

44 **Abstract**

45 Characterizing physico-chemical properties of dust-emitting sediments in arid regions is fundamental
46 to understand the effect of dust on climate and ecosystems. For high-latitude dust (HLD), this
47 knowledge is scarce. This study focuses on the particle size distribution (PSD), mineralogy, cohesion,
48 iron (Fe) mode of occurrence and Visible Near Infra-Red (VNIR) reflectance spectra of dust-emitting
49 sediments from dust-hotspots in Iceland (HLD region). Extensive analysis was conducted on top
50 sediments collected from seven dust-sources and an intensive at Jokulsá basin including top
51 sediments, sediments and aeolian ripples. Fully and minimally dispersed PSDs evidenced remarkable
52 similarities with an average median diameter of 56 ± 69 and 55 ± 62 μm . Mineralogical analyses showed
53 the prevalence of amorphous phases (68 ± 26 %), feldspars (17 ± 13 %), and pyroxenes (9.3 ± 7.2 %),
54 aligned with the reflectance spectra. Fe content reached 9.5 ± 0.40 wt %, mainly in silicate structures
55 (80 ± 6.3 %), complemented by magnetite (16 ± 5.5 %), hematite/goethite (4.5 ± 2.7 %), and readily
56 exchangeable Fe-ions or Fe nano-oxides (1.6 ± 0.63 %). Icelandic top sediments have coarser PSD
57 compared to the high dust-emitting crusts from mid-latitude arid regions, distinctive mineralogy, and
58 threefold bulk Fe content, with a large presence of magnetite. The congruence between fully and
59 minimally dispersed PSDs underscores a reduced particle aggregation and cohesion of Icelandic top
60 sediments, suggesting that aerodynamic entrainment of dust may also play a role upon emission in
61 this region, aside of saltation bombardment. The analysis of an extensive sampling in Dyngjusandur
62 allowed this study to present a conceptual model to encapsulate Iceland's rapidly evolving high dust-
63 emitting environments.

86 1. Introduction

87 Dust particles created by wind erosion of arid surfaces can traverse considerable distances, spanning
88 continents and oceans, and influencing the Earth's climate (Kok et al., 2023). The impact of dust on
89 climate and the environment strongly depends upon its shape, particle size distribution (PSD) and
90 composition, which to a large extent are determined by its associated source of sediments (Kok et al.,
91 2023). While most of the dust is produced in hot, arid, subtropical sources like the Sahara, and most
92 studies have concentrated on these regions, but dust produced in cold high-latitude environments,
93 defined as dust emitted from latitudes $\geq 50^\circ$ N and $\geq 40^\circ$ S, receives increasing attention due to its
94 regional and potentially global significance (Bullard et al., 2016; Meinander et al., 2022). High-latitude
95 dust (HLD) is emitted from regions as Iceland, Greenland, Svalbard, Alaska, Canada, Antarctica, New
96 Zealand, and Patagonia, and its physical, chemical and optical properties can differ strongly from those
97 of crustal dust produced in lower latitude sources, and affect, among other, atmospheric (Johnson et
98 al., 2010), marine (Jickells et al., 2005), and cryospheric (Oerlemans et al., 2009) processes.

99 Numerous geophysical processes, especially glacial and periglacial ones, occurring in high latitude
100 regions under current environmental conditions favor the emission of contemporary dust (Bullard,
101 2013; Bullard et al., 2016). Physical weathering of rocks by glaciers produces a vast amount of silt and
102 sand that is transported from underneath the glacial margins by glacial rivers (Palacios et al., 2022).
103 At a certain point, these glacial rivers flow out from the glacier and form floodplains where the silt and
104 sand are deposited, enabling dust emission to the atmosphere by strong winds. Additionally, in active
105 volcanic regions, massive volumes of volcanic ash can be trapped by ice in glaciers across geological
106 history and be supplied as sediment to the glacial rivers upon melting. Such regions are common in
107 Iceland, and include Dyngjúsandur, Skeiðarársandur, Mælifellssandur and Mýrdalssandur (Arnalds et
108 al., 2001). In Iceland, active volcanoes erupt every 3-5 years, depositing thick layers of tephra ranging
109 from millimetres to centimetres (Arnalds et al., 2016). This process has the potential to lead to the
110 formation of new dust sources when new basalt fields obstruct river flows and create ephemeral lakes.
111 All these processes together make Iceland one of the most active dust hotspots in the world, with
112 $>20,000$ km² of sandy deserts (≈ 20 % of Iceland) exposed to aggressive aeolian activity releasing
113 millions of tonnes of dust to the atmosphere (Arnalds et al., 2016; Baldo et al., 2020). Icelandic dust is
114 emitted, transported and deposited over land, sea, and ice of the North Atlantic, covering areas in
115 Iceland, north-western Europe, north-eastern America and Greenland (Arnalds et al., 2014; Baldo et
116 al., 2020). Icelandic dust can reduce surface albedo and either increase or decrease melting of glaciers
117 and ice caps via deposition depending on the deposited layer thickness (Dragosics et al., 2016;
118 Wittmann et al., 2017; Möller et al., 2016, 2018). Icelandic dust is also rich in iron (Fe) (e.g. Arnalds et
119 al., 2014), which depending on its mode of occurrence can exert different climate and ecological
120 effects. Fe-oxide minerals strongly absorb solar radiation (Formenti et al., 2014; Engelbrecht et al.,
121 2016; Di Biagio et al., 2019; Zubko et al., 2019), potentially contributing to direct radiative effects in
122 the Arctic (Kylling et al., 2018). The deposition of soluble Fe from Icelandic dust to the ocean can
123 impact Fe biogeochemistry and primary productivity in the subpolar North Atlantic Ocean, which is
124 seasonally Fe limited (Arnalds et al., 2014). Icelandic dust can also be a sporadically important source
125 of ice-nucleating particles (INP) at mid to high latitudes (Sanchez-Marroquin et al., 2020; Shi et al.,
126 2022), relevant to the cloud-phase climate feedback (Murray et al., 2021).

127 Desert dust can also affect air quality, and accordingly human health (Goudie & Middleton, 2006; De
128 Longeville et al., 2010; Karanasiou et al., 2012; Pérez García-Pando et al., 2014). Thorsteinsson et al.

129 (2011) reported ambient concentrations of atmospheric particulate matter (PM) $<10 \mu\text{m}$ (PM_{10}) higher
130 than $100 \mu\text{g}/\text{m}^3$, on a 30 min basis, during various dust storms in Reykjavik, with dust transport from
131 the Landeyjarsandur area (100 km ESE of the capital). Dagsson-Waldhauserova et al. (2016) reported
132 mean 5 minutes averages PM_{10} and PM_1 levels of 158-583 and 97-241 $\mu\text{g}/\text{m}^3$, respectively at
133 Landeyjarsandur, and 7-486 $\mu\text{g}/\text{m}^3$ PM_{10} at Hagavatn (both major dust hotspots). Dagsson-
134 Waldhauserova et al. (2015) reported similar PM_{10} levels in Reykjavik, but higher in
135 Kirkjubæjarklaustur (up to $6500 \mu\text{g}/\text{m}^3$, 1 min basis).

136 Dyngjusandur, Dyngjuvatn, Hagavatn, Mælifellsandur, Mýrdalssandur, Landeyjarsandur and
137 Skaftarsandur (Figure 1) are the most active dust emission areas in Iceland (Arnalds, 2020). The
138 emission of dust in these regions depends on the season. In the long cold periods, the snow cover
139 prevents dust emissions (Arnalds, 2010). After thawing, the soils have too much moisture to be able
140 to emit; nonetheless, during summer (mostly August) there is a higher probability for dust emission,
141 especially in inland areas, such as Dyngjusandur (Figure 1), where the periodic passage of fronts from
142 the Arctic and low pressure systems are common and are associated with high winds, generally
143 between 5 and 15 m/s, with peaks of up to 30 to 50 m/s, 10 m height (Einarsson, 1984, Olafsson et al.,
144 2007).

145 Glaciofluvial sediments in Iceland may exhibit distinct particle size characteristics. Samples collected
146 in Dyngjusandur, Hagavatn, Landeyjarsandur, Mælifellsandur, Myrdahlsandur, and Sandkluftavatn
147 generally display unimodal distributions with a notably diverse profile, featuring average diameters
148 ranging from 20 to $98 \mu\text{m}$ (Meinander et al., 2022). Icelandic dust is mostly made up of basaltic
149 particles (Baratoux et al., 2011; Thorpe et al., 2019). The dust emitting sediments mainly consist of
150 volcanic glass (up to 80-90 %, except for some dust hotspots, such as Hagavatn, with <40 %), with
151 minor proportions of anorthite (0-20 %), augite (0-10 %), and traces of forsterite, microcline, Ti-
152 magnetite and quartz (Baldo et al., 2020). Wada et al. (1992), reported the occurrence of plagioclase,
153 augite, halloysite, allophane and imogolite in sediment samples at Thingvallasveit, Myrdalur,
154 Biskupstungnaafrettur and Godafoss; while Thorpe et al. (2019) that of plagioclase, augite, olivine,
155 volcanic glass and secondary minerals in soil samples at Hvítá. Baratoux et al. (2011) reported that
156 dust near Dyngjusandur was made up of 80-90 % of volcanic glass, and traces of pyroxene, olivine and
157 plagioclase, and that from Lambrahaun was made up of 0-20 % of volcanic glass with very high
158 plagioclase and olivine contents. Dagsson-Waldhauserova et al. (2015) showed that a deposited dust
159 sample from a top snow layer in Reykjavik reflected the major basaltic composition of the source
160 lands, with mean values of 40-50 % SiO_2 , 14-20 % Al_2O_3 , 8-16 % CaO, 2-4 % $\text{Na}_2\text{O} + \text{K}_2\text{O}$, 4-9 % MgO,
161 10-17 % FeO and 0.8-5 % of TiO_2 , which is in concordance with that of PM_{10} and PM_{20} obtained by
162 resuspension of sediment samples in a chamber (Baldo et al. 2020). Dagsson-Waldhauserova et al.
163 (2015) also showed that deposited dust from Mælifellsandur and Skeidarársandur were similar in
164 composition, with 42-45 % SiO_2 , 14-15 % Al_2O_3 , 11-12 % CaO, 4.0-4.1 % $\text{Na}_2\text{O} + \text{K}_2\text{O}$, 4.9-6.2 % MgO,
165 14-17 % FeO and 3.5-5.6 % of TiO_2 .

