Abstract. Due to ongoing climate change, methane (CH_4) emissions from vegetated wetlands are projected to increase during the 21st century, challenging climate mitigation efforts aimed at limiting global warming. However, despite reports of rising emission trends, a comprehensive evaluation and attribution of recent changes remains limited. Here we assessed global wetland CH_4 emissions from 2000 to 2020 based on an ensemble of sixteen process-based wetland models. Our results estimated global average wetland CH_4 emissions at 158±24 (mean ± 1σ) Tg CH_4 yr^{-1} over a total annual average wetland area of 8.0±2.0 Mkm^2 for the period 2010-2020, with an average increase of 6-7 Tg CH_4 yr^{-1} in 2010-2019 compared to the average for 2000-2009. The increases in the four latitudinal bands of 90°S-30°S, 30°S- 30°N, 30°N-60°N, and 60°N-90°N were 0.1-0.2 Tg CH_4 yr^{-1}, 3.6-3.7 Tg CH_4 yr^{-1}, 1.8-2.4 Tg CH_4 yr^{-1}, and 0.6-0.8 Tg CH_4 yr^{-1}, respectively, over the two decades. The modeled CH_4 sensitivities to temperature show reasonable consistency with eddy covariance-based measurements from 34 sites. Rising temperature was the primary driver of the increase, while precipitation and rising atmospheric CO_2 concentrations played secondary roles with high levels of uncertainty. These modeled results suggest climate change is driving increased wetland CH_4 emissions and that direct and sustained measurements are needed to monitor developments.

1 Introduction

Wetlands are the largest single source in the global methane (CH_4) budget, representing ~25-35% of the total combined natural and anthropogenic sources (Kirschke et al., 2013; Saunois et al., 2016, 2020), with an uncertainty range of 100-230 Tg CH_4 yr^{-1} (Cao et al., 1996; Gedney et al., 2004; Bousquet et al., 2006; Petrescu et al., 2010; Spahni et al., 2011; Melton et al., 2013; Bridgham et al., 2013; Bloom et al., 2017; Poulter et al., 2017). Covering 8-10% of the global land surface (Zhang et al., 2021a), wetland area is sensitive to climate variations (Zhang et al., 2018; Zhu et al., 2017). Over the last deglaciation, wetlands played an important role in driving the rise of atmospheric CH_4 concentrations (Hopcroft et al., 2017; Nisbet et al., 2023; Kleinen et al., 2023). In recent decades, wetlands have experienced unprecedented and ongoing changes, including continuous thawing of permafrost (Natali et al., 2019; Treat et al., 2018), land-use change (Fluet-Chouinard et al., 2023), a lengthening of the growing season in the Arctic (Arndt et al., 2019), and expansion in tropical areas due to enhanced precipitation (Fleischmann, 2023). Recent evidence from in situ measurements (Rößger et al., 2022), data driven estimates (Yuan et al., 2024; Ying et al., 2024), and satellite observations (Feng et al., 2022) suggests that these ongoing changes could enhance wetland CH_4 emissions and thus affect the trajectory of atmospheric CH_4 concentration. Furthermore, atmospheric $\delta^{13}C$-CH_4 records also show a trend toward increased depletion since the late 2000s (Lan et al., 2021; Nisbet et al., 2019), indicating that isotopically light biogenic sources, such as wetlands (Basu et al., 2022; Feng et al., 2022), agricultural, and waste sources (Schaefer et al., 2016; Zhang, et al., 2021b) have become dominant contributors to the rise in atmospheric CH_4. Current estimates of wetland CH_4 emissions (hereafter denoted as eCH_4) in response to climate change are projected to increase by up to 15-30% by 2050 (Koffi et al., 2020; Zhang et al., 2017), accounting for 25-40% of the pledged reduction in anthropogenic emissions (Shindell et al., 2019). These trends and projections suggest that the emerging wetland-CH_4 climate feedback that influences atmospheric CH_4 concentration requires a better understanding of long-term changes in eCH_4.

Directly diagnosing the variations and trends of eCH_4 at large scales is challenging. Site-level measurements, such as those from chamber and eddy covariance techniques, are useful for identifying underlying mechanisms and monitoring CH_4 fluxes at the landscape scale but are difficult to upscale due to large uncertainties in extrapolation and the high spatial heterogeneity of wetland CH_4 fluxes (Chu et al., 2021; Kuhn et al., 2021). Interpreting eCH_4 using satellite observations and inversions of atmospheric concentration data is also subject to uncertainties in anthropogenic sources, other natural sources, atmospheric chemistry, and model errors associated with atmospheric transport (Gatti et al., 2021; Gloor et al., 2021; Palmer et al., 2022; Patra et al., 2011; Zhang et al., 2021c). Global wetland models, integrated within land biosphere models, can serve to bridge our understanding of wetland CH_4 processes and diagnosing wetland CH_4 dynamics at large scales (Melton et al., 2013; Wania et al., 2013). These models provide mechanistic explanations for the causes of changes in eCH_4 dynamics. Furthermore, recent advances in wetland models (Arora et al., 2018; Kaiser et al., 2017; Shu et al., 2020; Grant 2017; Chang et al. 2020) show significant potential for improving our understanding of eCH_4 through the incorporation of complex biogeochemical processes.

Current studies have reached various conclusions on the change in eCH_4 over the last decades. Studies based on single biogeochemical models (Zhang et al., 2018; Zhu et al., 2017) suggest a significant increase in eCH_4 from 2000-2006 to 2007-2017, while atmospheric inversions (Zhang et al., 2021c; Yin et al., 2021; Basu et al., 2022; Feng et al., 2022) suggested even higher rate increases, from 2 Tg CH_4 yr^{-1} yr^{-1} to 3 Tg CH_4 yr^{-1} yr^{-1} during the post-2010 period. Poulter et al., (2017) reported no significant change between the 2000-2006 and 2007-2012 periods based on an ensemble of wetland models, while Saunois et al. (2020) show a slight increase (~2 Tg CH_4 yr^{-1}) in average for 2007-2017 compared to the 2000-2006 level using a large set of wetland CH_4 models. However, these models demonstrate considerable differences in estimated eCH_4, both spatially and temporally (Ma et al., 2021; Parker et al., 2020; Chang et al., 2023), primarily due to the sensitivity of their estimations to the wetland areal extent, the implemented biogeochemical structures, and parameterizations. The multi-model ensemble approach is applied to increase the skill, reliability, and consistency of model forecasts, potentially offsetting individual model errors (Schaefer et al., 2012). However, a recent study (Chang et al. 2023) found that down selecting atmospheric inversion and wetland model CH_4 predictions based on a comparison to eddy covariance data did not reduce uncertainty in global eCH_4 estimates. Therefore, it has become necessary to thoroughly evaluate the performance of these models using the most recent generation of wetland models against an increasingly dense network of observations (Delwiche et al., 2021; Knox et al., 2019) from eddy covariance sites.

