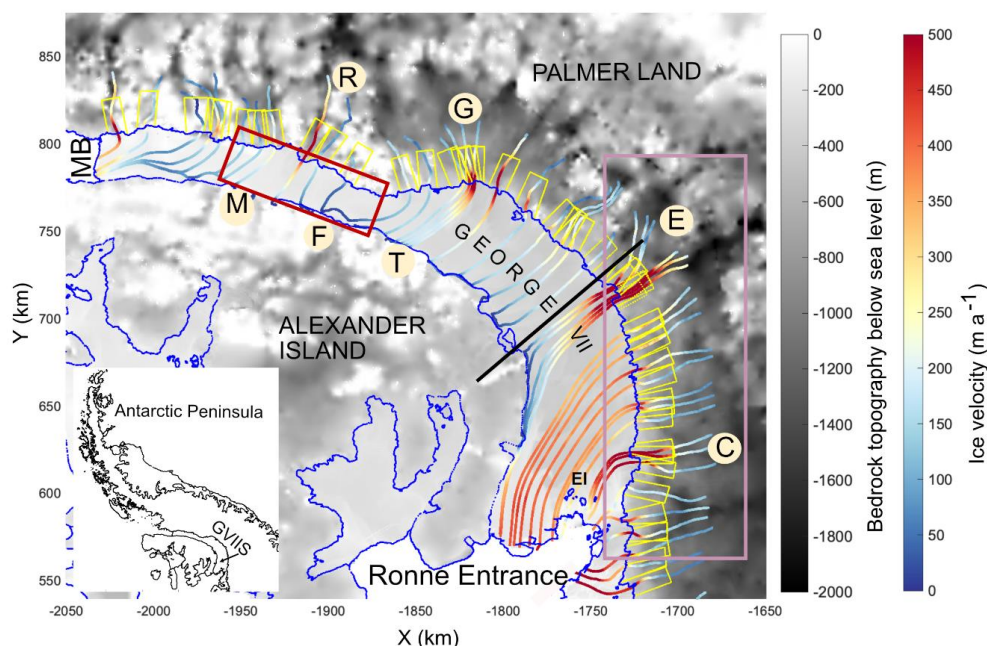

125 **2. Study area and datasets used**

126 **2.1 George VI Ice Shelf (GVIIS): Setting**

127 GVIIS (Fig. 1) is the largest ice shelf on the western AP (~ 23,000 km²; Adusumilli et al., 2020).
128 GVIIS has two calving fronts ~ 450 km apart. The outlet glaciers feeding GVIIS have
129 accelerated in recent decades but grounding line positions have remained relatively stable since
130 the mid-1990s (Boxall et al., 2022). Average melt rates during 1994-2018 are ~ 4.3 ± 2.2 m a⁻¹,
131 equivalent to a total meltwater flux of 88.8 ± 45.7 Gt a⁻¹ (Adusumilli et al., 2020). Measurements
132 suggest a net thinning (Fricker and Padman, 2012; Paolo et al., 2015) and mass loss (Rignot et
133 al., 2013; Adusumilli et al., 2020); however, averaged over the entire ice shelf, the mass change
134 is within the range of uncertainty. The relatively high basal melt rates are driven by intrusions of
135 warm (~ 1 °C) CDW. Access holes through the ice shelf indicate that the water column is
136 strongly stratified, with a maximum temperature of ~ 1.29 °C (Middleton et al., 2022). Each
137 summer, GVIIS-N experiences extensive surface melt and persistent melt ponding (Fig. 1;
138 Banwell et al., 2021). On the Palmer Land side, the major outlet glaciers draining into GVIIS-S

139 sit on retrograde bed slopes below sea level (Fig. 1) with implications for unrestricted flow of the
140 grounded ice (through MISI) if the ice shelf disintegrates.

141
142 *Figure 1: George VI Ice Shelf in the AP with bed topography from BedMachine (Morlighem et*
143 *al., 2020) to identify regions below sea level, and ice velocity streamlines (2018) using ITS_LIVE*
144 *(Gardner et al., 2018). The black boxes (20×10) km extent are used for ice flux estimates.*
145 *Glaciers and locations discussed in the text are Ryder (R) and Goodenough (G) glaciers, ERS 1*
146 *and 2 (E) and Cryosat (C) ice streams, Moutonée Lake (M), Fossil Bluff (F), Two Step Cliffs (T),*
147 *Marguerite Bay (MB), and Eklund Islands (EI). Black line near E roughly follows an ice divide*
148 *and delineates the northern and southern sectors of GVIIS. The red box is the general location of*
149 *summer surface melt ponds. The purple box locates the region in the southern sector that is*
150 *identified as vulnerable in the future by modeling studies (Schannwell et al., 2018).*

151

152 **2.2 Datasets**

153 We use ice velocity data from ITS_LIVE (Gardner et al., 2018), grounding lines from SCAR and
154 InSAR compilations (Rignot et al., 2022), and ice thickness and bedrock topography from
155 BedMachine V3 (Morlighem et al., 2020). We also use ice sheet model Úa (Gudmundsson et al.,
156 2020) for strain rate calculations and experiments with basal friction (see Section 3.5). The
157 velocity fields are used to calculate the ice flow streamlines, strain rates, and dynamic thickness
158 change. Ice thickness and velocity are both used to calculate ice discharge.