166 Several atmospheric modelling studies have already attempted at representing HLD (Thorsteinsson et
167 al., 2011; Groot Zwaaftink et al., 2017; Beckett et al., 2017; Cvetkovic et al., 2022; Meinander et al.,
168 2022). However, the inclusion of HLD in Earth system models is only at its early stages (Shi et al., 2022),
169 and it is currently a challenge. While the fundamental processes governing aeolian dust emissions in
170 HLD should be broadly consistent with those in temperate regions, many HLD source regions exhibit

171 additional or amplified processes unique to their environment. These include the highly dynamic
172 nature of many of its sources, their potential expansion driven by glacier melting and retreat in a
173 warming climate (Meinander et al., 2022), the emission mechanisms and its distinct physicochemical
174 properties. Currently, there is a lack of information on the PSD and mineralogy of dust sources to feed
175 model simulations of emission and transport of dust for climate and environmental impact assessment
176 (Laurent et al., 2008; Perlwitz et al., 2015a and b; Kok et al., 2021). This is especially evident for HLD,
177 where dust observations are scarce (Cvetkovic et al., 2022) and mineralogical maps for dust modelling
178 are not available (Claquin et al., 1999; Journet et al., 2014; Green et al., 2020). Specifically, the size
179 and mode of occurrence of Fe require investigation (Mahowald et al., 2005). It is known that
180 hematite/goethite increases the radiative forcing of dust whereas nano Fe-oxides and easily
181 exchangeable Fe might increase the fertilising effect of dust in ocean and terrestrial ecosystems (Baldo
182 et al., 2020). However, magnetite has different wavelength-dependent optical properties than
183 hematite/goethite (Matsui et al., 2018), and for Icelandic dust it might be the principal contributor to
184 its radiative absorption effect on climate. Also, the high proportions of volcanic glass can influence the
185 radiative forcing of Icelandic dust (Baldo et al., 2023). All in all, there is a pressing need for an improved
186 understanding of the formation and distribution of sediments in HLD hotspots, encompassing an in-
187 depth examination of their compositional and physical attributes. Specifically, a characterization of
188 the PSD, mineral composition, the mode of occurrence of Fe and Visible Near Infra-Red (VNIR)
189 reflectance spectral signatures is essential for accurate representation of HLD sources and the
190 associated dust effects in forthcoming Earth System models. The analysis of both minimally disturbed
191 PSD (MDPSD) and fully disturbed PSD (FDPSD) can further help in understanding the degree of particle
192 aggregation and sediment cohesion (González-Romero et al., 2023), which should contribute towards
193 understanding and constraining dust emission schemes in these regions.

194 This study aims at investigating the major patterns of sediments and processes that account for the
195 high dust emission in Dyngjusandur (Figure 1), one of the most active dust emission areas in Iceland
196 and, more generally, in HLD sources. The major focus is to understand the geological controls for
197 sediment accumulation, while characterizing the mineralogical composition, PSD, mode of occurrence
198 of Fe, degree of cohesion and VNIR reflectance spectra of the dust-emitting sediments in the Jokulsá
199 á fjöllum basin from Vatnajökull (front of the glacier) to Holuhraun (lava field in the middle of the
200 basin) and towards the sea (Figure 1). As a result, a conceptual model for the accumulation of fine-
201 grained sediments and dust emission in the region is elaborated. Additionally, the analysis of samples
202 from other prominent Icelandic dust sources, including Dyngjuvatn, Hagavatn, Landeyjasandur,
203 Mælifellsandur, Mýrdalssandur and Skaftarsandur (Figure 1), are used to evaluate to what extent
204 sediment properties differ across Icelandic dust-hotspots. Finally, the properties of Iceland's dust
205 emitting-sediments are compared with those from a hotspot recently analysed with the same
206 techniques in the Moroccan Sahara (González-Romero et al., 2023).

207 **2. Methodology**

208 **2.1 FRAGMENT field campaigns**

209 This study is part of the FRontiers in dust minerAloGical coMposition and its Effects upoN climaTe
210 (FRAGMENT) project. FRAGMENT has performed a set of coordinated and interdisciplinary field
211 campaigns over remote dust sources in Morocco (2019), Iceland (2021), United States (2022) and

212 Jordan (2022). The project aims to better understand and quantify the properties of dust-source
213 sediments and their relationship to the properties of the emitted dust, evaluate and improve ongoing
214 spaceborne spectroscopy retrievals of surface minerals and improve the Earth system model
215 representation of dust mineralogy. The FRAGMENT campaigns in Morocco, Iceland and Jordan
216 included detailed regional sediment sampling along with an intensive wind erosion and dust emission
217 intensive measurement campaign in one location (e.g., in Morocco, see González-Romero et al., 2023,
218 González-Florez et al., 2023; Panta et al., 2023; Yus-Díez et al., in prep/in submission 2023). The
219 FRAGMENT campaign in the US included sediment sampling only.

220 This study reports the results from the sediment sampling carried out in the Dyngjusandur basin and
221 other dust emission hotspots in Iceland. The intensive wind erosion and dust emission field campaign
222 took place in Dyngjusandur, 300 m away from the newest parts of the Holuhraun lava field, where
223 Jökulsá water flow is accumulated after flash floods, creating an endorheic lake. The results of the
224 intensive field campaign will be presented in forthcoming studies.

225 **2.2 Study site**

226 In northern Iceland, in the Jökulsá á Fjöllum basin, Dyngjusandur has been reported as the largest and
227 most active dust-emitting area by Arnalds et al. (2010) (Figure 1). The glacier Vatnajökull is the source
228 of sand, silt and clay size particles that are transported northwards through the Jökulsá á Fjöllum river
229 and tributaries as Kreppa, Arnardalsá and Skardsá, to the sea (Figure 1). The Bárðarbunga eruption
230 and the Holuhraun lava field cut the basin flow 16 km away from Vatnajökull, forming the ephemeral
231 Dyngjusandurvatn lake (referred in this study as Dyngjusandur), which is affected by flooding
232 recurrently every summer (Figure 1). The ponded waters are filtered through the Holuhraun lava field,
233 connecting again after the lava field with the Jökulsá á Fjöllum river (Arnalds et al., 2016), and allows
234 the deposition of fresh sediments at Dyngjusandur, which can emit dust under favourable conditions.
235 Sediment samples were collected along the river to characterise the variability of the particle size and
236 composition of sediments from the Vatnajökull moraine itself (front moraine) down to the sea (Jökulsá
237 á Fjöllum basin), with an exhaustive sampling that aimed to better characterise sediments from this
238 dust-emission hotspot, located in the surroundings of the Dyngjusandur lake, before the Holuhraun
239 lava field (Figure 1). Furthermore, other dust-emitting sediments were collected in different hotspot
240 sources around Iceland, including Dyngjuvatn (an endorheic lake near the Jökulsá á Fjöllum basin but
241 not connected to it and not to be confused with Dyngjusandur), Hagavatn (an ephemeral lake where
242 sediments pond, sediment and sort), Skaftarsandur (riverine sediments near the sea coast),
243 Landeyjarsandur (riverine sediments that flow towards the ocean and deposit), Mælifellsandur (a river
244 that surrounds the glacier and contributes with fresh sediment) and Mýrdalssandur (riverine
245 sediments on a wide riverbed) (Figure 1).

246 **2.3 Sampling**

247 The samples collected are representative of surfaces that can be found in the dust-emitting and sandy
248 areas over Iceland. These include the top first centimetre (top sediment in this study) of freshly
249 deposited sediments from dust-emission hotspots, underlying sediments (fluvial sediments in this
250 study), and aeolian ripples found near and around these hotspots (Figure 2). We used a metallic
251 shovel, the same as in González-Romero et al. (2023), of about 5 cm² and 2 cm height to sample, and
252 we also noted coordinates, photos of location and area and characteristics of the sample. Samples

253 were stored in plastic bags and transported to the laboratory. Once in the laboratory, samples were
254 dried for 24-48 h at 50 °C and riffled into smaller equal and homogeneous sub-samples for further
255 treatments and analysis.

256 **2.4 Analyses**

257 2.4.1 Particle size distribution

258 Particle size distributions (PSDs) were analysed through fully dispersed (natural aggregates totally
259 dispersed, as much as possible through a dispersion shaking) and minimally dispersed methods
260 (natural aggregates minimally dispersed, dry measurements) according to González-Romero et al.
261 (2023). A coarser minimally dispersed PSD would indicate high aggregation, while similarity between
262 the minimally and totally dispersed PSDs would indicate a low aggregation of particles in dust-emitting
263 sediments; this has key implications for the mechanisms of dust emission. In both cases, PSDs were
264 determined by laser diffraction with a Malvern Mastersizer 2000 Scirocco and a Hydro G accessories,
265 for minimally and fully dispersed conditions, respectively. In the totally dispersed conditions, we
266 followed the procedure presented in Sperazza et al. (2004).