Here we conducted ensemble simulations of 16 wetland biogeochemical models following a common modeling protocol to provide monthly integrated global eCH_4 for the period of 2000-2020, as part of the Global Carbon Project's Methane Budget activity. The inundation dynamics of each model were simulated using a model-specific prognostic hydrological modeling approach as well as a set of diagnostic satellite-driven simulations. A set of factorial simulations were carried out to isolate the effects of temperature, precipitation, and rising atmospheric CO_2 concentration. The modeled temperature sensitivity was evaluated against the global eddy covariance database, FLUXNET-CH_4 (Delwiche et al., 2021; Knox et al., 2019), and a data-driven global wetland CH_4 upscaling dataset UpCH_4 (McNicol et al., 2023) based on FLUXNET-CH_4. In addition, we examined the changes in eCH_4 for the year 2020, which was characterized as an extremely warm and wet year with the highest growth rate of atmospheric CH_4 observed over the study period.

2 Methods

2.1 Wetland model ensemble

Sixteen wetland models participated in the ensemble simulations (Table S1). Wetland CH_4 models can be generally described as functions describing the biogeochemical processes that control CH_4 production and oxidation through methanogenesis and methanotrophy, and the biophysical processes that regulate CH_4 transport from the soil to the atmosphere (Table S1). Methanogenesis in the models is linked to different proxies (e.g., carbon substrate, heterotrophic respiration, net primary

production) with a wide range of model complexity - more sophisticated models include wetland Plant Functional Types (PFTs) and explicitly simulate the processes of CH_4 production, consumption, and transport, while the simplified models use generalized empirical equations to simulate net fluxes without explicitly calculating individual components of the CH_4 flux.

Wetlands were defined as naturally vegetated forested and non-forested ecosystems with saturated/inundated areas, excluding coastal wetlands, cultivated wetlands such as rice paddies, and open water systems such as rivers, lakes, ponds, and reservoirs. A prognostic wetland inundation scheme and a diagnostic wetland dataset Wetland Area and Dynamics for Methane Modeling (WAD2M v2; Zhang et al., 2021a) are applied to identify the wetland areal dynamics. The prognostic wetland areal dynamics were independently determined by each model's hydrological modules, which use water table depth or soil moisture, combined with sub-grid topographic conditions to determine saturated areas within a land surface grid-cell (Zhang et al., 2016; Xi et al., 2022). Among the participating models, there was a large variation in complexity and in the level of comprehensiveness with which wetland extent were characterized. The modules for simulating inundation ranged from simplified TOPMODEL approaches to more sophisticated representations of water-table variation, with the estimated magnitude being influenced by the hydrologic schemes utilized and the sensitivities to precipitation. The prognostic modeled wetland extent showed large variability in estimated magnitude but was consistent with satellite-based inundation products in predicting different phases of inundation (Xi et al., 2022; Zhang, et al., 2021a). The ensemble mean of the modeled wetland extent is close to 7.5 Mkm^2 as estimated by WAD2M but higher than the 4.6 Mkm^2 by the satellite-based product Global Surface Water Extent and Dynamics version 2 (GIEMS2; Prigent et al., 2020). The modeled temporal variations in wetland areas have high correlations with the satellite-based products for the temperate region and high latitudes (Fig. S1), except for the tropics. The modeled temporal variations in wetland areas show high correlations with satellite-based products for temperate regions and high latitudes (Fig. S1), except in the tropics. The limited agreement in the tropics may be due to the influence of aerosols and clouds on satellite-based measurements, as well as the process-based model's performance limitations in representing wetland areas. The diagnostic runs are exclusively used for temperature dependence calculations due to a discontinuity issue in the WAD2Mv2 over a few tropical hotspots, which affect a subset of wetland models that are particularly sensitive to inundation in the hotspots.

2.2 Modeling protocol and simulation setups

The modeling protocol aimed to provide wetland CH_4 fluxes and quantify the associated uncertainties arising from model differences, meteorological forcing, and wetland extent dynamics. To quantify meteorological forcing uncertainty, we used two climate inputs, a ground-based monthly climate dataset from the Climatic Research Unit (CRU) (Harris et al., 2014), up to 2020 and a harmonized daily dataset from the Global Soil Wetness Project-3 GSWP3-W5E5 through the year 2019, which is a multiple-source-based daily dataset (Cucchi et al., 2020; Dirmeyer et al., 2006) used in the Inter-Sectoral Impact Model Intercomparison Project 3a (ISIMIP3a). For models that require 6-hourly meteorological forcings, a temporal-interpolation dataset CRU-JRA was applied based on the Japanese Reanalysis Agency (JRA55), aligned with CRU. The atmospheric CO_2 concentration values for 1861-2020 were obtained from the CMIP6 experimental protocol (Meinshausen et al., 2017).

Ancillary data, such as soil texture and CH_4-related parameter sets used model-specific inputs. All the models were run in 'natural vegetation' mode without transient effects of land use and land cover change. Methane oxidation in wetland soils was implicitly included in the estimate but the upland oxidative sink was not included as it was not part of the net wetland emissions calculations. Models included the spin-up period to pre-industrial conditions assuming net ecosystem exchange equilibrium before 1860 by recycling fixed CO_2 concentrations (1860 level of 286.42 ppm) and meteorology (1901-1920).

2.3 FLUXNET-CH_4 and machine learning-based upscaling product UpCH$_4$

FLUXNET-CH_4 is the first global dataset of CH_4 eddy covariance measurements that includes ~ 80 sites globally, including different wetland types from peatlands (e.g. bog, fen), mineral wetlands (e.g. marsh, swamp), and rice paddies. For this study, a subset of natural freshwater wetland sites was selected for the analysis. All the eddy covariance measurements used in this study were gap-filled daily total fluxes filled using an Artificial Neural Network (ANN) approach (Knox et al., 2019). In addition, a data-driven gridded dataset UpCH$_4$ (McNicol et al., 2023) for 2001-2018, which is based on 119 site-years of CH_4 fluxes from the FLUXNET-CH4 dataset, was applied in the comparison. This dataset used a random forest model to upscale ground-based eddy covariance CH_4 flux data and then was forced with globally-gridded predictor data and two wetland extent products, to predict wetland CH_4 emissions. The predictors included data sources from climate, biometeorological, and soil properties.