159

160 **3. Methods**

161 With changing ice velocities, the dynamic components that are most likely to affect the stability
162 of an ice shelf include ice discharge rates from the grounding line (“ice flux”), effective strain
163 rates, and strain-induced dynamic thinning (also referred as “dynamic thinning”). Below we
164 describe the methodology to quantify each of these.

165

166 **3.1 Velocity changes**

167 We calculate the differences in velocity from 2013 to 2018 using $\Delta v = v(2018) -$
168 $v(2013)$ from ITS_LIVE velocities (Gardner et al., 2018) for each year. Here $v(2013)$ and
169 $v(2018)$ are ITS_LIVE velocities from the two years. We chose these years because complete
170 coverage of GVIIS is available only since 2013, and ITS_LIVE annual values are available only
171 up to 2018. We exclude data where the velocities are $<1 \text{ m a}^{-1}$ or $> 2000 \text{ m a}^{-1}$, and where the
172 velocity error is $>15 \text{ m a}^{-1}$. While these numbers are arbitrary choices, we used them because we
173 are not interested in velocities that are too slow or too fast or have a larger error associated with

174 them. Values that are too fast or too slow could also be because of artifacts in the dataset. We
175 smooth the velocity fields with a gaussian filter at 4000 m for all analyses in this work.

176

177 **3.2 Velocity streamlines**

178 We created a set of velocity streamlines (Fig. 1) that originate ~ 40 km upstream of the
179 grounding line and run along the centerline of the glaciers originating from Palmer Land using
180 built-in MATLAB functions on the 2018 ITS_LIVE velocity field. Some of the larger outlet
181 glaciers, such as the Goodenough Glacier and the ERS 1 and 2 Ice Stream, are represented by
182 more than one streamline to account for multiple tributaries and larger glacier widths (Fig. 1).
183 Since the glaciers streaming from Alexander Island onto GVIIS are much smaller, we do not
184 identify their streamlines or calculate the impact of their changing flows on the ice shelf.

185

186 **3.3 Ice shelf effective strain rates and dynamic thinning**

187 For studying the dynamic changes near the grounding zone and an ice shelf, commonly the
188 steady-state mass balance equation is invoked as in Eq. (1):

$$189 \frac{\partial H}{\partial t} = -\nabla \cdot (HU) + \dot{a} - \dot{M}_b - \dot{M}_s \quad (1)$$

190 where H is the change in ice thickness through time t , U is the depth averaged ice velocity,
191 assumed to be the same as the observed surface velocity, \dot{M}_s is the surface melt and \dot{M}_b is the
192 basal melt. The first term on the right represents the strain-induced dynamic thinning term and
193 can be expanded as

$$194 D = H \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) + \left(u \frac{\partial H}{\partial x} + v \frac{\partial H}{\partial y} \right) \quad (2)$$

195 where u and v are the x and y components of U .

196 We assume that over an ice shelf, the vertical shear stress can be ignored (LeDoux et al., 2017);
197 therefore, the strain rates can be approximated by the terms within the first parenthesis of Eq. (2),
198 as in Das et al. (2020). The effective strain rates are second invariants of the strain rate tensor.
199 We ignore the shear components of strain rate because we are interested in the strain-induced
200 dynamic thinning, which we approximate by changes in the x and y components of ice velocity.
201 Strain-induced dynamic thinning is calculated using all the terms of Eq. (2) for each of 2013 and
202 2018. We then use the difference to estimate the rate of dynamic thickness change of the ice
203 shelf for that period.

204

205 **3.4 Ice flux along the grounding line**

206 The streamlines are roughly oriented along the fastest and thickest central parts of each glacier,
207 where the ice acceleration is also generally more pronounced. We estimate the ice fluxes, $F(t)$,
208 within the 20×10 km area around each streamline along the grounding line (Fig. 1, black boxes)
209 for each of 2013 and 2018 as the product of the mean ice velocity v_{mean} and ice thickness H_{mean}
210 and density of ice $\rho = 916.7 \text{ kg m}^{-3}$, converted to the units of $\text{Gt km}^{-1} \text{ a}^{-1}$.

$$211 \quad F = v_{mean} \times H_{mean} \times \rho \quad (3)$$

212 Ice flux change (ΔF) along the streamlines is then calculated as $\Delta F = F(2018) - F(2013)$. For the
213 larger glaciers, where we have multiple streamlines along the glacier, the value of ΔF around
214 each streamline is provided separately.

215

216 **3.5. Model details**

217 For model-based calculations we use the finite element ice sheet model $\acute{U}a$ (Gudmundsson,
218 2020). This uses the Shallow-Shelf Approximation (MacAyeal, 1989), a 2-dimensional

219 approximation which integrates over depth. Ice flow is controlled by Glen's flow law (Glen,
220 1958);

$$221 \quad \dot{\varepsilon}_{ij} = A\tau_e^{n-1}\tau_{ij} \quad (4)$$

222 where $\dot{\varepsilon}_{ij}$ are components of the strain rate tensor, A is a rate factor, τ_e is the effective stress, τ_{ij}
223 are components of the deviatoric stress tensor, and the exponent n is set equal to 3.

224

225 For basal drag, we use Weertman's sliding law (Weertman, 1957),

$$226 \quad \tau_b = C\frac{1}{m}(\|v_b\|^2)^{\frac{1-m}{2m}}v_b \quad (5)$$

227

228 where τ_b is basal stress, C is a sliding parameter, v_b is basal velocity and the exponent m is set to
229 3.