267 2.4.2 Mineralogical composition

268 X-Ray Diffraction (XRD), coupled with the Rietveld method, has been increasingly used as a fast and
269 reliable method to evaluate the content of the crystalline and amorphous phases in inorganic
270 materials (Rietveld, 1969; Cheary and Coelho, 1992; Young, 1993 and Topas, 2018). Quantification of
271 mixtures via the Rietveld method is generally restricted to crystalline phases for which structures are
272 well known. However, the addition of a known amount of an internal standard material allows the
273 quantification of any amorphous (non-crystalline) material in the mixture that has not been included
274 in the model, in our case, volcanic glass (De la Torre et al., 2001; Madsen, 2001, Scarlett and Madsen,
275 2006; Machiels et al., 2010; Ibañez et al., 2013). Sample preparation for quantitative mineralogical
276 analysis consisted of preliminary dry grinding of the samples in an agate mortar, mixed with a known
277 amount (10-20 %) of CaF₂ powder (Merck), as an internal standard to allow the determination of
278 amorphous contents, and finally dry grounded again to reduce the grain size distribution and
279 homogenise the mixture. The analysis was carried out by a Bruker D8 A25 Advance powder X-ray
280 diffractometer equipped with a LynxEye 1D position sensitive detector, monochromatic Cu K α
281 radiation ($\lambda = 1,5405 \text{ \AA}$) operating at 40 kV and 40 mA. The diffractograms were recorded by scanning
282 from 4° to 120° of 2 θ with a step size of 0.015° and a counting time of 1s/step maintaining the sample
283 in rotation (15/min). The mineral identification was performed by searches and comparisons of the
284 patterns from International Centre for Diffraction Database (ICDD, PDF-2) using DIFFRAC.EVA software
285 package (Bruker AXS). The quantitative analysis of the mineral phases was carried out by Rietveld full-
286 pattern analyses performed with the TOPAS 5 software (Bruker AXS), which uses least-square
287 procedures to minimise the differences between the observed and calculated diffractograms. The
288 abundances of the crystalline and amorphous phases were normalised to 100 %wt (weight
289 percentage). The quality of the fitting was evaluated by visually comparing the observed and
290 calculated diffractograms to achieve a realistic model and checking the residual factors (R_B , R_{wp} , R_{exp})
291 and goodness of fit (GOF) calculated by the TOPAS model (Rietveld, 1969; Toby, 2006).

292 2.4.3 Mode of occurrence of Fe

293 The samples were subjected to a series of sequential extractions (Figure S1) aimed at quantifying the
294 content of Fe, including readily exchangeable Fe, hematite and goethite, magnetite, as well as, Fe
295 bearing minerals and volcanic glass. Initially, a portion of each collected sample was subject to
296 duplicate acid digestion using a specialised two-step acid digestion method (Figure S1a) (Querol et al.
297 1993, 1997). This process was employed to ascertain the total Fe content. To validate the accuracy of
298 the analytical and digestion methods, reagent blanks and the standard reference materials NIST SRM
299 1633b (FA) were also subject to digestion. The determination of readily exchangeable Fe ions and
300 nano Fe-oxides, the quantification of crystalline Fe-oxides as hematite and goethite, and the
301 assessment of crystalline magnetite, were all conducted using the laboratory-based sequential
302 extraction method described by Shi et al. (2009) and Baldo et al. (2020). The initial sequential
303 extraction step involved combining 30 mg of the sample with 10 ml of the first extractant solution
304 (ascorbate solution as described in Figure S1b). The mixture was agitated for a period of 24 hours in a
305 light-controlled environment and subsequently filtered. Following this, another 30 mg of the same
306 samples underwent leaching with 10 ml of the second extraction solution (dithionite solution as
307 described in Figure S1c), with 2 hours of shaking under in a light-controlled environment, followed by
308 filtration. The solid residue resulting from this latter extraction was once again leached in a light-
309 controlled environment, this time using 10 ml of a third extraction solution (oxalate solution as
310 described in Figure S1d) and was shaken for a duration of 6 hours before undergoing another filtration.
311 The quantification of the dissolved Fe in each of the three solutions, as well as the bulk acidic digestion,
312 was performed using Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES).

313 The bulk Fe content is referred to as FeT. The Fe that is the extractable from the initial leaching process
314 is denoted as FeA, representing the Fe that is readily exchangeable, as well as the Fe present as nano
315 Fe-oxides. The Fe extracted from the second stage, minus FeA, is referred to as FeD, which
316 corresponds to the Fe content of goethite and hematite. Additionally, the Fe content of the third
317 extraction is referred to as FeM, equivalent to the Fe magnetite content. The sum of FeD and FeM is
318 equivalent to the total Fe present in crystalline Fe-oxides. Finally, the FeT minus the sum of FeA, FeD,
319 and FeM is designated as FeS, representing the content of structural Fe or Fe incorporated within the
320 structure of other minerals, such as pyroxenes, other Fe-bearing minerals, and volcanic glass.

321 For quality control purposes in each laboratory-based sequential extraction, 30 mg of the Arizona Test
322 Dust (ATD; ISO 12103-1, A1 Ultrafine Test Dust; Powder Technology Inc.) was subject to the same
323 extraction procedure. The averaged Fe content of the reference material 1633b was found to be
324 7.6±0.5 % (certified 7.8 %). Furthermore, the average values of the sequential Fe extraction of the ATD
325 reference material were 0.062±0.005, 0.45±0.01, and 0.042±0.002 % for FeA, FeA+FeD and FeM,
326 respectively, while the certified contents are 0.067, 0.48, and 0.047 %, respectively.

327 2.4.4 Scanning electron microscopy

328 Particles from sediment samples were deposited on graphite stubs and sputter coated with C for size,
329 morphology, mineralogy, and aggregate evaluation analysis with a JEOM JSM-7001F SEM-EDX
330 Scanning Electron Microscope (SEM).

331

332

333 **2.5 In-situ and airborne VNIR spectroscopy**

334 Reflectance spectra were measured at 17 sampling locations before and after sample collection using
335 an ASD Fieldspec 3 with contact probe attachment. This instrument measures wavelengths 350-2500
336 nm with spectral resolutions of 3 nm at 0.7 μm and 10 nm at 1.4 and 2.1 μm . Spectra are measured at
337 1.4 nm sampling for wavelengths 0.35-1.0 μm and 2 nm for 1.0-2.5 μm but are internally resampled
338 and output with 1 nm spacing. All measurements are relative to Spectralon and corrected for the
339 known reflectance properties of Spectralon. While we measured the subsurface after sampling, we
340 did not use those measurements as the soils were too saturated to see the mineralogy well. Surface
341 spectra are reported and compared with spectral libraries and the literature (e.g., Kokaly et al., 2017),
342 and band depths (Table S1) were calculated for key absorption features following the methods of Clark
343 and Roush (1984).

344 Additionally, airborne imaging spectrometer (AVIRIS) data operated by NASA/JPL was acquired at the
345 Jokulsá á Fjöllum basin, from the glacier down to Holuhraun lava field during the field campaign. Three
346 AVIRIS scenes with 224 contiguous channels of 10 nm and a wavelength range of 0.35-2.5 μm were
347 used to map spectral reflectance characteristics with the expert Tetracorder system (a modified
348 absorption band-shaped comparison technique between obtained data and a library reference
349 spectrum, Clark et al. 2003, 2023). The AVIRIS raw data were calibrated to radiance, ratioed to the
350 solar spectrum and the atmospheric scattering and absorptions were removed to derive apparent
351 surface reflectance (Thompson et al. 2019 and or Brodrick et al. 2021). The AVIRIS reflectance image
352 cubes were mapped with tetracorder, which analyzed the spectra for hundreds of minerals, mineral
353 mixtures, coatings, vegetation, man-made materials and other compounds. Tetracorder analyses
354 different spectral regions for different compounds. While some minerals have unique spectral
355 features (e.g., hematite, pyroxene), others have broadly-overlapping absorption features and only
356 categories can be determined, e.g., Fe^{2+} bearing mineral.

357 **3. Results and discussion**

358 **3.1 Particle size distribution**

359 **3.1.1 Particle size distribution in the Jökulsá á Fjöllum basin**
360 The PSD of the sediments collected were analysed and the obtained minimally dispersed particle size
361 distributions (MDPSD, i.e., near-natural aggregation state) and fully dispersed particle size
362 distributions (FDPSD, i.e., aggregates completely dispersed) were compared to evaluate the state of
363 particle aggregation in dust-emitting sediments. Jökulsá á Fjöllum basin includes Dyngjusandur
364 (approximately 14 to 18 km away from the Vatnajökull glacier, see in detail in 3.1.2).

365 Both the MDPSD and FDPSD of the three types of sediments (top surface, fluvial and aeolian ripples)
366 are characterised by left-skewed log-normal PSDs. PSDs of top sediment, fluvial sediments and aeolian
367 ripples differ considerably, with an increasingly coarser PSD (Figure 3). The mean of the median
368 diameters (mean median) from the FDPSDs of all samples types collected in the Jökulsá á Fjöllum basin
369 was $133 \pm 174 \mu\text{m}$ [6.8,738, minimum and maximum], while that of MDPSDs reached $107 \pm 129 \mu\text{m}$
370 [6.4,502], indicating the variability of particle sizes. FDPSDs of top sediments had a much finer mean
371 median diameter ($31 \pm 15 \mu\text{m}$) compared to the other type of samples: 102 ± 91 and $354 \pm 203 \mu\text{m}$ for

372 fluvial sediments and aeolian ripples, respectively (Table 1). Similar results, in absolute and relative
373 values, were obtained for MDPSDs for all types of samples (Table 1).