2.4 Time series decomposition and statistical analyses

To attribute the time series of global wetland CH_4 emissions to what we consider the dominant drivers of change (i.e., temperature, precipitation, and CO_2 concentration), we applied a multiple regression approach (Piao et al., 2013) to estimate the parameters of global wetland CH_4 sensitivity to climate drivers using the following equation:

$$y = \beta CO_2 + \gamma Tmp + \delta Pre + c + \varepsilon \quad (1)$$

where y is the global annual total wetland CH_4 emission of each model from the transient run, or from the observation-based upscaling dataset UpCH$_4$, and Tmp, Pre, and CO_2 are the mean annual temperature, total annual precipitation, and mean atmospheric CO_2 concentration for that year, respectively. γ, δ, β, and c are regression coefficients and ε is the residual error term. The regression coefficients were calculated using a maximum likelihood estimate. Changes in other meteorological forcings may also influence the estimation of y. These confounding drivers, such as solar radiation and wind speed, although they are considered to have minor impacts on the variations of eCH$_4$, were implicitly accounted for in the regression coefficients.

2.5 Model factorial experiment

To further separate the contribution of different controls on the change in methane emissions (ΔeCH$_4$) by climate variations and rising CO_2, we used a subset of four models that conducted factorial experimental simulations by holding each factor

constant during part of the transient runs. This subset of the wetland models (i.e., ELM-ECA, LPJ-wsl, SDGVM, and VISIT) performed a set of factorial simulations to specifically attribute the effect of temperature, precipitation, and rising CO_2 concentration on wetland CH_4 fluxes with the climatology of 2000-2006 for 2007-2020. The simulations were performed by running the model keeping one-factor constant at a time to estimate the contribution of each component to the total range of variations (Table S2). For these factorial simulations, we evaluated the annual amplitude of wetland eCH_4 as a relative percentage change to minimize the impacts of different modeling implementation choices, such as different input variables among models. The effect of the total changes on the relative change in amplitude was represented by the difference between the transient (one factor is time-varying) and baseline (static at 2000-2006 levels) runs. For simplicity, the relative contribution of a single driver to eCH_4 variations was quantified as the transient run minus the specific control run. To calculate the contribution of each driver using the subset of the models, we calculated weighting factors per year across the models, with lower bias resulting in higher weight relative to the full ensemble mean using an inverse function.

2.6 Temperature dependence calculation

To further evaluate the response of eCH_4 to rising temperatures, we calculated the modeled seasonal eCH_4 temperature dependence, referred to as the apparent Q_{10} metric at the locations of 34 FLUXNET-CH_4 sites. This seasonal Q_{10} differs from the intrinsic Q_{10} prescribed in the parameterization of respiratory processes in each model. Here it represents the overall response of eCH_4 along geographic temperature gradients. The apparent Q_{10} is defined as eCH_4 sensitivity to temperature change. We calculated apparent Q_{10} based on CH_4 emitting strength over a standard wetland area, which was calculated as the CH_4 fluxes divided by inundated area on a per-pixel basis to exclude the effect of inundation dynamics. To derive the temperature sensitivity of eCH_4 at the soil or ecosystem level, we applied the following equation:

$$R(i) = R_b(i) Q_{10}^{\frac{T(i) - T_{ref}}{\Gamma}} \quad (2)$$

where R(i) is the net wetland flux at the location of site *i*, $R_b(i)$ is the basal net CH_4 flux at the reference temperature T_{ref}, and T(i) is ambient temperature. The parameters Q_{10}, $\Gamma = 10°C$, and $T_{ref} = 15°C$ are all time-independent constants. The Q_{10} acting on specific time scales can be obtained from eCH_4 at corresponding specific time scales (i.e., seasonal total and annual total) by fitting an exponential regression with modeled eCH_4 and air temperature from CRU or GSWP3-W5E5. To quantify the uncertainty in observed apparent Q_{10}, we employed 1000 sets of resampled FLUXNET-CH_4 observations generated based on a Gaussian distribution. The uncertainty range in measured seasonal mean CH_4 fluxes was determined by aggregating the uncertainty of daily total fluxes obtained through ANN gap filling.

3 Results and Discussion

3.1 Changes in eCH4 during the period of 2000-2020

The multi-model ensemble based on the prognostic inundation schemes shows that the average annual global eCH_4 over the period 2000-2020 was 156±24 Tg CH_4 yr^{-1} (mean±1σ). The average annual eCH_4 increased from 153 ±23 Tg CH_4 yr^{-1} during 2000-2009 to 158±24 Tg CH_4 yr^{-1} during 2010-2020. 15 out of 22 model simulations show significant positive linear trends ($p < 0.01$) with an ensemble mean increase rate of 0.6±0.3 Tg CH_4 yr^{-1} yr^{-1} over 2000-2020 (Fig. 1a; Table 1; Fig. S2). Differences in total annual emissions between the two sets of simulations driven by two different climate datasets CRU and GSWP3-W5E5, agree well in the magnitude of the annual anomalies. Notable eCH_4 variations to climate events were observed, such as the rise during the 2010 La Niña (+5.2 Tg CH_4 yr^{-1}) and the decline during the 2015 El Niño (- 4.6 Tg CH_4 yr^{-1}) after removing the positive linear trends. The multi-model ensemble wetland eCH_4 response to climate events is consistent with those reported by earlier studies (Zhang et al., 2018; Zhu et al., 2017) using single wetland models, indicating a modulation of the phase of eCH_4 anomaly (ΔeCH_4) by the El Niño-Southern Oscillation. The model ensemble demonstrates a consistent increase in interannual variability (IAV) in ΔeCH_4 from 3.6±1.6 Tg CH_4 yr^{-1} during 2000-2009 to 4.7±1.5 Tg CH_4 yr^{-1} during 2010-2020, suggesting a potential increase in eCH_4 variability under climate change.