230

231 The unstructured triangular meshes for $\dot{U}a$ are generated using Mesh2D (Engwirda, 2014). In
232 this work we use two meshes covering the George VI area, on a rectangle with boundaries at $x =$
233 -2100 km and -1700 km, $y = 900$ km and 550 km in polar stereographic coordinates, with
234 uniform resolutions of 4 km and 10 km.

235

236 The 4-km smoothed velocities are interpolated onto each mesh, and used as the observational
237 input for an inversion process in $\dot{U}a$, in order to produce fields of values for basal sliding
238 parameter C and rate factor A . This method involves minimizing a cost function J of form

$$239 \quad J = I + R, \quad (6)$$

240 where I is a misfit function given by

$$241 \quad I = \frac{1}{2A} \int ((u - u_{obs})/u_{err})^2 dA + \frac{1}{2A} \int ((v - v_{obs})/v_{err})^2 dA \quad (7)$$

242 and R is a regularization term given by

$$243 \quad R = \sum_{k=1,2} \frac{1}{2A} \int \left(\gamma_s^2 \left(\nabla(p_k - p_{k,prior}) \right)^2 + \gamma_a^2 (p_k - p_{k,prior})^2 \right) dA \quad (8)$$

244

245 in which $A = \int dA$ is the total area, u and v are the modeled velocity components, u_{obs} and v_{obs}

246 are the observed velocity components, u_{err} and v_{err} are the observational errors, γ_s and γ_a are

247 slope and amplitude regularization parameters, $p_1 = \log_{10} A$, $p_2 = \log_{10} C$ and $p_{k,prior}$ are prior

248 values, or initial estimates, for the parameters p_k . More details on the inversion process in Úa

249 can be found in Barnes et al. (2021) and its applications in Das et al. (2023).

250

251 The inversion outputs are used in calculations of velocities within the model. These are snapshot

252 calculations with no time dependence, using the geometry from BedMachine and not evolving

253 the ice thickness. The velocities are calculated in three different cases. Firstly, we use the

254 original inversion outputs, fields of values for A and C derived from the process described above.

255 To investigate the effect of variability in basal friction, which is an uncertainty within the model

256 as it is not an observed quantity, we perform two more calculations with the values of C across

257 the entire domain multiplied by 0.95 (a 5% reduction in the sliding parameter) and by 1.05 (a 5%

258 increase to the sliding parameter). For all the calculated velocities, the components of the strain

259 rate tensor are then calculated as stated in section 3.3. Within the model domain, the calculation

260 is performed on six integration points within each finite element, defined by Gauss-Jacobi

261 quadrature.

262 **3.6 Strain rate and qualitative length-scale analysis**

263 The appropriate length-scales for smoothing the velocity fields and calculating strain rates is an

264 ongoing topic of much discussion (e.g. Alley et al., 2018). On Ross Ice Shelf, Das et al. (2020)

265 used a 15 km velocity smoothing window to calculate strain rates, based on scales of
266 uncertainties in both ice thickness and velocity. However, it is not necessarily easy to identify
267 what grid resolution is needed for ice shelves. Because of the size of GVIIS and its smaller ice
268 streams and glaciers, a 15 km grid will undesirably smooth out the dynamic changes of the
269 individual glaciers. To assess length-scales (e.g., Alley et al., 2018), we calculate strain rates
270 using a 4 km square grid using ITS_LIVE velocities explained in the previous sections and
271 compare with a 4 and 10 km grid calculated using the ice flow model *Úa*, also described in the
272 previous sections.