374 The mean median diameter along the basin (from the glacier to the sea) of top sediments clearly
375 decreases, from 76 μm for FDPD and 52 μm for MDPSD close to the moraine, down to 12 μm for
376 FDPD and 11 μm for MDPSD just before the Holuhraun lava field (Figure 4) due to size segregation
377 during ponding and sedimentation of high sediment load water at Dyngjusandur. After the Holuhraun
378 lava field the mean median diameter of the top sediments increases again to up to 47 μm for FDPD
379 and 41 μm for MDPSD, due to sediment input from tributary channels of the Jökulsá river, and then
380 decreases again, down to 29 μm for FDPD and 27 μm for MDPSD, near the sea (Figure 4). For fluvial
381 sediments and ripples there are not enough samples, and the decreasing trend was not observed.

382 The analyses show similar results for MDPSD and FDPD for samples with relatively finer mean median
383 diameters. However, and unexpectedly, MDPSD were finer than FDPD samples for coarser mean
384 diameters. It is hypothesised that this might be due to the presence of pumice low-density particles,
385 fragile and easy to break into smaller light particles, which float in water, and therefore not detected
386 by the laser diffractometer in the case of the FDPD, while the dry method used for obtaining the
387 MDPSD does not segregate pumice particles.

388 The mean diameter of the top sediments is reduced along the path from the glacier to the lava field.
389 This reduction occurs due to several factors. On the one hand, there is particle size segregation driven
390 by fluvial transport that carries sediment from the moraine to more distant areas. On the other hand,
391 vertical micro-segregation occurs during deposition at the ephemeral lake formed by the Holuhraun
392 lava field, which effectively acts as a natural dam. Because of this dam-like effect, sediment-laden
393 waters are temporarily impounded. Finer-grained top sediments gradually accumulate on top of the
394 coarser sediment layer deposited during the initial stage of the flooding-ponding-drying cycle. These
395 episodic events typically occur at intervals ranging from one to several days during the summer
396 season.

397 The water accumulated in this natural dam gradually permeates through the rocks and sediments and
398 subsequently flows through the Holuhraun lava field. These processes lead to sediment removal from
399 the water. This filtered water continues its course until it connects with tributary channels and the
400 segment of the Jökulsá á Fjöllum river that encircles the lava field. At this juncture, these sediment-
401 laden channels merge with clearer waters originating from the lava field post-filtration. Moreover,
402 beyond the lava field, the channels are typically incised, and flooding events are infrequent.
403 Consequently, the prevalence of fine-grained top sediments along this stretch, on the way to the sea,
404 is rare. This reduction in fine sediment cover significantly diminishes the potential for dust emissions.
405 Once the water reaches the sea, sediment deposition leads to extensive mudflats adorned with top
406 sediments, where emission becomes more likely once again if conditions are favourable.

407 3.1.2 Particle size distribution at different Icelandic dust hotspots

408 The median FDPDs of top sediments found in most Iceland's dust-emitting regions (Dyngjusandur,
409 Skaftarsandur, Landeyjarsandur and Mælifellsandur) closely resemble the MDPSDs (Figure 5). This
410 underscores the limited degree of particle aggregation in these areas. However, in the cases of
411 Dyngjuvatn, Mýrdalssandur and Hagavatn the FDPDs and MDPSDs of top sediments differ slightly
412 (Figure 5).

413

414 The mean median diameter of both the FDPD and MDPSD for the 23 top sediments sampled across
415 Iceland is 56 ± 69 μm [2.9,263, min., max.] and 55 ± 62 μm [3.3,234], respectively. Notably, top
416 sediments from Mýrdalssandur and Dyngjuvatn exhibit coarser mean median diameters, measuring
417 147 ± 108 and 146 ± 156 μm for FDPD, and 163 ± 92 and 100 ± 105 μm for MDPSD, respectively. These
418 diameters are more than two times coarser than the overall Iceland mean median diameter (Table 2).
419 Conversely, Skaftarsandur, Mælifellsandur and Landeyjarsandur show mean median diameters that
420 are similar those of the average top sediments in Iceland (Table 2). On the other hand, the top
421 sediments from Dyngjusandur and Hagavatn (the largest dust hotspots associated with ephemeral
422 lakes) exhibit the finest mean median diameters, specifically 24 ± 15 and 16 ± 12 μm for FDPD, and
423 24 ± 1 and 26 ± 26 μm for MDPSD, respectively. These diameters are approximately two times finer than
424 the average of top sediments in Iceland (Table 2).

425 Our results show a general lack of cohesion in the dust-emitting top sediments of Iceland sources, as
426 evidenced by the similar FDPD and MDPSD results. As discussed in Section 4 and 5, this strongly
427 suggests that in addition to saltation, aerodynamic entrainment of dust without saltation as an
428 intermediate process is likely a complementary dust emission process in Iceland due to reduced
429 cohesive forces.

430 3.2 Mineralogy

431 3.2.1 Mineralogy at Jökulsá á Fjöllum basin

432 Different sediments and locations of the Jökulsá á Fjöllum basin were analysed to describe the
433 variability in the region and therefore explain probable mineralogic fingerprints important for dust
434 emission models. The results show that amorphous phase is the prevailing component of the samples
435 analysed (79 ± 11 %wt), being most probably volcanic glass and its nano sized weathering product
436 (hydrated amorphous Si-bearing). Also showed anorthite (11 ± 6.6 %, a Ca-plagioclase, $[\text{Ca}_{0.95-1}\text{Na}_{0.05-0.05}]\text{Al}_2\text{Si}_2\text{O}_8$),
437 augite (7.7 ± 5.4 %, a pyroxene, $[\text{Ca}_x\text{Mg}_y\text{Fe}_z][\text{Mg}_{y1}\text{Fe}_{z1}]\text{Si}_2\text{O}_6$), andesine (1.7 ± 5.9 %, a
438 plagioclase, $[\text{Na}_{0.5-0.7}\text{Ca}_{0.5-0.3}]\text{Al}_2\text{Si}_2\text{O}_8$), analcime (0.19 ± 0.36 %, a Na-zeolite probably formed from the
439 devitrification of volcanic glass during weathering, $\text{Na}[\text{AlSi}_2\text{O}_6]\cdot\text{H}_2\text{O}$), magnetite (<0.5 %, Fe_2O_4) and Ca-
440 mordenite (<0.1 %, a Ca-zeolite, $\text{Ca}_4[\text{Al}_8\text{Si}_4\text{O}]_{96}\cdot 28\text{H}_2\text{O}$) (Figure 6, Table S2).

441 The average composition of the top sediment samples comprises approximately 75 ± 12 % volcanic
442 glass, 11 ± 7.4 % anorthite, 9.9 ± 6.4 % augite, 3.6 ± 8.1 % andesine, along with trace amounts of
443 0.26 ± 0.40 % analcime, 0.16 ± 0.34 % Ca-mordenite, and <0.5 % magnetite. Fluvial sediments and
444 aeolian ripples have similar (or slightly higher) content of volcanic glass (80 ± 12 and 86 ± 4.7 %,
445 respectively), augite (6.6 ± 4.0 and 4.8 ± 1.7 %), and magnetite (<0.5 and <0.5 %). Anorthite is enriched
446 in fluvial sediments and aeolian ripples compared to top sediments (13 ± 7.7 and 9.6 ± 2.9 %, respectively)
447 and also analcime for the underlying fluvial sediments (0.23 ± 0.43 %), with andesine and
448 Ca-mordenite contents being below the XRD detection limits in both the underlying fluvial sediments
449 and aeolian ripples (Figure 6, Table S2). The slight enrichment of fluvial sediments and aeolian ripples
450 in volcanic glass and the slight depletion in augite is likely due to the coarser particle size and the
451 prevalence of relatively large particles of high glass basalt with fine inclusions of crystalline minerals.
452 As these coarser particles break down into finer particles the occurrence of particles made of the
453 crystalline inclusions might increase. Thus, the finer top sediments might be slightly enriched in these

454 crystalline fine minerals (and slightly depleted in glass) in comparison to the coarser underlying fluvial
455 sediments and aeolian ripples.

456 The mineral composition of fluvial sediments is very homogeneous across the Jökulsá á Fjöllum basin;
457 however slight differences were observed for top sediment samples before and after the natural dam
458 of the Holuhraun lava field (Figure S2, Table S2). Before the natural dam, top sediments are enriched
459 in volcanic glass relative to those between the Holuhraun lava field and the sea (82 ± 2.2 and 60 ± 9.5 %,
460 respectively). Furthermore, after the Holuhraun field, andesine, traces of Ca-mordenite and hematite
461 are detected (11 ± 11 , 0.48 ± 0.46 , and <0.5 %, respectively). For fluvial sediments we observe similar
462 trends with volcanic glass enrichment before the Holuhraun lava field (85 ± 2.9 and 51 ± 18 %) and
463 minerals as andesine (16 ± 18 %), forsterite (Mg_2SiO_4) (2.8 %, 1 sample) and analcime (0.25 %, 1 sample)
464 being detected only after the Holuhraun lava field (Table S2). No trends were found for ripples due to
465 a lack of samples after the Holuhraun lava field. These differences are probably due to the different
466 source areas for pre- and post- Holuhraun lava field samples.

467 Reflectance spectra of aeolian ripples (Figure 7a) have broad electronic transitions due to Fe^{2+} with a
468 minimum at ~ 1.05 μm . Most spectra also have an inflection indicating a second electronic transition
469 of Fe^{2+} at ~ 2 μm (e.g., Burns, 1993). These spectra also have vibrational absorption features, with
470 combination bands of H_2O at 1.91 μm and Si-OH and/or Al-OH at 2.2 μm (e.g., Clark et al., 1990).
471 Overall, spectra are consistent with volcanic glass (Bell et al., 1976; Horgan et al., 2014) with possible
472 minor contributions of pyroxene (e.g., Cloutis and Gaffey, 1993) and weak hydration, likely mostly
473 from a hydrated amorphous silica product such as hydrated basaltic glass, allophane, imogolite, or
474 opal (e.g., Anderson and Wickersheim, 1964; Goryniuk et al., 2004; Rampe et al., 2012).