The models consistently show that 2020 is the strongest positive anomaly year during 2000-2020, with a net increase of 2 [-2, 7] Tg CH_4 yr^{-1} (mean [min, max]) in 2020 compared to 2019. This positive anomaly in 2020 (Table 1) is broadly consistent with a recent study (Peng et al., 2022) that reported 6±2.3 Tg CH_4 yr^{-1} based on simulations of two bottom-up models with different climate datasets. The discrepancy in estimated magnitude between the Peng et al. (2022) and our results are partly due to the parameterizations of CH_4 module that causes lower annual magnitude in this study (~ 162±23 Tg CH_4 yr^{-1} in 2020) compared to the Peng et al. (2022) study (177±31 Tg CH_4 yr^{-1} in 2020). Additionally, the precipitation inputs in the climate forcing used in this study show a lower positive anomaly (~ of 20 mm yr^{-1} in CRU over global wetland) in precipitation in 2020 compared to the reanalysis-based estimates (~ 40-117 mm yr^{-1} over global wetland used in the study by Peng et al., (2022), which leads to lower estimates of wetland area and consequently lower emissions in this study. Moreover, our model ensemble does not indicate a strong increase (-0.2[-1.5-0.7] Tg CH_4 yr^{-1}) in eCH_4 in Africa in 2020. This contrasts with recent atmospheric inversions (Feng et al., 2023; Qu et al., 2023), which suggest a large increase of 11-17 Tg CH_4 yr^{-1} above 2019 levels in African CH_4 emissions for 2020. The estimated increase from these inversions is equivalent to 55%-85% of total eCH4 in Africa during 2010-2019 in our study (Figure 2). These discrepancies highlight the need for further studies to investigate the differences between these two approaches, including uncertainty in climate inputs in process-based bottom-up models and partitioning difference sources in atmospheric inversions.

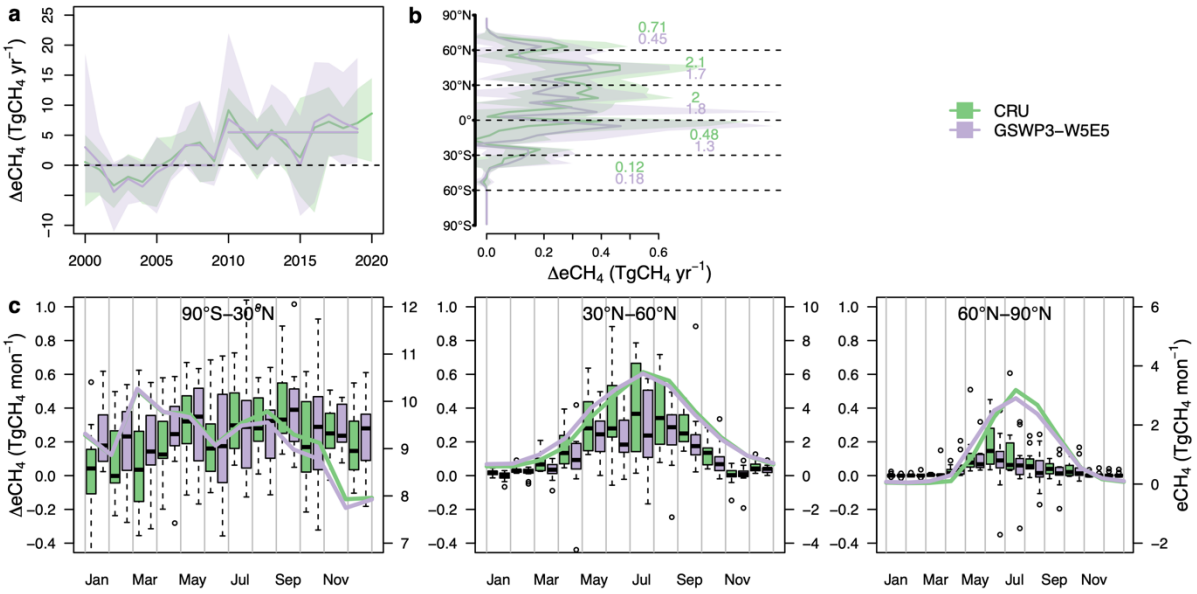

Figure 1: Simulated model ensemble changes of global wetland CH_4 emissions for 2000-2020. The change is expressed as the difference (ΔeCH_4) relative to the mean of the 2000-2009 level from the two sets of simulations with prognostic wetland emission models grouped by different climate datasets, CRU and GSWP3-W5E5. a, Time series of annual total anomalies during 2000-2020, with the shaded area representing the range between minimum and maximum modeled emissions. The horizontal lines represent the ensemble means of 2000-2009 (152 Tg CH_4 yr^{-1}) and 2010-2019 (158 Tg CH_4 yr^{-1}), respectively. b, Latitudinal gradient of mean ΔeCH_4, with the mean annual total ΔeCH_4 for each of the 30° latitude bins from the two sets of simulations shown. c, Boxplots of mean seasonal ΔeCH_4 for the three regions. The central mark and the bottom and top edges of the box indicate the median, and the 25th and 75th percentiles of the ensemble, respectively. The colored lines represent the average seasonal cycle of 2000-2009 from the simulations grouped by two climate datasets, CRU and GSWP3-W5E5.

There were widespread net increases in eCH_4 across all latitudinal bands during 2010-2020, compared to the average of 2000-2009, with the largest magnitudes occurring in the 90°S- 30°N bands (there are relatively few wetlands in the southern extra-tropics 90°S-30°S, contributing 0.1-0.2 Tg CH_4 yr^{-1}) and temperate regions (30-60°N) (Fig. 1b). The annual magnitude of eCH_4 increased by 3.7-3.8 Tg CH_4 yr^{-1}, 1.8-2.4 Tg CH_4 yr^{-1}, and 0.6-0.8 Tg CH_4 yr^{-1} in the tropical, temperate, and Arctic wetlands, respectively. The tropics have experienced the largest increases in annual total emissions with an increase of 3% relative to 2000-2009 (Table 1). This finding is aligned with the results of several recent atmospheric inversions (Basu et al., 2022; Feng et al., 2022; Lan et al., 2021) using satellite observations and/or isotopic measurements that suggest a large increase in microbial emissions for post-2007 period in the tropics. While the increase in annual total emissions from temperate wetlands is lower than that from the tropics, they nevertheless show a larger relative increase of 5-8% compared to 2000-2009. Arctic wetlands also show an increased rate of 5-7% relative to the same period.