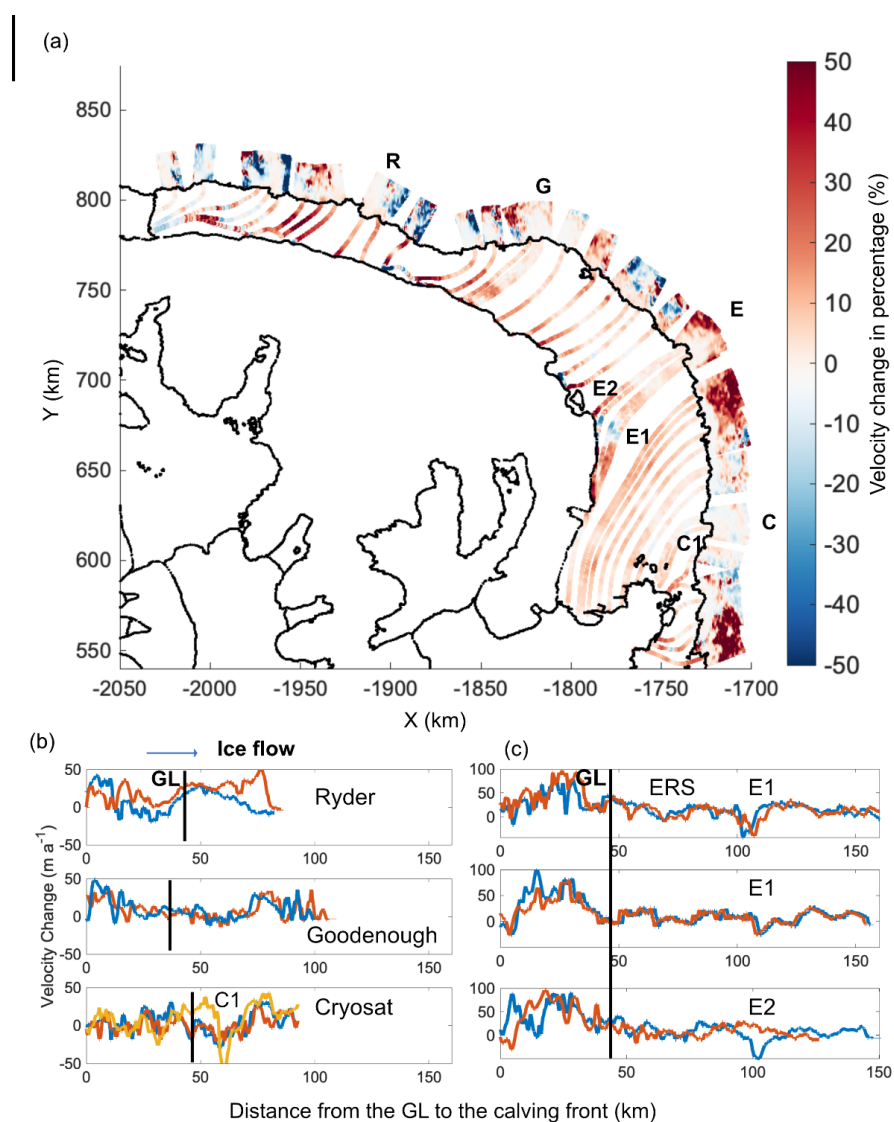

273 **4. Results**

274 **4.1 Velocity changes on the GVIIS grounding zone and on the ice shelf**

275 The change in velocity from 2013 to 2018 within the 20×10 km boxes defining grounded glacier
276 and ice stream outlets (Fig. 2) show a coherent increase in annual velocity during this period on
277 many of the outlet glaciers from Palmer Land side of GVIIS. The average velocity increase (Δv)
278 between 2013 and 2018 is $\sim 16 \text{ m a}^{-1}$ ($\sim 8\%$) within all the boxes. We express the velocity
279 increase (Δv) as a percentage change from 2013 in Fig. 2a to demonstrate the significance. The
280 actual Δv along the streamlines of the major outlet glaciers are shown in the panels of Fig. 2b-c.
281 These outlet glaciers are among the fastest changing regions of GVIIS. The average Δv on the
282 ice shelf is $\sim 12 \text{ m a}^{-1}$ ($\sim 7\%$) with the southern sector experiencing a larger Δv than the northern
283 sector. The area within these boxes covers the grounding zone as well as an extended section
284 upstream along the centerline of each glacier. The velocity increase over the ERS Ice Stream
285 grounding zone is one of the larger increases on GVIIS with an average of $\sim 33.4 \text{ m a}^{-1}$ (Fig. 2a,
286 c). The mean velocity increase of the glaciers located immediately south of ERS and north
287 CryoSat (between E1 and C1 streamlines, Fig. 2a-b) is $\sim 44 \text{ m a}^{-1}$. This region between ERS and

288 Cryosat ice streams is experiencing the largest velocity increase on the ice shelf. This region on
 289 the ice shelf is almost freely floating without impinging on either Alexander or Eklund Islands
 290 and is important for the stability of GVIIS-S.

291

292 *Figure 2: ITS_LIVE velocity on grounding zone of GVIIS glaciers: (a) Difference in velocity (%)*

293 *between 2013 and 2018 along the 20×10 km boxes in Fig. 1 along the grounding zones and*

294 *streamlines on the ice shelf. The major glaciers include the Ryder Glacier (R), the Goodenough*
295 *Glacier (G), the ERS 1 and 2 ice stream (E) and the CryoSat Ice Stream (C); (b) Velocity*
296 *difference (Δv) between 2013 and 2018 for Ryder, Goodenough glaciers and CryoSat Ice*
297 *Stream; (c) Δv between 2013 and 2018 on the ERS 1 and 2 ice streams. The black line shows the*
298 *approximate position of the GL from Fig. 1.*

299

300 The mean velocity increase along the grounding zones of the other larger glaciers including
301 Goodenough (G) Ryder (R), and CryoSat (C) is $\sim 8 \text{ m a}^{-1}$ (Fig. 2a, b). Unlike other ice shelves,
302 the velocity does not keep increasing in the direction of ice flow along the streamlines as ice
303 moves away from the grounding zone (Fig. 2a, 2b-c). GVIIS is unique because ice sourced from
304 some glaciers from the Palmer Land side impinge on Alexander and Eklund Islands, and the non-
305 uniform velocity response likely results from the backstress these glaciers receive from the
306 grounded regions. In the case of the ERS Ice Stream and the glaciers south of it, the velocity
307 increase upstream is $> 30\%$ (Fig. 2a). While the source of velocity increase for ERS and glaciers
308 south of it is unknown, we speculate that the surface meltwater reaching the bed near Ryder
309 Glacier (Pedley et al., 1988) provides the basal lubrication required for local acceleration at the
310 grounding zone, which slows further downstream (Fig. 2b).