475 Spectra of top sediments are more variable (Figure 7b). All have broad Fe^{2+} electronic transitions
476 centred at 1.00-1.05 μm likely due to volcanic glass and pyroxene, as in the aeolian ripples. Most lack
477 an electronic transition near 2.0 μm , although one sample from a floodplain appears to have a weak
478 feature. All spectra have H_2O combinations at 1.91 μm , and most have OH overtones at 1.41-1.44 μm
479 (e.g., Clark et al., 1990). Other than from a few places on the moraine, all top sediments spectra also
480 have narrower features at 2.20-2.22 μm , which are combination bands of Si-OH and/or Al-OH (e.g.,
481 Clark et al., 1990). One spectrum (#21) also has a weaker Fe(III)-OH combination band at 2.29 μm , seen
482 in hydroxylated Fe-bearing minerals such as Fe smectite clay or ferrihydrite (e.g., Bishop et al., 2008).
483 Spectra from three sites on the moraine have broader, deeper 1.4 and 1.9 μm features, indicating that
484 the soil was wetter.

485 AVIRIS imaging spectroscopy data from the glacier to Holuhraun lava field, show the presence of water
486 in the sediments (absorption features between 1 to 1.5 μm), with clinopyroxene presence (absorption
487 features at 2-micron band), olivine, and Fe^{2+} bearing minerals, some of which may be Fe^{2+} in the
488 volcanic glass. These results are aligned with mineralogy from XRD and in-situ reflectance spectra
489 (Figure 8). In the main study areas, at AVIRIS scale, there are only trace to small local outcrops of
490 minerals as hematite, goethite, calcite, dolomite, chlorite/serpentine, gypsum, illite, muscovite,
491 montmorillonite, and vermiculite (Green et al., 2020). Some trace calcite is seen in Figure 8 and local
492 outcrops of chlorite/serpentine. The strong signatures of Fe^{2+} bearing minerals in the dark soils and
493 rocks make it difficult to detect hematite and goethite unless the concentration is high enough for the
494 Fe^{3+} absorptions to be stronger than Fe^{2+} absorptions.

495 3.2.2 Mineralogy of sediments from different Icelandic dust-emitting hotspots
496 The average composition of the top sediments from the Iceland's dust-emitting hotspots is also
497 dominated by volcanic glass (68 ± 26 % wt), followed by anorthite, augite and andesine (15 ± 11 and
498 8.6 ± 9.0 and 7.4 ± 19 %), Fe-diopside (1.4 ± 3.4 %), a pyroxene with a >50 % MgSiO_3 and 45-50 % CaSiO_3
499 composition), and traces of quartz (0.21 ± 0.47 %), forsterite (0.61 ± 1.7 %), wairakite (0.19 ± 0.92 %),
500 analcime (0.11 ± 0.28 %), Ca-mordenite (<0.1 %), magnetite and hematite (<0.5 and <0.5 %) and pyrite
501 ($\text{FeS}_2 <0.5$ %) (Figure 9, Table S3).

502 Volcanic glass content is higher at Dyngjuvatn, where top sediments are enriched in pumice, with a
503 contribution of 89 ± 3.8 %, followed by 82 ± 2.3 % at Dyngjusandur, 81 ± 2.8 % at Mælifellsandur, 75 ± 8.9
504 % at Mýrdalssandur, 68 % (1 sample) at Skaftarsandur and 38 ± 3.9 % at Landeyjarsandur (Figure 9,
505 Table S3). At Hagavatn, however, the glass content reached only 13 ± 14 %, with the mineralogy being
506 dominated by andesine (53 ± 11 %) and augite (29 ± 3.8 %), with minor proportions of forsterite (4.7 ± 1.3
507 %), hematite (<0.5 %) and magnetite (<0.5 %) (Figure 9, Table S3). Thus, in this case, the very high
508 content of crystalline phases indicates a sediment originating from a slowly cooled lava allowing a
509 widespread crystallisation of minerals from the melt.

510 A very similar mineral composition was found among top sediments from Mælifellsandur,
511 Dyngjusandur, Skaftarsandur and Mýrdalssandur, where the main content was volcanic glass with
512 some plagioclase and pyroxene species (Figure 9, Table S3). The highest content of volcanic glass was
513 found at Dyngjuvatn and the lowest content at Hagavatn. The occurrence of magnetite was higher at
514 Landeyjarsandur, Mælifellsandur and Mýrdalssandur, than in other dust-emitting hotspots, according
515 to XRD analysis. As seen in section (3.1.2), Hagavatn and Dyngjusandur's top sediments have the
516 smallest particle size, coinciding with the lowest volcanic glass content, in the first case, but quite high
517 in the second. Meanwhile Dyngjuvatn's (pumice-rich) top sediments have the coarser particle size and
518 the highest volcanic glass content. Mælifellsandur's and Mýrdalssandur's top sediments have similar
519 mineral composition, but those of Mýrdalssandur are coarser (near the river mouth) in particle size
520 compared to Mælifellsandur (upstream near the glacier). Landeyjarsandur's top sediments are similar
521 in particle size to the ones from Mælifellsandur, but with half of the volcanic glass, and therefore with
522 more plagioclase and pyroxene.

523 Compared to Baldo et al. (2020), who analysed PM_{10} mineralogy sampled in laboratory resuspension
524 of Icelandic sediments, samples for the current study are very similar for Hagavatn, Mælifellsandur
525 and Dyngjusandur, meanwhile for Landeyjarsandur and Mýrdalssandur the present results are lower
526 for volcanic glass and so, higher for pyroxene and plagioclase. Baratoux et al. (2011) found a similar
527 mineral composition of sediments from eolian ripples at Dyngjusandur, with predominance of volcanic
528 glass (80-90 %). Moroni et al. (2018) found that the mineral composition of glaciofluvial sediments
529 was dominantly volcanic glass in Dyngjusandur, Mýrdalssandur and Mælifellsandur, with lower
530 proportions of plagioclase and pyroxene.

531 **3.3 Mode of occurrence of Fe**

532 3.3.1 Mode of occurrence of Fe at Jökulsá á Fjöllum basin

533 Iron speciation in dust-emitting sediments and surfaces control the amount of iron in the emitted dust
534 and therefore the effect in ocean and terrestrial ecosystems and climate. The average of FeT content

535 in the dust emitting sediments of the Jokulsá á Fjöllum basin is 9.5 ± 0.40 %wt (Table S4). Top sediments
536 as well as underlying fluvial sediments and eolian ripples exhibit similar average FeT contents with
537 values of 9.5 ± 0.39 %, 9.5 ± 0.43 %, and 9.4 ± 0.41 %, respectively (Figure 10, Table S4). FeS, which
538 represents structural Fe found in volcanic glass and certain Fe-bearing crystalline species, constitutes
539 for the majority of FeT content, accounting for 80 ± 6.3 %. This is, followed by smaller proportions of
540 FeM (magnetite) at 16 ± 5.5 %, FeD (hematite/goethite) at 2.6 ± 1.6 %, and FeA (readily exchangeable
541 Fe) at 1.2 ± 0.40 % (Figure 10, Table S4). It is worth noting that these proportions are quite consistent
542 across top sediments, fluvial sediments and eolian ripples, with FeS, FeM, FeD and FeA percentages
543 of 79 ± 6.5 %, 16 ± 5.4 %, 3.5 ± 1.5 % and 1.3 ± 0.39 % in the top sediments. In fluvial sediments, these
544 values are 82 ± 8.7 %, 15 ± 7.8 %, 2.2 ± 1.4 % and 1.2 ± 0.44 % and in eolian ripples, they are 80 ± 2.4 %, 18 ± 2.4 %, 1.2 ± 0.41 % and 0.85 ± 0.22 % respectively (Figure 10, Table S4). Notably, there is a difference
545 in magnetite proportions between fluvial sediments from the pre-Holuhraun lava field and those from
546 the post-Holuhraun, with FeM accounting for 19 ± 4.5 % and 11 ± 1.3 % of total Fe, respectively. This
547 variation results in a reverse scenario for FeS, with percentages of 77 ± 6.4 % and 84 ± 1.9 %, respectively
548 (Figure 10, Table S4).
549

550 3.3.2 Mode of occurrence of Fe at different Icelandic dust-emitting hotspots

551 The content of FeT and proportions of FeS, FeA, FeD and FeM in sediments from Iceland's dust-
552 emitting hotspots are summarised in Table S5 and Figure 11.

553 The average FeT content in Iceland's top sediments is 9.3 ± 1.5 %, with the highest concentrations
554 observed in Mælifellsandur and Mýrdalsandur, ranging from 10.0 % to 11.6 % wt, while the lowest are
555 found at Hagavatn and Dyngjuvatn, ranging from 5.5 % to 9.1 % wt. On average, FeS accounts for
556 79 ± 5.4 % of the FeT, with minimum proportions of 65 % in one sample from Dyngjusandur and a
557 maximum of 89 % in one from Mælifellsandur. However, most samples are in the range of 75-80 %.

558 FeM constitutes 15 ± 4.6 % of FeT, with minimum proportions of 7.2 % in one sample from
559 Landeyjarsandur and a maximum of 25 % in one from Dyngjusandur, but most samples fall within the
560 10-20 % range, with the highest proportions typically exceeding 20 % in Dyngjusandur. FeD accounts
561 for 5.0 ± 3.1 % of FeT, with minimum proportions of 1.4 % in one sample from Dyngjusandur and a
562 maximum of 12 % in one from Hagavatn, but most samples fall within the 2-9 % range. FeA represents
563 only 1.6 ± 0.74 % of FeT, with minimum proportions of 0.75 % in one sample from Dyngjusandur and a
564 maximum of 3.4 % in one from Hagavatn, but the majority of samples fall within the 1-2 % range.