The increase in eCH_4 occurs in parallel with differing patterns of enhanced seasonal cycles between tropical and extratropical wetlands (30°N-90°N) (Fig. 1c). In temperate and Arctic wetlands, the majority of the increase in emissions (60-92%) occurred primarily during the growing season (May-October). Specifically, increases in Arctic wetlands occurred during the early

growing season (May-July), aligning with findings from a data-driven estimate (Yuan et al., 2024) and a long-term eddy covariance-based study (Rößger et al., 2022) that observed early growing season increases in eCH_4 due to continuous warming in a Siberian wetland. In contrast, the increase in emissions within the 90°S-30°N band exhibited relatively minor seasonal variations throughout the year, with the May-October period accounting for a 24% greater increase in ΔeCH_4 compared to the November-April period (Fig. S3).

Table 1. Summary of wetland CH_4 emissions (Tg CH_4 yr^{-1}) over different time periods by latitudinal bands for the prognostic wetland simulations. The ensemble mean with minimum and maximum (numbers within brackets) are listed, respectively.

3.2 Spatial distribution of eCH_4

A few key regions contribute significantly to global emissions (Fig. 2a,c). These regions are mainly floodplains located along major river basins such as the Amazon, Ganges, Mississippi, and Yangtze; tropical peatlands in the Congo and Southeastern Asia; and high-latitude peatlands in the Hudson Bay Lowland (HBL) and West Siberian Lowland (WSL). However, inter-model variabilities in eCH_4 reveal varying levels of spatial agreement between models, with the largest discrepancies coming from South America and Africa. South America is one of the largest contributors to the global total eCH_4. Still, the net change in that region shows only a moderate increase, with diverging trends within the Amazon basin during the 2010s (Fig. 2b,d). The uncertain temporal trends are consistent with a long-term, large-scale atmospheric inversion based on airborne campaigns (Basso et al., 2021). South Asia and Africa are among the regions with the largest increases in the tropics, next to North America, but have high uncertainty with a lower level of agreement among the models (Fig. S4). The model ensemble shows that Northwestern South Asia has a significant percentage increase in eCH_4 during 2010-2019 relative to its average levels from 2000-2009, suggesting a possible high sensitivity of eCH_4 to climate change in this region.

The comparison with previous estimates from bottom-up approaches and top-down atmospheric inversions (Table S3) suggests that the model ensemble mean generally captures well the spatial distribution of annual eCH_4, with a potential underestimation

for a few methane hotspots (Fig. S5). The model ensemble means for the Amazon basin, HBL, and WSL show good agreement with atmospheric inversions (Bergamaschi et al., 2013; Pickett-Heaps et al., 2011; Ringeval et al., 2014; Tunnicliffe et al., 2020; Wilson et al., 2016, 2021) and bottom-up modeling estimates (Bansal et al., 2023; Bloom et al., 2017; Bohn et al., 2015), with relatively low uncertainty. The model ensemble highlights WSL and HBL as CH_4 hotspots in the high latitudes, with good agreements of annual magnitudes with atmospheric inversions and in situ observations (Bohn et al., 2015; Glagolev et al., 2011; Pickett-Heaps et al., 2011), while the models have lower estimates for Alaska compared to the inversions (Chang et al., 2014; Miller et al., 2016). However, for the two hotspots of the Pantanal and Sudd wetlands, the models tended to underestimate the annual eCH_4 compared to a few recent satellite-based estimates (Gerlein-Safdi et al., 2021; Gloor et al., 2021; Lunt et al., 2021; Pandey et al., 2021), with a large uncertainty range of up to two orders of magnitude across the model ensemble (Fig. S5). In addition to the regions where eCH_4 are being underestimated, recent studies (France et al., 2022; Shaw et al., 2022) based on aircraft measurements suggest that the bottom-up models likely underestimate high eCH_4 fluxes in some little-studied wetlands, such as those in Zambia and Bolivia. The underestimations by process-based wetland models can be attributed to: 1) the challenge in accurately capturing the areal dynamics of wetlands under varying hydrological conditions, such as in flat terrains that receives lateral transport of water from upper streams (Li et al., 2024; Lunt et al., 2021; Gerlein-Safdi et al., 2021); 2) existing knowledge gaps in mapping wetlands in remote areas, which affect the parameterization of inundation modeling; 3) the limited representation of water table regulation (Chen et al., 2021) and wetland PFTs (Bastviken et al., 2023) on eCH_4 in biogeochemical models.