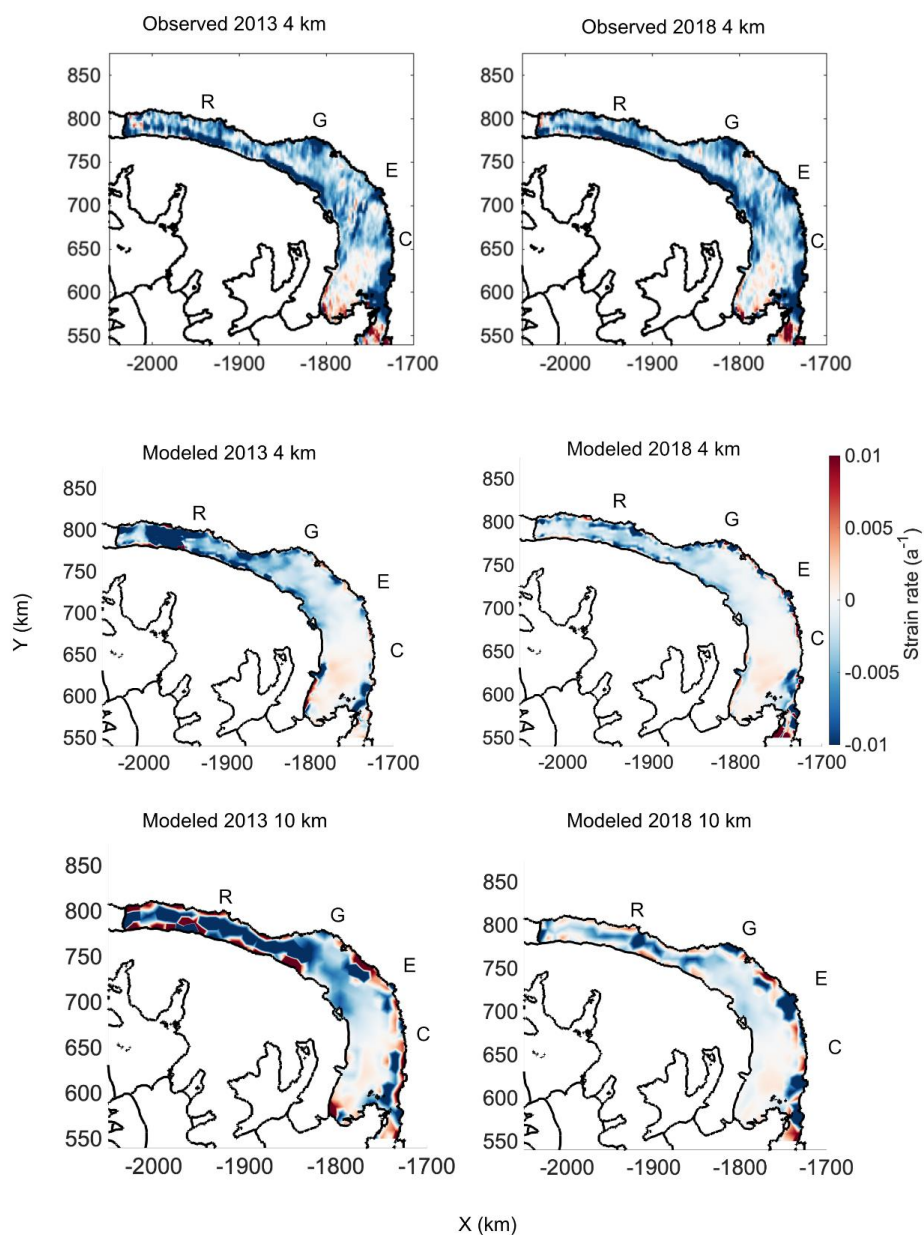

311

312 **4.2 Effective strain rates of GVIIS during 2013 and 2018**

313 Estimates of strain rates (units of a^{-1}) from ITS_LIVE velocities (4 km, Fig. 3 a-b) and strain
314 rates from modeled velocities in \dot{U}_a (4 km, Fig. 3c–3d; 10 km Fig. 3e–3f) show similar large-
315 scale spatial patterns and variabilities in the observed and modeled values. The observed sets are
316 more detailed, although has a higher likelihood of noise. The strain rate fields calculated from \dot{U}_a

317 are smoother, as noise in the observations is removed by regularization within the inversion
318 process. This means that the strain fields from Úa show less detail than the observations, but are
319 useful for capturing large scale patterns more clearly. Here, positive sign indicates divergence
320 implying strain thinning and negative sign indicates compressive strain rates that lead to
321 localized thickening of the ice shelf. On GVIIS-S, dynamic thinning is experienced in the region
322 bordered by ERS (E) and CryoSat (C) ice streams (Fig. 3). The velocity increase of this band is
323 discussed in Section 4.1.

324

325

326 *Figure 3: Strain rates calculated at 4 km and 10 km grid spacing (a) for 2013 using ITS_LIVE*

330

331 **4.3 Length scales of effective strain rates on GVIIS**

332 For this work, we use a 4-km length scale for all analyses, as a compromise between
333 measurement noise and width of individual glaciers and ice streams (see Section 3.6). We also
334 calculate strain rates on a 10 km mesh using $\dot{U}a$ (Fig. 3e-f). The 10 km strain rate product is
335 smoother than the 4 km product, but we lose information of the small-scale variations in strain
336 rates. In this work, we use the 4 km grid for both observation-based and modeled strain rates to
337 calculate dynamic thinning to preserve the local variability of strain rates that are difficult to
338 observe in the 10 km grid.