565 The absolute contents of magnetite and hematite/goethite are quite low in the samples, making XRD
566 quantitative analysis uncertain. Consequently, the correlation with FeM and FeD is weak. This
567 highlights the importance of employing the chemical sequential extraction (Shi et al. 2009) to assess
568 the mode of occurrence of Fe and further constrain the mineral content of iron oxides. As mentioned
569 in previous sections (3.1.2 and 3.2.2), Dyngjusandur and Hagavatn have similar mean median particle
570 size, but different volcanic glass content. The content of FeS is similar between them, but in the other
571 hand, Hagavatn has higher proportions of FeA and FeD than FeM and Dyngjusandur more proportion
572 of FeM than FeA and FeD. Nevertheless, no correlation was found between mineralogy (from XRD)
573 and Fe speciation.

574

575 **3.4 Spectroscopic indicators of mineral sorting**

576 Spectra acquired in situ of top sediments and ripples show systematic variations with distance from
577 their source (Figure 12). Aeolian ripples, composed of ~100 μm -sized grains weathered out of recent
578 lava flows, were generally measured on or near the lavas from which they are sourced and are coarser
579 grained than top sediments. Thus, their spectra are dominated by primary volcanic phases, including
580 volcanic glass and pyroxene, with minor alteration, either by magmatic fluids (hydrating the volcanic
581 glass) or later alteration. Their spectra are dark (low albedo), have weaker H_2O combination bands at
582 1.91 μm , and stronger Fe^{2+} electronic transitions near 1 and 2 μm than most top sediments.
583 Interestingly, the depth of the absorption feature around 2.21 μm is slightly stronger in these samples
584 and most likely is from a hydrated amorphous silica phase (Figure 12c). These samples unsurprisingly
585 show no systematic trends with distance from the glacier.

586 Top sediments, on the other hand, show stronger trends with distance from the glacier (Figure 12).
587 The albedo, measured as the mean from 1.62-1.63 μm is brighter with increasing distance (Figure
588 12d). This may be due to a change in mineralogy from primary volcanic glass, olivine, and pyroxene to
589 brighter alteration products, including zeolites and phyllosilicate minerals, or due to decreasing
590 particle size, as volume scattering is enhanced with smaller grains. More likely, it is a combination of
591 both factors. With the exception of locations on the moraine that were wetter at the surface, the
592 depth of the absorption feature due to H_2O at 1.91 μm increases with distance from the glacier (Figure
593 12b). Conversely, the depth of the ≈ 1 μm Fe^{2+} electronic transition decreases (Figure 12a). These
594 variations are most likely the result of mechanical sorting, with finer grained hydrated, altered phases
595 becoming dominant downstream relative to coarser, unaltered volcanic glass.

596 The loss of volcanic glass and potentially amorphous hydrated silica within top sediments is also
597 supported by closer examination of the spectra. In spectra of some top sediments, the ≈ 1.0 μm Fe^{2+}
598 electronic transition minimum shifts to slightly shorter wavelengths (≈ 1.03 μm in top sediments vs
599 1.05 μm in ripples), and a secondary electronic feature at ≈ 1.2 μm is typically weaker or absent. These
600 shifts are consistent with the proportion of pyroxene to volcanic glass increasing (Horgan et al., 2014).
601 In addition, the ≈ 2.2 μm combination feature shifts from 2.22-2.25 μm in the ripples to 2.21 μm in
602 some top sediment samples. The longer wavelength minima and broader features are more typical of
603 hydrated amorphous silica (e.g., opal), whereas the shorter wavelength minima suggest the presence
604 of a more ordered phase with Al-OH bonds.

605 **4. Contrasts in composition, particle size distribution, aggregation/cohesion and reflectance**
606 **spectra between Icelandic hotspots and a typical hot desert dust hotspot**

607 Our findings reveal significant between sediments from the Moroccan Sahara (as described in
608 Gonzalez-Romero et al., 2023) and those collected and analysed in Iceland. It is important to note that
609 the Moroccan samples used for comparison were obtained from the Lower Drâa Valley, an arid inland
610 drainage basin and a prominent dust hotspot, which is broadly representative of numerous crustal
611 dust source areas in hot desert environments.

612 The differences in sediment composition are closely intertwined with the particle size distribution and
613 aggregation/cohesion characteristics of these sediments. For instance, when we examine the mean

614 median diameters of the FDPD and MDPSD for top sediments collected from the lowlands and the
615 ephemeral lakes of Iceland (Dyngjúsundur), we observe a relatively close similarity in sizes (31 and 32
616 μm , respectively) (as detailed in Table 3). In contrast, crusts from the lowlands in the Saharan source
617 exhibit markedly different mean median diameters (7 and 131 μm , as reported by González-Romero
618 et al., 2023) (Table 3). Therefore, the FDPD mean diameters for just crusts in the lowlands of the
619 Saharan source are four times finer than those found in top sediments in Iceland. For the underlying
620 fluvial sediments, we found that the MDPSD median diameters are 1.5 times coarser in the Saharan
621 source in comparison to Iceland (115 and 74 μm , respectively). In contrast, for the FDPD the mean
622 median diameter is finer in the Saharan source than in Iceland (22 and 102 μm , respectively).

623 The resemblance between the FDPD and MDPSD of top sediments in Dyngjúsundur, as well as the
624 significant disparity with those from the Sahara, are attributed to the varying levels of aggregation and
625 cohesion. These differences in aggregation are further substantiated by SEM observations (as shown
626 in Figure 13a and b). They are likely a consequence of the paucity of cementing minerals in the Iceland
627 top sediments, namely low levels of carbonate and sulphate content, as well as the absence of clay
628 minerals. These factors contribute to the prevalence of dispersed and non-cohesive sediments in
629 Iceland. The underlying fluvial sediments which consist mainly of coarse particles, primarily individual
630 granules derived from volcanic rock (as depicted in Figure 13c), also stands in contrast to the Sahara's
631 dust-emitting sediments, which often exhibit particle aggregation. Notably distinct were Iceland's
632 dust-emitting top sediments that showed a high enrichment of pumice, an exceedingly fragile and
633 low-density volcanic rock, as seen in the Dyngjuvatn samples. In these cases, the particles often
634 displayed elongated shapes and were accompanied by aggregation of finer particles (refer to Figure
635 13d, e, and f). This distinctive characteristic led to a measurement artifact that resulted in unusually
636 coarser FDPD readings compared to MDPSD.

637 The lack of aggregation and cohesion of Icelandic dust-emitting sediments in comparison to the
638 Saharan source strongly suggests that saltation in Iceland should be efficient, while at the same time
639 dust could be emitted also by direct aerodynamic entrainment. Usually, dust emission due to
640 aerodynamic entrainment is much less efficient than that generated by saltation bombardment,
641 because interparticle cohesive forces, encompassing Van der Waals forces, electrodynamic forces, and
642 chemical forces (e.g., Castellanos, 2005), increase on average with decreasing particle size. This results
643 in an average minimum entrainment threshold for sand-size particles of around 70 - 100 μm (Shao
644 and Lu, 2000; Shao and Klose, 2016). Toward smaller and larger particle sizes, increasing cohesive and
645 gravitational forces, respectively, require stronger lifting forces for particle entrainment. However, if
646 cohesive forces are weaker than on average, as it is the case in Iceland, the entrainment threshold for
647 dust-size particles can be reduced to a value similar to or possibly even lower than for sand-size
648 particles, enabling efficient direct aerodynamic dust emission without saltation as an intermediate
649 process (Klose and Shao, 2013; Shao and Klose, 2016).

650 In contrast to Saharan dust-emitting sediments, which comprise quartz, feldspars, clays, calcite,
651 dolomite, hematite/goethite, and halite, sediments from Iceland's dust sources are predominantly
652 composed of amorphous volcanic glass. They also contain anorthite (Ca-plagioclase), augite
653 (pyroxene), and andesine (plagioclase), with smaller quantities of analcime, magnetite, Ca-modernite,
654 and hematite. These pronounced differences in composition have distinct implications for ice
655 nucleation, radiative forcing, and nutrient deposition. While the effects of the main minerals in hot

656 deserts on these processes are relatively well-understood, the impact of volcanic glass, which
657 constitutes the majority of Icelandic dust, remains largely unexplored and requires further research.
658 One notable difference is the average iron (FeT) content in Icelandic sediments, which is
659 approximately three times higher than that in Saharan sediments. Additionally, the proportion of FeS
660 in FeT is greater in Iceland than in the Sahara, comprising 79 % vs 67 % for top sediments, 82 % vs 68
661 % for underlying fluvial sediments, and 80 % vs 73 % for eolian ripples (as detailed in Table 4 and Figure
662 14). The proportion of Fe from hematite and goethite (FeD %) in Iceland is lower than in the Sahara
663 (1-7 % vs 31 %) while the proportion of FeM is higher in Iceland (9.5-18 % vs negligible) yielding to a
664 potentially different climate effect from the emitted dust (Table 4 and Figure 14). Furthermore, the
665 proportion of FeA, which is highly bioavailable, is lower in Iceland for top sediments (1.3 % vs. 1.9 %
666 of the FeT content), fluvial sediments (1.2 % vs. 1.4 %), and eolian ripples (0.85 % vs. 1.0 %) (as shown
667 in Table 4 and Figure 14). It is important to note that, even though the % FeA in Icelandic sediments is
668 slightly lower, the amount of bioavailable Fe per mass in Iceland's dust-emitting sediments is higher
669 than that of Saharan sediments due to the higher FeT contents in Icelandic samples. Similar
670 mineralogical content was found by Baldo et al. (2020), with a major proportion of volcanic glass in
671 the sediments, followed by anorthite and augite at Dyngjuvatn and Hagavatn. Fe proportions and total
672 amount are also very similar to those obtained by Baldo et al. (2020).