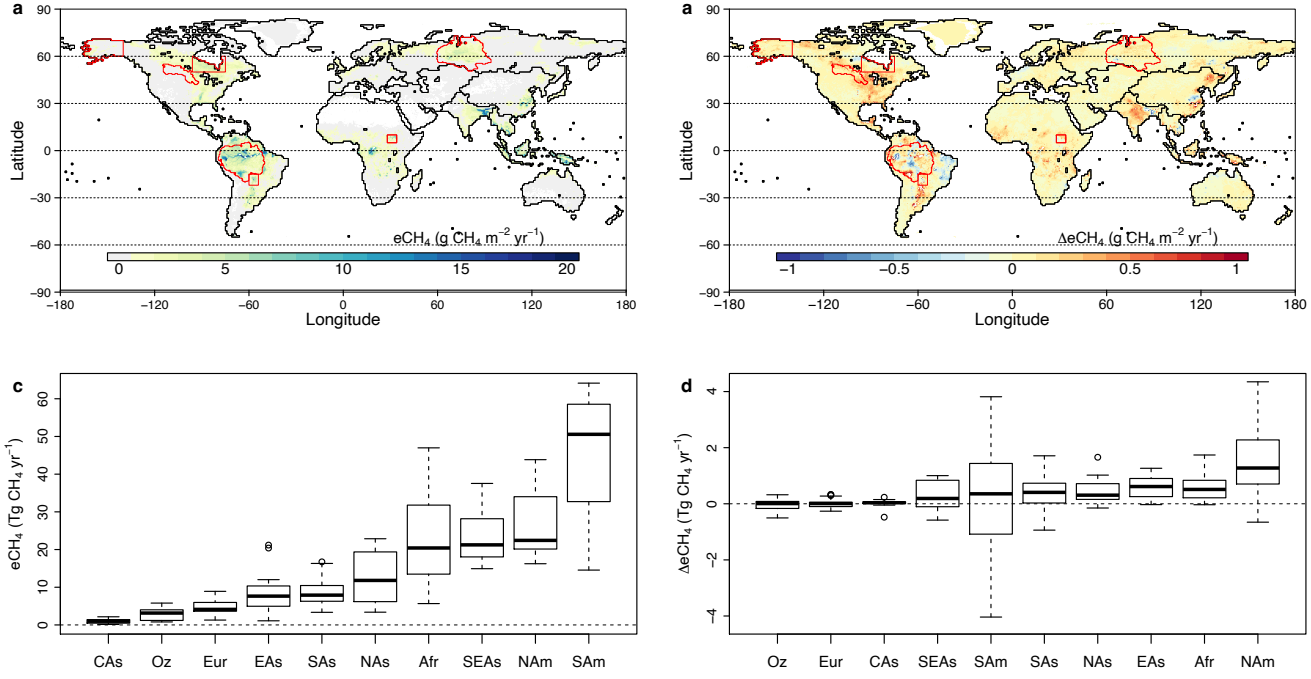

Figure 2. Spatial distribution of eCH_4 and the average change between the 2010s and 2000s. a. Map of mean eCH_4 (Unit: $gCH_4\ m^{-2}\ yr^{-1}$ per 0.5 deg grid cell) for 2000-2020. The regions defined in c, d and regional CH_4 hotspots in Table S3 are outlined in black and in red,

315 respectively. b. Map of change in mean annual wetland emissions (ΔeCH_4) between the 2010s and 2000s. c. Boxplot of mean annual eCH_4 and d. ΔeCH_4 by regions for 2000-2020 in ascending order for median estimates, Afr: Africa; CAs: Central Asia; EAs: East Asia; Eur: Europe; NAm: North America; NAs: North Asia; Oz: Oceania; SAm: South America; SAs: South Asia; SEAs: Southeast Asia.

3.3 Attribution of wetland CH_4 changes

320 To evaluate the relative contribution of different factors on global eCH_4, we calculated the sensitivity of eCH_4 to mean annual temperature (denoted as γ), annual total precipitation (denoted as δ), and CO_2 concentration (denoted as β) using a multiple regression approach for each model run over the period of 2000-2020. The same approach was applied to the upscaled gridded machine learning dataset $UpCH_4$, which uses eddy covariance measurements from FLUXNET-CH_4 as training inputs. The model ensemble suggests that temperature is the primary driver of the increase in eCH_4 (Fig. 3a). The regression coefficients
325 for γ is 4.6 Tg CH_4 yr^{-1} $°C^{-1}$, with a range of -0.4 and 9.0 Tg CH_4 yr^{-1} $°C^{-1}$ between the 10^{th} and 90^{th} percentiles among all models. This mean temperature sensitivity is slightly higher than the γ coefficient of 3.2-4.1 Tg CH_4 yr^{-1} $°C^{-1}$ estimated for $UpCH_4$. In contrast, precipitation contributed little to the increase from the prognostic simulations, with a coefficient δ of 0 to 0.3 Tg CH_4 yr^{-1} mm^{-1}. The coefficient δ was lower at -0.05-0 Tg CH_4 yr^{-1} mm^{-1} for $UpCH_4$, as precipitation was not chosen as a model training predictor through its feature selection, based on site-level eddy covariance measurements (McNicol et al.,
330 2023). However, precipitation is a more dominant factor at large scales, especially for tropical floodplains, which contribute the largest proportion of emissions but are poorly represented by eddy covariance measurements. The model ensemble estimated β remains small, ranging from 0 to 0.3 Tg CH_4 yr^{-1} ppm^{-1}, while $UpCH_4$ suggests a β at -0.01 Tg CH_4 yr^{-1} ppm^{-1}. However, other confounding drivers might influence eCH_4 as well, such as solar radiation, wind speed, and nitrogen deposition. Thus, the inferred sensitivities are implicitly accounted for in the regression coefficients despite their relatively small impacts
335 compared to the major drivers.

Generally, the factorial simulations of the four-model subset indicated a consistently positive contribution (three out of four) from rising temperature to ΔeCH_4, with a large variability (s.d.=4.3 Tg CH_4 yr^{-1}) of contributions from precipitation (Fig. S6). The strength of the CO_2 fertilization effect varied among models and was moderate but positive in all models. Two models
340 (ELM-ECA and SDGVM) were among the models with higher sensitivity to climate variations while LPJ-wsl and VISIT were close to the full ensemble mean. ELM-ECA produced a negative temperature effect on eCH_4, likely due to its modeled nutrient constraints and higher temperature sensitivity for methanotrophic compared to methanogenic processes. Considering the deviation of each model from the full ensemble mean, the weighted mean (Fig. S7) contributions for temperature, precipitation, and CO_2 concentration from the subset models were 3.2, 1.8, and 1.4 Tg CH_4 yr^{-1}, respectively. The results from the subset of
345 the models consistently demonstrate that temperature is the primary factor influencing eCH_4.

Overall, the interannual variations of modeled eCH_4 were primarily associated with rising temperature, altered precipitation patterns, and rising atmospheric CO_2 concentrations that stimulated ecosystem productivity through the CO_2 fertilization effect (Yvon-Durocher et al., 2014). We note that a recent study found strong hysteresis in the seasonal temperature dependence of observed eCH_4 using the FLUXNET-CH_4 dataset (Chang et al. 2021). Those hysteretic features likely result in uncertainty in annual temperature sensitivity estimates but would not bias the conclusion of temperature as a dominant controller of eCH_4 at the decadal time scale. The links between rising temperature and enhanced net CH_4 fluxes are evident (as described below), as the annual global average temperature over wetland areas has significantly ($p < 0.01$) increased by 0.5-0.7 °C from 2000-2020 (Fig. 3b). The modeled interannual variations of wetland extent dynamics reproduced the response to strong climate events (e.g., positive anomaly during the La Niña phase in 2010/2011 (Boening et al., 2012) and 2020). Both climate-forcing datasets suggest no significant trend in the anomaly of annual mean wetland area globally over the same period based on the prognostic hydrological simulations (Fig. 3b). Similarly, no significant regional trends in wetland area were found for most of the sub-regions, with the exception of South America, which shows a decrease, and East Asia, which shows a slight increase (Fig. S8). Considering that the extent of modeled wetland areas is primarily driven by precipitation, we do not detect a substantial contribution of changes in wetland extent to the long-term increase in eCH_4 over 2000-2020 based on the climate datasets. However, considerable differences in annual and seasonal precipitation estimates between the climate datasets used in this study and those derived from reanalysis or satellite-based products (Zhang et al., 2023a) result in large uncertainties in the estimated trends in wetland extent.