339

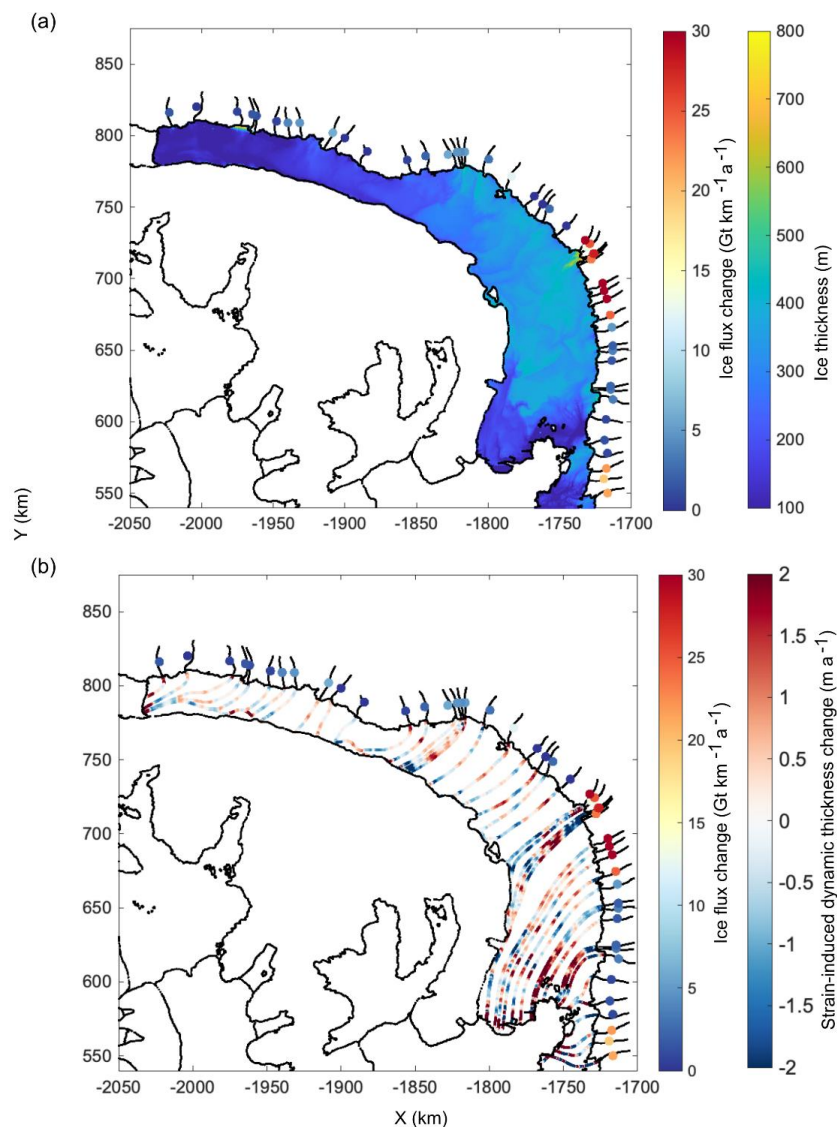

340 **4.4 Increased ice flux across Palmer Land grounding zone and dynamic thickness change**

341 Most outlet glaciers have experienced increased ice flux between 2013 and 2018 along the 20×10
342 km boxes near the grounding line for each streamline, particularly on the GVIIS-S sector that
343 also has thicker ice (Fig. 4a) and a submarine, retrograde bed (Fig. 1). ERS Ice Stream is the
344 largest ice stream on the ice shelf, and is experiencing one of the highest increases in ice flux ΔF
345 by $21 \pm 19 \text{ Gt km}^{-1} \text{ a}^{-1}$ between 2013 and 2018 (Fig. 4a). The glaciers bounded by ERS and
346 Cryosat forming the freely floating region discussed earlier has an average ΔF of $20 \pm 11 \text{ Gt km}^{-1}$
347 a^{-1} , also a high value similar to ERS Ice Stream. Cryosat, Ryder and Goodenough each
348 experienced flux increases during the same period, with ΔF values of 2.4 ± 2.4 , 2.4 ± 2.2 , 5 ± 4.3
349 $\text{Gt km}^{-1} \text{ a}^{-1}$, respectively. The mean ΔF during 2013–2018 for all the 20×10 km boxes of GVIIS
350 were $8.9 \pm 6.8 \text{ Gt km}^{-1} \text{ a}^{-1}$. Our results show that the strain-induced dynamic thickness change

351 increases progressively from north to south (Fig. 4b). Near the Eklund Islands, where recent
352 calving events have concentrated, the strain-induced dynamic thickness change between 2013
353 and 2018 is $\sim 2 \text{ m a}^{-1}$, (Fig. 4b) and is of the same order of magnitude as the basal melting rates
354 from previous studies.