673 Spectra of dust source sediments from Morocco are markedly different than those from Iceland as
674 seen also in the mineralogy (Figure 7a, b, and c). Spectra from Morocco have electronic transitions
675 and charge transfers of Fe³⁺ at wavelengths <1 μm, related to hematite and goethite presence (Figure
676 7a, b, and c), whereas spectra from Iceland have broader Fe²⁺ electronic transitions at wavelengths >1
677 μm and sometimes near 2 μm, related to the volcanic glass and pyroxene proportion (Figure 7c). At
678 longer wavelengths, spectra of sediments from Morocco show features of phyllosilicates, including
679 illites and smectites, whereas in Iceland this is not observed, except the 2.2 micron feature in Figure 7
680 may be due to hydrated silica plus phyllosilicates such as montmorillonite.

681 **5. A conceptual model for dust emission, particle size and mineralogy for Dyngjusandur, a** 682 **major Iceland dust hotspot**

683 Dust-emission in Iceland is primarily governed by glaciofluvial environments. These regions are
684 characterized by the melting of glaciers that have accumulated substantial volcanic sediments and ash
685 over geological time. Subsequently, the fluvial erosion of these sediments transports significant
686 quantities of fine materials, which are deposited in extensive, flat areas during floods (Figure 15). This
687 phenomenon is particularly prevalent in the Jokulsá á Fjöllum basin and other similar locations like
688 Dyngjuvatn, Mælifellsandur, and Mýrdalssandur, with heightened activity during the summer months
689 when glacial melting accelerates. Once these deposited fine sediments dry out, they become prone to
690 dust emission when appropriate wind patterns prevail. In the Jökulsá á Fjöllum basin, this scenario is
691 specially favoured, with a glacial river flowing from the Vatnajökull moraine to Holuhraun, where a
692 recent volcanic eruption (July 29, 2014 to February 27, 2015 with an 85 km² of surface, Geiger et al.,
693 2016) generated a natural dam, and some of the fluvial channels arising from the moraine transport
694 large volumes of sediments across a flat and extensive region (Figure 15). In this endorheic flat,
695 continuous summer floods lead to cyclic sediment deposition. Coarser fluvial sediments are deposited
696 first and are subsequently covered by top sediments of very fine grains formed after each cycle
697 through the deposition of suspended fine particles following drying or infiltration of ponded waters

698 (Figure 16). Following sediment deposition, waters infiltrate and traverse the lava field, flowing to the
699 other side of the natural dam with minimal sediment load. On the other side of the dam, these pristine
700 waters join those from the other channels unaffected by the dam and flow toward the sea. Because
701 the dam stops part of the floods and because the river is more incised, overflows and sediment flats
702 alongside the river are very reduced from the dam to the sea. However, large flooding flats at the sea
703 once again contain sediments prone to dust emission. Such sedimentation, particle size fractionation,
704 drying and dust emission processes are generally repeated daily under favourable conditions in
705 summer. The aeolian ripples are formed in the dry part of the cycle and can be mobilised by the wind
706 and trigger the emission of dust by saltation. However, the lack of cohesive forces in the sediments
707 may also allow direct aerodynamic entrainment of dust at lower wind speeds without the need of
708 saltation (Figure 16).

709 6. Conclusions

710 This study has undertaken a comprehensive examination of dust-emitting sediments in Iceland,
711 focusing on their particle size distributions, mineralogy, and Fe mode of occurrence. Our findings
712 reveal distinctive characteristics among various sites, with Hagavatn and Dyngjusandur exhibiting the
713 finest particle size distributions, and Mýrdalssandur and Dyngjuvatn showing the coarsest. Despite
714 these variations, the overall particle size distributions in Iceland's top sediments, whether fully or
715 minimally dispersed, exhibit remarkable similarities. Notably, these distributions sharply contrast with
716 those observed in a dust hotspot in the Moroccan Sahara. Iceland's top sediments are approximately
717 four times coarser than fully dispersed Moroccan crusts, yet, these fully dispersed Iceland top
718 sediments are finer than the minerally dispersed Moroccan crusts, prevalent in the Moroccan Sahara.
719 These distinctions underscore the relatively limited interparticle cohesion in Iceland, a characteristic
720 that sets it apart. The scarcity of cohesion implies an efficient saltation bombardment process, and at
721 the same time suggests the possibility of direct aerodynamic entrainment of dust in this region. This
722 contrasts with the cohesive sediments typically found in hot desert environments, where interparticle
723 cohesion hinders dust aerodynamic entrainment, making saltation the primary mechanism for dust
724 emission.

725 Iceland's dust-emitting sediments primarily consist of black volcanic glass, constituting a substantial
726 proportion ranging from 70% to 85% by weight. Plagioclase and pyroxenes contribute 10% to 15% and
727 4% to 8%, respectively, with traces of zeolites and Fe-oxides present. Consistent compositional
728 patterns emerge across most dust-emitting regions in Iceland, except for Landeyjarsandur and
729 Hagavatn. In these regions, sediments display diminished glass content (35% and <0.1%, respectively)
730 and heightened levels of plagioclase and pyroxenes, reaching up to 65% and 31%, respectively. These
731 compositional variations are starkly distinct from Saharan dust-emitting sediments, owing to the
732 differing volcanic and sedimentary origins of the respective dust sources. Notably, in Saharan
733 sediments, the presence of salts, carbonates, and clays promotes the formation of aggregates that
734 increase particle size and sediment cohesion. The composition of Fe-oxides also varies between the
735 two regions, with hematite and goethite being predominant in the Sahara, while Iceland's sediments
736 predominantly contain magnetite. The specific role of black volcanic glass in dust-radiation and dust-
737 cloud interactions remains inadequately described, contributing to a limited understanding of its
738 impact on climate. Further research is essential to unravel the complexities of these interactions and
739 their implications for climate.

740 The distribution of Fe in the top sediments of Jökulsá á Fjöllum, as well as in the underlying fluvial
741 sediments and the aeolian ripples, exhibits homogeneity in its mode of occurrence. The averaged bulk
742 Fe content (FeT) is 9.5 ± 0.40 %wt, with structural Fe (FeS) constituting $80 \pm 6.3\%$, and Fe in magnetite
743 (FeM) accounting for $16 \pm 5.5\%$. Minor variations are observed in the proportions of Fe as
744 hematite/goethite (FeD) and readily exchangeable- and nano-Fe (FeA). Notably, the top sediments
745 display a significant presence of readily exchangeable Fe and hematite/goethite, attributed to
746 heightened glass weathering in the fine top sediment compared to coarser underlying layers and
747 aeolian ripples. Similar trends were identified in various Icelandic sources, with Mælifellsandur and
748 Mýrdalssandur exhibiting higher mean FeT ($11 \pm 0.48\%$ and $11 \pm 0.41\%$, respectively). Hagavatn and
749 Skaftarsandur showed a maximum proportion of FeA ($2.7 \pm 1.0\%$) and (2.6%, 1 sample), respectively.
750 Landeyjarsandur displayed the maximum FeD proportion ($7.2 \pm 2.1\%$), while Dyngjusandur exhibited
751 the highest proportion of FeM ($18 \pm 4.6\%$). In comparison to the Moroccan Saharan, although
752 proportions are similar, the bulk Fe content in Iceland is threefold higher. Consequently, for the same
753 emitted dust mass, the absolute mass of FeA is three times greater, with FeD being smaller, and FeM
754 emerging as the major contributor, resulting in a potentially distinct impact on oceans and terrestrial
755 ecosystems and yielding diverse implications for climate.

756 Airborne and in-situ spectroscopy results are broadly consistent with XRD and size results. The spectra
757 of ripples are dark (low albedo) and dominated by primary volcanic phases and show no systematic
758 trends with distance from the glacier. Top sediments show trends with distance from the glacier
759 (Figure 12), with the albedo being brighter with increasing distance partly due to decreasing particle
760 size, which most likely is the result of mechanical sorting, with finer grained hydrated, altered phases
761 becoming more prevalent downstream relative to coarser, unaltered volcanic glass. There is lack of
762 significant clay minerals, carbonates and salts (even though, traces of carbonates and serpentines
763 have been found with Tetracorder). The marked differences in composition between Icelandic and
764 Moroccan sources are also captured. Spectra from Morocco have electronic transitions and charge
765 transfers of Fe^{3+} at wavelengths $< 1 \mu\text{m}$, related to hematite and goethite, while spectra from Iceland
766 have broader Fe^{2+} electronic transitions at longer wavelengths, related to the volcanic glass and
767 pyroxene.

768 A conceptual model has been formulated to elucidate the elevated dust emissions observed in
769 Dyngjusandur, Iceland. This model encompasses several key factors contributing to the phenomenon.
770 Firstly, the historical entrapment of substantial amounts of volcanic sediments and ash by the glacier
771 has established a reservoir of materials awaiting liberation. The accelerated melting of the glacier,
772 particularly intensified during summer and influenced by underlying volcanism, releases significant
773 volumes of fresh sediment. Notably, a volcanic field active in 2014-2015 functions as a natural dam,
774 triggering extensive floods that inundate large plains with sediments prone to inducing dust emissions.
775 These floods exhibit a daily recurrence under specific summer conditions, fostering sedimentation,
776 particle fractionation, drying, and cycles of dust emission. The inherent nature of the sediments,
777 characterized by black basalt detritus and volcanic ash with a predominant glassy composition, results
778 in minimal particle aggregation and cohesion. Moreover, the frequent and extensive vertical particle
779 size segregation during the flooding cycles contributes to the coverage of vast areas with very fine
780 sediments, thereby facilitating dust emission. The synergy of these geological, climatic, and
781 environmental factors provides a comprehensive understanding of the intricate processes driving high
782 dust emissions in Dyngjusandur.