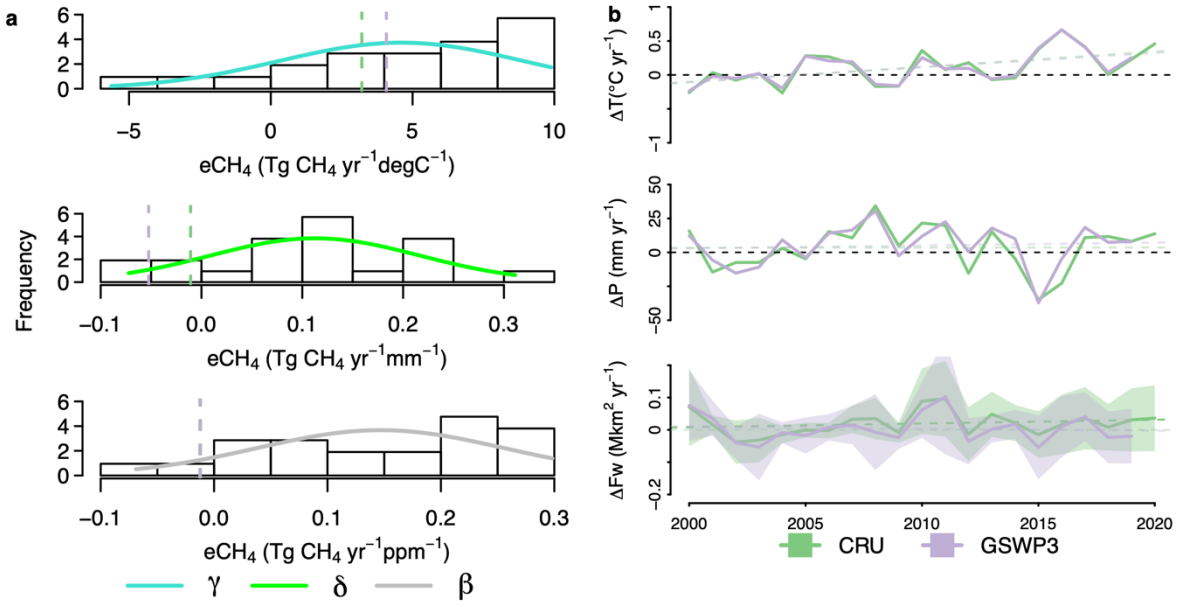

Figure 3. Attributions of ΔeCH$_4$ during 2000-2020. a. Histogram showing the sensitivity coefficients derived from a multiple regression approach (See Methods) for temperature (γ), precipitation (δ), and atmospheric CO_2 concentration (β). The curves represent probability distributions of sensitivity coefficients across the models, assuming a Gaussian distribution. Vertical lines represent estimates from the machine learning-based dataset UpCH$_4$, with different colors corresponding to different climate datasets. b. Time series of anomalies for annual mean temperature (ΔT), annual total precipitation (ΔP), and annual mean wetland extent (ΔFw) for 2000-2020 for CRU and 2000-2019 for GSWP3. The shaded area in ΔFw represents the minimum and maximum range from the prognostic model simulations. Dashed lines are linear fitted trends for corresponding variables.

3.4 Temperature sensitivity of wetland CH$_4$ models

The modeled CH$_4$ emissions show an exponential relationship between eCH$_4$ and air temperature, with higher temperatures corresponding to higher mean eCH$_4$ during the peak growing season (JJA, June-July-August) in the Northern Hemisphere (Fig. 4a). The model ensemble mean of eCH$_4$ response to temperature shows good agreement within the range of the spread when compared to the site-level measurements from FLUXNET-CH$_4$ and the gridded product UpCH$_4$. The model ensemble mean has a higher CH$_4$ emitting strength (i.e., CH$_4$ emission per standard wetland area) for the high latitudes, leading to lower apparent Q_{10}. This implies that the model ensemble estimated temperature sensitivity for the high latitudes could be potentially overestimated during the JJA season. The apparent Q_{10} values for individual models show a large spread (Fig. S9), with eleven out of the sixteen models having statistically significant ($p < 0.01$) exponential relationships. The good agreement between the ensemble mean and observations suggest that the ensemble approach provides a better constraint compared to single models alone. Furthermore, it is important to acknowledge that the sparse spatial coverage of FLUXNET-CH$_4$ over low latitudes, especially for underrepresented areas such as Africa, Southeast Asia, and South America, limits our ability to evaluate temperature dependencies over high-temperature regions (Fig. S10).

The modeled apparent Q_{10} exhibits an average temperature dependence similar to that of ecosystem respiration, as reported by previous studies (Bloom et al., 2017; Mahecha et al., 2010; Yvon-Durocher et al., 2014), indicating that the underlying factors controlling the response of eCH$_4$ and ecosystem respiration to temperature covary. The modeled temperature dependences are more constrained with less spread for JJA and SON (September-October-November) than DJF (December-January-February) and MAM (March-April-May) when most site-level measurements have limited availability. The seasonal variations of modeled apparent Q_{10} differ from site-level observations or UpCH$_4$, reflecting discrepancies in the involved processes between eddy covariance and land surface models. Given that underrepresented processes such as substrate supply tend to have higher sensitivity of ecosystem metabolic processes to temperature, it is likely that the models do not entirely capture the fine-scale processes that affect the overall temperature response (Chang et al. 2021). In addition, the absence or underrepresentation of certain biophysical processes could lead to lower modeled apparent Q_{10}. For instance, the ensemble mean of modeled apparent

Q_{10} for SON seasons is underestimated, likely linked to the limited representation of processes during the freeze/thaw cycle (e.g., zero-curtain period), as suggested by previous observational studies (Mastepanov et al., 2008; Zona et al., 2016).