355

364

365 **4.5. Changes in modeled strain rates of GVIIS with changes in basal friction C**

366 We carry out some simple simulations to investigate the effect of changing basal sliding, which
367 can be seen as a proxy for basal lubrication due to subglacial discharge resulting in a scenario
368 where ice velocity at the grounding zone increase. Taking the output from an inversion in Úa, we
369 change the basal sliding parameter by 5% in each direction and recalculate strain rates from the
370 resulting modeled velocity fields. The results are shown in Fig. 5a–b. When the sliding
371 parameter is increased, the increase in velocity of the glaciers flowing into GVIIS results in a
372 more compressive regime in the narrow northern section (Fig. 5b), comparatively little overall
373 change in the strain on the southern sector, and a more divergent regime in the Ronne Entrance.
374 Part of the southern sector does have a slight divergence signal, although much lower in
375 magnitude than the changes elsewhere in the domain, on the order of $10^{-5} a^{-1}$. When lowering the
376 basal sliding, the opposite is true, although it is not clear what actual processes could result in a
377 higher value of C . The modeled velocities used in this case are calculated instantaneously with a
378 new value of C on the same geometry, but if allowed to evolve over time differences in thickness
379 may also result, which could lead to further changes in the strain regimes.

380

381

382 *Figure 5: Strain rate (a^{-1}) differences Original-percent changes in the value of C using $\dot{U}a$ (a)*

383 *5% increase and (b) 5% decrease in C from the original shows only the northern half (north of*
384 *streamline E1) is sensitive to changes ice flux across the grounding line in the shorter term.*

385

386 **5. Discussion**

387

388 The observed increase in velocity at the grounding zone and on the ice shelf from 2013 to 2018
389 is consistent with Boxall et al. (2022), who used Copernicus Sentinel 1A/B between 2014 and
390 2020 over GVIIS outlet glaciers. Their austral summer velocity increase rates of $\sim 22 \text{ m a}^{-1}$ and \sim
391 15% increase near the grounding zone is consistent with our mean annual velocity change of \sim
392 16 m a^{-1} during 2013-2018 along the grounding zones of the Palmer Land outlet glaciers.
393 Furthermore, between 1992 and 2015, a 13% increase in ice velocity was observed on the
394 Western Palmer Land (Hogg et al., 2017).

395

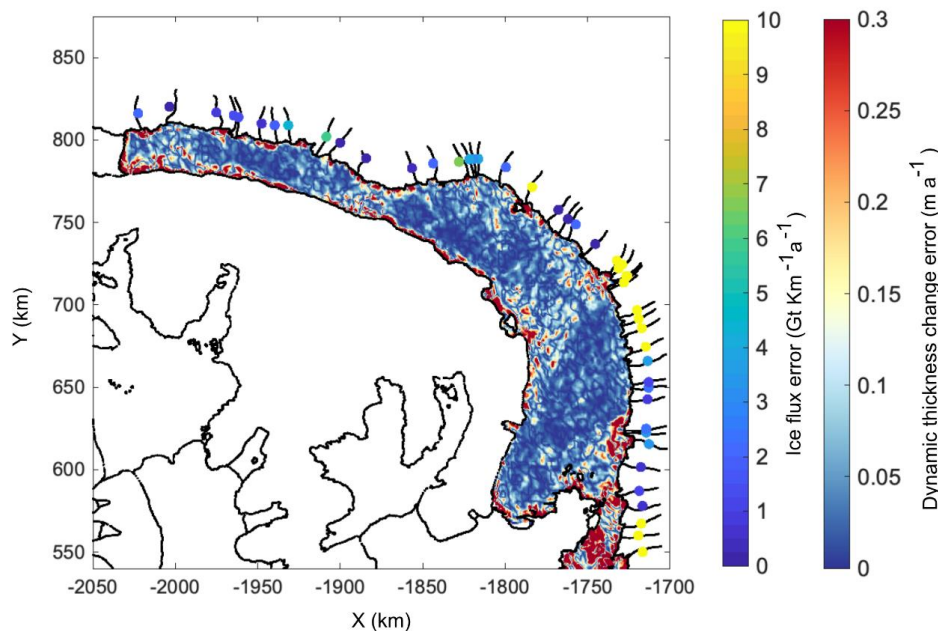

396 The error estimates are calculated separately for the strain thinning and ice flux as follows:

$$\epsilon_{Flux} = \Delta F_{mean} \sqrt{\left[\left(\frac{\epsilon_{velocity2013}}{M_{velocity2013}} \right)^2 + \left(\frac{\epsilon_{velocity2018}}{M_{velocity2018}} \right)^2 + \left(\frac{\epsilon_{IceThickness}}{M_{IceThickness}} \right)^2 \right]} \quad (9)$$

398

399 where ϵ_{Flux} is the error in ice flux in $Gt\ km^{-1}\ a^{-1}$, ΔF_{mean} is the mean flux change within the
 400 20×10 km boxes, ϵ is the standard deviations of the various components, M is the mean of the
 401 various components used in calculating the ice flux.

402

403 *Figure 6: Error estimates in dynamic thickness change on the ice shelf and ice flux calculated*
 404 *within each 20×10 boxes*

405

406 The errors in dynamic thinning are calculated for each component of velocity for both 2013 and
 407 2018. The error in ice thickness is counted twice because of the two years used in dynamic
 408 thinning calculations.

409

410 $\epsilon_{DT} =$

$$411 \sqrt{D_{diff}^2 \left[\left(\frac{\epsilon_{Xvelocity2013}}{M_{Xvelocity2013}} \right)^2 + \left(\frac{\epsilon_{Yvelocity2013}}{M_{Yvelocity2013}} \right)^2 + 2 \left(\frac{\epsilon_{IceThickness}}{M_{IceThickness}} \right)^2 + \left(\frac{\epsilon_{Xvelocity2018}}{M_{Xvelocity2018}} \right)^2 + \left(\frac{\epsilon_{Yvelocity2018}}{M_{Yvelocity2018}} \right)^2 \right]}$$

412 (10)

413 where ϵ_{DT} is the error in dynamic thinning (m a^{-1}), D_{diff} is the difference in dynamic thinning
414 between 2013 and 2018, ϵ terms within the square root are the standard deviations of the various
415 components, and the M components are the average values of those components.