783 **Code availability.** The code used in this paper is provided by Clark (2023, <https://github.com/PSI->
784 [edu/spectroscopy-tetracorder](https://github.com/PSI-edu/spectroscopy-tetracorder)).

785 **Data availability.** Data used in this paper are given in the main paper itself and in the Supplement. If
786 **needed, data are also available upon request by emailing the authors.**

787 **Author contributions.** CPG-P proposed and designed the field campaign with contributions of AA,
788 KK, MK and XQ. The Campaign was implemented by CPG-P, AA, CGF, AGR, KK, MK, AP, XQ and JYD.
789 The samples were collected by CPG-P, AA, AGR, MK, AK, RG and XQ and analysed by AGR, PC and
790 NM. Spectroscopy was analysed by AK, RG, BLE, PB and RNC. AGR performed the visualization and
791 writing of the original draft manuscript and CPG-P and XQ supervised the work. CPG-P and XQ re-
792 edited the manuscript and all authors contributed in data discussion, reviewing and manuscript
793 finalization.

794 **Competing interests.** At least one of the (co-)authors is a member of the editorial board of
795 Atmospheric chemistry and Physics.

796 **Acknowledgements**

797 The field campaign and its associated research, including this work, was funded by the European
798 Research Council under the Horizon 2020 research and innovation programme through the ERC
799 Consolidator Grant FRAGMENT (grant agreement No. 773051) and the AXA Research Fund through
800 the AXA Chair on Sand and Dust Storms at BSC. CGF was supported by a PhD fellowship from the
801 Agència de Gestió d'Ajuts Universitaris i de Recerca (AGAUR) grant 2020_FI B 00678. KK was funded
802 by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – 264907654;
803 416816480. MK has received funding through the Helmholtz Association's Initiative and Networking
804 Fund (grant agreement no. VH-NG-1533). We acknowledge the EMIT project, which is supported by
805 the NASA Earth Venture Instrument program, under the Earth Science Division of the Science Mission
806 Directorate. We thank Dr. Eva L. Scheller for the help during the field spectroscopy measurements.
807 We thank Dr. Pavla Dagsson Waldhauserova from the Agricultural university of Iceland for the
808 invaluable support and help during the field campaign. We thank Thomas Dirsch for the uncountable
809 driving hours and mechanical support during the soil sampling. We thank Paul Ginoux for providing
810 high-resolution global dust source maps, which were very helpful for the identification of the
811 FRAGMENT experimental sites. We thank the staff from the ranger station at Dreki as well as the
812 wardens of the Dreki campsite and the Dreki mountain rescue service for their valuable support and
813 advice. We also thank Vilhjalmur Vernharðsson and his crew from Fjalladýrð for their permanent
814 logistic help. Without all of them, the measurement campaign would not have been successfully
815 feasible.

1131 **Figure captions:**

- 1132 **Figure 1.** Location of Iceland dust hotspots and samples. Black polygon marked the limits of Holuhraun lava field
1133 and in red are marked the area of the different dust hotspots in Iceland. Basemap: Imagery data from
1134 © Google Earth Pro v: 7.3.6.9345. Jökulsá á Fjöllum is marked as (a) and AVIRIS data flight images where
1135 used in the zoom in from Dyngjusandur (b) and Dyngjuvatn (c) for a more actualized vision of the lakes.
1136 **Figure 2.** Examples of samples collected in Iceland from top sediments (a), fluvial sediments (a) and eolian ripples
1137 (b)).
1138 **Figure 3.** Minimally dispersed particle size distribution (MDPSD) and fully dispersed particle size distribution
1139 (FDPSD) of top sediment, fluvial sediments and eolian ripple samples.
1140 **Figure 4.** Mean median diameters of top sediments along the Jökulsá á Fjöllum river, according to the distance
1141 to the glacier moraine. The grey column indicates the location of the Holuhraun lava field and the red
1142 vertical line, a tributary channel of Jökulsá á Fjöllum.
1143 **Figure 5.** Particle size distributions of top sediment samples from different dust-emitting hotspots in Iceland as
1144 determined by MDPSD and FDPSD.
1145 **Figure 6.** Contents of volcanic glass and crystalline minerals in top sediments, underlying fluvial sediments and
1146 eolian ripples from the Jökulsá á Fjöllum basin.
1147 **Figure 7.** Reflectance spectra measured of surfaces in the field: (a) ripples in Iceland, (b) top sediments in Iceland,
1148 and (c) example spectra from Morocco. In (a) and (b), spectra are offset for clarity and are ordered by
1149 distance from the glacier.
1150 **Figure 8.** Imaging spectrometer data from AVIRIS and analysed with Tetracorder (Clark et al., 2003, 2023). A)
1151 Grey scale image of 3 AVIRIS flight lines mosaicked for this study. The white circle is the primary study
1152 area and the grey rectangle is secondary sampling. B) Pyroxene composition map. The pyroxene
1153 dominant in the region are clinopyroxenes. C) Olivine composition map, which indicates the olivine are
1154 high iron content. However, in areas of significant Fe²⁺ bearing volcanic glass could bias this result. D)
1155 Fe²⁺ bearing minerals, which in those area is probably mostly due to volcanic glass. Note few locations
1156 mapped any Fe³⁺ bearing minerals. E) Map the EMIT 8 minerals with absorptions in the 2-2.5 micron
1157 spectral region. Only trace calcite and outcrops of chlorite/serpentine were found. F) Tetracorder map
1158 of water and significant water bearing sediments. Where strong water absorptions are seen, detection
1159 of other minerals is difficult and usually blank in panels B-E.
1160 **Figure 9.** Contents of volcanic glass and crystalline minerals in top sediments, underlying fluvial sediments and
1161 eolian ripples from different dust-emitting hotspots. Dyn: Dyngjusandur, Dvt: Dyngjuvatn, Lan:
1162 Landeyjarsandur, Mýr: Mýrdalsandur, Ska: Skaftarsandur, Mæl: Mælifellsandur, Hgv: Hagavatn.
1163 **Figure 10.** Average percentage of FeS, FeM, FeD and FeA for the Jökulsá á Fjöllum basin and average amount of
1164 each Fe mode of occurrence according to the total content of Fe.
1165 **Figure 11.** Average percentage of FeS, FeM, FeD and FeA for Dyn: Dyngjusandur, Dvt: Dyngjuvatn, Lan:
1166 Landeyjarsandur, Mýr: Mýrdalsandur, Mæl: Mælifellsandur, Hvt: Hagavatn and Ska: Skaftarsandur and
1167 average amount of each Fe mode of occurrence according to the total content of Fe of the same dust
1168 emitting sources.
1169 **Figure 12.** Trends in infrared spectral features with distance from the glacier. (a) The depth of a broad absorption
1170 feature at 1.035 µm (BD1035) due to Fe²⁺ in volcanic glass and/or pyroxene. (b) The depth of an
1171 absorption feature at 1.9 µm (BD1900) due to H₂O. (c) The depth of an absorption feature at 2.21 µm
1172 (BD2210) due to Si-OH or Al-OH. (d) The albedo (brightness), calculated as the mean reflectance at 1.62-
1173 1.63 µm. Black points are spectra of ripples, and gray are spectra of top sediments.
1174 **Figure 13.** SEM microphotographs of collected dust samples: a) Particles from a top sediment sample from
1175 Dyngjusandur showing dispersed particles. b) Particles from a top sediment sample from the lowlands
1176 of M[']Hamid, Morocco (see González-Romero et al., 2023), showing finer particle size and a high degree
1177 of agglomeration. c) Particles from underlying fluvial sediments, from Dyngjusandur, showing a large
1178 particle size and fresh volcanic glassy material. d, e, and f) Samples of top sediments (d and e) from

1179 Dyngjuvatn, showing abundant elongated particles and agglomerates of particles derived from the
1180 breaking of larger pumice particles. g) Image showing particles with magnetite inclusions.

1181 **Figure 14.** Average amount of each Fe mode of occurrence for top sediment JaF: Jökulsá á Fjöllum top sediment
1182 average, Sediment JaF: Jökulsá á Fjöllum sediment average, Ripple JaF: Jökulsá á Fjöllum ripples
1183 average, Dyn: Dyngjusandur, Dvt: Dyngjuvatn, Lan: Landeyjarsandur, Mýr: Mýrdalsandur, Mæl:
1184 Mælifellsandur, Hvt: Hagavatn, Ska: Skaftarsandur, Crust S: Average crust from Sahara, Sediment S:
1185 Average sediment from Sahara and Ripple S: Average ripple from Sahara and average percentage of
1186 FeS, FeM, FeD and FeA normalised by the amount of FeT.

1187 **Figure 15.** Conceptualization of the origin, transport, sedimentation and emission of dust emitting sources,
1188 sediments and dust along Iceland, using the example of the Jökulsá á Fjöllum basin. t1: The glacier feeds
1189 the fluvial systems with fine particles that are transported and size segregated along the basin, t2: in
1190 flat areas or if a volcanic eruption forms a dam, the sediments deposits, t3: under favourable conditions
1191 the dust emission occurs in different parts of the basin by saltation and aerodynamic entrainment.

1192 **Figure 16.** Example of how particles, mainly volcanic glass with minor proportions of pyroxenes, feldspars and
1193 some iron oxides are transported, segregated and after drying and under favourable conditions,
1194 aerodynamic entrainment and saltation bombardment.