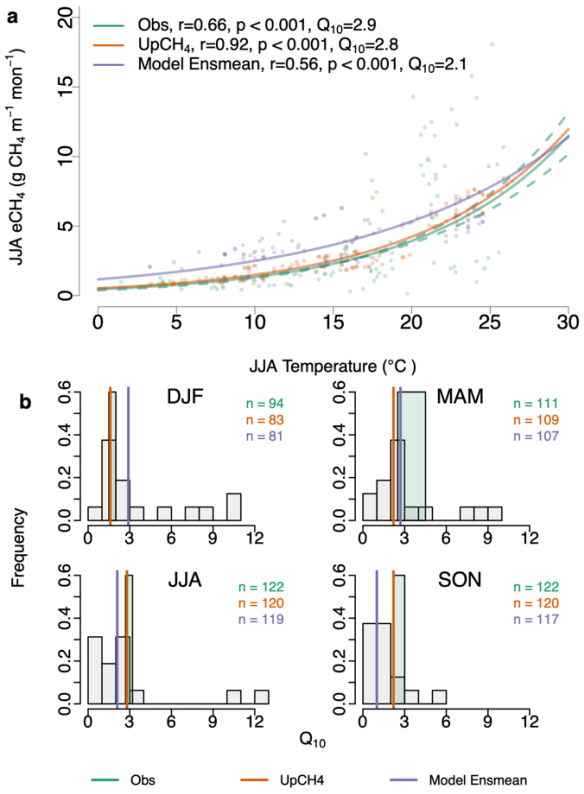

Figure 4. Temperature sensitivity of simulated seasonal eCH_4 across locations of FLUXNET-CH4 sites. a. Model ensemble mean ('Model Ensmean') of simulated eCH_4 against seasonal mean temperature for the JJA season along the temperature gradient at the locations of FLUXNET-CH_4 sites in comparison to the estimates from eddy covariance measurements ('Obs'; Fig. S10; Table S4) and $UpCH_4$. Each dot represents the value at one site for an individual year when observations are available. The unit of the simulated CH_4 emissions is g CH_4 m^{-1} $month^{-1}$ per standard wetland area to exclude the effect of inundation on eCH_4. The exponential fitted curves are shown. b. Histogram of the seasonal Q_{10} for the 16 individual models for the months DJF, MAM, JJA, and SON. Sample sizes are shown in the plot. The Q_{10} values derived from FLUXNET-CH_4, $UpCH_4$, and the model ensemble mean are vertical solid lines, with a width of the bar for 'Obs' indicating the uncertainty range of Q_{10} based on measurement uncertainty.

4 Conclusions

Our results estimated global average wetland CH_4 emissions at 158±24 (mean ± 1σ) Tg CH_4 yr^{-1} for the period 2010-2020, with an average decadal increase of 6-7 Tg CH_4 yr^{-1} compared to the decade of 2000-2009. The increases in the four latitudinal

bands of 90°S-30°S, 30°S- 30°N, 30°N-60°N, and 60°N-90°N were 0.1-0.2 Tg CH_4 yr^{-1}, 3.6-3.7 Tg CH_4 yr^{-1}, 1.8-2.4 Tg CH_4 yr^{-1}, and 0.6-0.8 Tg CH_4 yr^{-1}, respectively, during the two decades. Our analysis reveals how global wetlands respond to variations in the primary climatic controls of temperature, precipitation, and rising CO_2 concentrations. The model average shows good agreement with eddy covariance measurements on temperature dependence, confirming the primary role of temperature in the rising trajectory of eCH_4 at decadal timescales. Furthermore, the modeled ensembles of prognostic wetland extents offer a complementary approach to satellite-based estimates (Prigent et al., 2020; Zhang, et al., 2021a) and enable further investigation into the uncertainties in wetland area estimation. These differences can motivate improvements to inundation schemes through an improved water table position (Chen et al., 2021) and lateral flow representation. Note that a large portion of tropical wetlands comprises inundated floodplains connecting rivers, where the leaching of methane production from wetlands to river networks is not accounted for in the wetland models. The prognostic models estimate an annual mean maximum wetland area of 8.0±2.0 Mkm^2, with a seasonal cycle (annual maximum minus annual minimum) of 4.7±2.0 Mkm^2. Resolving the large uncertainty in wetland areas and seasonal variation remains a high priority to refine bottom-up estimates of eCH_4. Lastly, our results highlight the important but highly uncertain CO_2 fertilization effect on eCH_4. The mean sensitivity coefficient β and results from the factorial experiment suggest a net increase of eCH_4 of 0.1%-2.3% relative to the annual total under an average ~20 ppm increase in atmospheric CO_2 concentration. In comparison, a synthesis study based on field experiments (van Groenigen et al., 2011) shows a narrower range of 0.3%-0.6% average increase for every 20 ppm increase, assuming a linear fertilization effect between CO_2 concentration and eCH_4.

Our results show that an ensemble of process-based wetland methane models provides quantification for uncertainty in eCH_4, as well as better constraints than a single model on the predicted trend and magnitude of eCH_4. However, nominally distinct models might have similar biases because of similarities in the way they represent a subset of processes (see Table S1 for the model summary). Future evaluation of modeled processes, such as oxidation, production, and transport pathways, along with model error across different time scales using statistical tools could help identify similarities in model behaviors to guide model development (Zhang, 2023b). Furthermore, the eCH_4 estimates are subject to forcing uncertainty, given that the two climate datasets applied in the simulation protocol do not cover the full magnitude and variability of climatic variables. Specifically, precipitation has a significant impact on wetland extent and anaerobic soil conditions but has large uncertainty in spatiotemporal patterns (Sun et al., 2018). Thus, we recommend future ensemble simulations consider the uncertainty in climate variables among different datasets. In addition, the sensitivity parameters derived from the multiple regression are not independent of climate datasets. Thus, they are affected by the choice of meteorological drivers. Overall, quantitatively accounting for model performance and dependence and thoroughly evaluating the effectiveness (Chang et al., 2023) could improve the wetland model ensemble estimation in future studies.

Code and data availability

The code for the wetland models is available upon request from the respective model groups. The wetland ensemble results is publicly available at the Zenodo Repository 10.5281/zenodo.11309188. The wetland estimates from individual models are available upon request from respective model groups. The FLUXNET-CH_4 dataset is publicly available at the link: https://fluxnet.org/data/fluxnet-ch4-community-product/. The UpCH_4 dataset can be found at the link in McNicol et al., (2023).

Author contribution

BP and ZZ designed the simulation experiment with contributions from JM and WR. ZZ conducted data collection and data analysis. JM, WR, GB, PC, NG, PH, AI, AJ, FJ, TK, TL, XL, PM, JM, CP, SP, ZQ, QS, HT, XX, YY, XY, WZ, QZ, QZ, QZ, and ZZ performed the simulations. ZZ prepared the manuscript with contributions from all co-authors.