416

417 Our error ranges for ice fluxes are quite high for some regions because of the large variability of
418 the velocity and ice thickness along the 20×10 km boxes (Fig. 6). These boxes are located
419 roughly along the centerlines of the glaciers where the variability in both ice thickness and
420 velocity are the highest. The standard deviation of velocity within the 20×10 regions is the
421 largest contributor of errors in our estimates. The dynamic thinning, on the other hand, is
422 calculated only on the ice shelf where the variability of ice thickness and velocity changes are
423 relatively smaller than the grounding zone areas, and therefore the errors in dynamic thinning are
424 also low.

425

426 An important simulation experiment shows that with little decrease in basal friction C upstream
427 of the grounding zone, GVIIS-N becomes more compressive. We anticipate that as ice flux
428 increases in the northern sector, the ice shelf may temporarily become more compressive until
429 ice loss also increases through the calving front. GVIIS-N has less occurrences of fractures
430 despite the presence of pervasive melt ponds, primarily due to its compressive stress regime.
431 This might suggest that although the ice flux and the prevalence of melt ponds increases, the
432 northern part may be resistant to hydrofracture, at least until competing processes take over.

433 On the other hand, the same basal friction C simulation shows that GVIIS-S continues to
434 experience diverging ice strain rates independent of the changes in basal friction. The southern
435 calving edge is also identified by Fürst et al., (2016) as a vulnerable part of the ice shelf. This
436 sector also experiences extensive basal melting on the order of $\sim 3\text{-}4\text{ m a}^{-1}$ (Adusumilli et al.,
437 2020; 2018) due to warmer ocean temperatures at depth (Giulivi et al., 1997; Jenkins and Jacobs,
438 2008). Our estimates of strain-induced dynamic thickness change rates of $\sim 2\text{ m a}^{-1}$ or higher is
439 comparable to the basal melt rates here. The southern sector has thicker ice and has larger ice
440 streams located on retrograde bed slopes below sea level (Fig. 1). Based on these results, we
441 suggest that in the near future, GVIIS-S is more susceptible to unstable changes, and ice
442 dynamics precondition the ice shelf for a rapid retreat.

443

444 However, this contrasts with the Early Holocene retreat of GVIIS that is hypothesized to have
445 progressed from north to south (Smith et al., 2007). The period of absence of George VI Ice
446 Shelf between $\sim 9.6\text{-}7.7\text{ ka B.P.}$, immediately postdates evidence for warmer sea surface
447 temperatures (Shevenell et al., 2011; Etourneau et al., 2013) and ice core evidence of a
448 widespread Early Holocene climatic optimum $\sim 11.5\text{-}9.0\text{ ka B.P.}$ (Masson et al., 2000; Mulvaney
449 et al., 2012). These results, interpreted through modern observations of basal melting and
450 surface melt water ponding, suggest that the Early Holocene retreat was driven by a combination
451 of surface and basal melting. Similar warming conditions exist on GVIIS in recent years as well,
452 and are believed to be the primary drivers of modern ice shelf mass loss.

453

454 Dynamic thinning redistributes mass on an ice shelf, and thinning in vulnerable regions and
455 retreats of ice fronts will make the ice shelf dynamically unstable. The relative roles of

456 hydrofracture of the northern, thinner portion of the ice shelf and the reduced buttressing of the
457 large fluxes from the relatively larger southern glaciers and ice streams will determine whether
458 future loss proceeds from the north or the south.

459

460 **6. Conclusions**

461 In this work we use satellite remote sensing data and numerical modeling to examine the
462 vulnerability of George VI Ice Shelf, Antarctic Peninsula that has been undergoing extensive
463 basal melting and has been recently deemed unstable. We observe increased strain induced
464 dynamic thickness change on the southern sector of GVIIS of $> 2 \text{ m a}^{-1}$ which is comparable to
465 the basal melt rates from previous satellite-derived estimates and demonstrate the importance of
466 dynamic changes on an ice shelf. Our observations of strain-induced dynamic thickness change,
467 ice velocity and ice flux increase across the grounding zone of the southern part of George VI
468 shows that it is currently more vulnerable than the northern sector. This is in sharp contrast to
469 limited paleo observations that suggest that the early Holocene retreat of George VI proceeded
470 from North to South, and both atmospheric and ocean conditions were responsible for the
471 disintegration. To explore the dynamic differences between GVIIS-N and GVIIS-S, we use a
472 numerical model and change the basal friction parameter C by 5% in either directions. We find
473 that even with this small reduction in C , the northern sector becomes more compressive, which
474 makes it resistant to hydrofracture despite the proliferation of surface melt ponds there. On the
475 other hand, the southern sector continues to experience diverging strain rates for the same
476 numerical setup. Based on our observations of change in velocity, ice flux and dynamic thinning,
477 we conclude that: basal lubrication of southern glaciers and ice streams may increase grounded
478 ice loss; and a positive feedback between ice discharge and dynamic thinning on vulnerable

479 regions of an ice shelf can act over short time scales to precondition the ice shelf collapse in the
480 future.
