Abstract.

Moisture budget assessments from reanalyses and climate models have provided fundamental insights into the maintenance and response to perturbations of the hydrological cycle in the Mediterranean region. Here we perform similar analyses using the latest generation European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis ERA5, and we complement previous work by further decomposing the mean flow into contributions by the zonal-mean flow, which is dominated by the mean meridional circulation, and by zonally anomalous circulations and/or moisture, namely the stationary eddies. According to ERA5, in the annual mean, net evaporation (negative $P - E$) over the ocean and net precipitation (positive $P - E$) over land are primarily due to submonthly transient eddies converging moisture originating from the ocean into the surrounding land. Overall, total stationary eddies reinforce the transient tendency over the ocean but oppose it over land, with the zonal-mean flow exerting a minor drying tendency limited to the region's southernmost latitudes. The divergent total stationary-eddy moisture flux arises from a strongly divergent zonally anomalous circulation acting on the zonal-mean moisture and is opposed by a convergent pure stationary-eddy moisture flux. The relative magnitude of these terms changes over the seasonal cycle, explaining the transition from net precipitation during winter (DJF) to net evaporation during summer (JJA) over land. More specifically, as transient eddies weaken during the warm season, the strengthened divergent total stationary-eddy moisture flux becomes dominant and causes strong drying and negative net precipitation. Somewhat surprisingly, moisture flux divergence by the mean meridional circulation is found to play a minor role in the Mediterranean region across all seasons except autumn (SON).

1 Introduction

The Mediterranean climate is broadly defined as a temperate climate occurring from subtropical to lower middle latitudes characterized by dry, hot summers and moderately wet winters. Regions experiencing this climate type include California and southwestern Australia, as well as the Mediterranean region itself, from which the name for this type of climate originates. In the Mediterranean, midlatitude winter storms provide the moisture flux convergence sustaining the cold-season precipitation. Thanks to the moderate subtropical temperatures, precipitation is primarily in the form of rainfall, except at high elevations over the Alps and other mountain ranges (Şahin et al., 2015).

25 In summer, the region is under the influence of strong subsidence, which gives rise to stable conditions, clear skies, and precipitation minima (D’Agostino and Lionello, 2020). This strong seasonal cycle leads to an imbalance between precipitation and evaporation, with the latter exceeding the former, and a climate that can be categorized as semi-arid (Seager et al., 2014a, b).

The strong seasonality in the hydrological cycle and the resulting water scarcity in all Mediterranean-type climate regions explain the high concern for their water resources (Giorgi and Lionello, 2008; Zappa et al., 2015; Seager et al., 2014a). For instance, the climate of the Mediterranean region is distinctively sensitive to the spatial and temporal characteristics of winter storms as they move into the region (Şahin et al., 2015; Lionello and Scarascia, 2018). The quantity and intensity of the unique and irregular pattern of associated winter rainfall (D’Agostino and Lionello, 2020) is significantly influenced by the intensity and position of the North Atlantic storm track and the rapid development of extratropical cyclones across the region (Lionello and Scarascia, 2018; Ukhurebor et al., 2022). Even relatively minor perturbations in the general circulation of the atmosphere, such as shifts in the location of midlatitude storm tracks or subtropical highs, both due to natural variability and anthropogenic climate change, can lead to substantial changes in the Mediterranean climate (Mariotti et al., 2002; Giorgi and Lionello, 2008; D’Agostino et al., 2020). Not surprisingly, many studies have identified the Mediterranean region as a climate-change “hotspot” marked by temperatures increasing faster than the globally averaged temperature and a propensity for increased aridity (Seager et al., 2014a; Byrne and O’Gorman, 2015; Lionello and Scarascia, 2018; D’Agostino and Lionello, 2020).

40 Previous work has leveraged global reanalyses and several diagnostics to understand how the hydrological cycle is maintained both at the global and regional scales. Among those, the atmospheric moisture budget has been particularly powerful, as it has allowed for an understanding of how convergence of moisture flux by atmospheric circulations leads to net precipitation (that is, the difference between precipitation and evaporation, $P - E$) (e.g., Seager et al., 2007; Li et al., 2013; Wills and Schneider, 2015; Şahin et al., 2015; D’Agostino et al., 2020; Minallah and Steiner, 2021). The same budget has also been applied to the decomposition of future precipitation projections within the Coupled Model Intercomparison Project (CMIP) model archives into a more robust and theoretically constrained thermodynamic component and a more uncertain and less understood dynamic component, both at the global and regional scales (e.g., Held and Soden, 2006; Byrne and O’Gorman, 2015; Seager et al., 2010, 2014a, b).

In a seminal contribution to the understanding of the maintenance of the hydrological cycle in the Mediterranean region, Seager et al. (2014a) studied its atmospheric moisture budget within the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim reanalysis and CMIP5 climate model simulations. By decomposing the moisture flux convergence into contributions from the monthly mean flow and from eddying motions, i.e., variations from the temporal monthly mean (see Fig. 4d, 4e, 4f), they showed how convergence by submonthly transient eddies, partially offset by divergence by the time-mean flow, sustains positive net precipitation over land areas in winter (November to April). Şahin et al. (2015) further showed that the transient eddy moisture flux originating from the North Atlantic Ocean sustains wet conditions in western and central Europe in winter. Contrarily, the contribution from transient storms over the Mediterranean basin weakens in summer due to weaker thermal contrasting properties and resulting less-frequent frontal activities.

One thing that appears to be missing in the literature for a more detailed understanding of the Mediterranean hydrological cycle is, however, separating the time mean into contributions from the time- and zonal-mean flow (the mean meridional

60 circulation) and from stationary eddies. It is clear that the zonally symmetric mean-flow moisture flux in lower latitudes is associated with subsidence within the descending branch of the Hadley cell (Held and Soden, 2006; Byrne and O’Gorman, 2015; Wills and Schneider, 2015; D’Agostino and Lionello, 2020). However, the extent to which the subsidence over the Mediterranean region is linked to the zonal-mean circulation in both annual and seasonal means remains somewhat unclear. Variations about the zonal mean due to surface forcing or stationary eddies are expected to make a significant contribution to the spatial variability in the moisture flux and its convergence (Chen and Bordoni, 2014; Wills and Schneider, 2015; Wills et al., 2016), as it is well known that orography and land-sea heating contrast are major factors that force extratropical stationary waves (Held et al., 2002; Wills and Schneider, 2015). Orographically forced stationary waves can lead to low-level divergence and the formation of subtropical midlatitude dry zones, as well as low-level stationary-eddy mass convergence associated with wet zones (Broccoli and Manabe, 1992). Specific to the Mediterranean region, enhanced summer subsidence has been related to a forced response to Asian monsoon heating, amplified by topography in the Middle East (Rodwell and Hoskins, 1996, 2001; Simpson et al., 2015).

Several studies have exposed and quantified the impact of low-frequency stationary waves on both regional and global hydroclimate variability. For instance, Chen and Bordoni (2014) used observations and general circulation model (GCM) simulations to explore the influence of the Tibetan Plateau on the East Asian Summer Monsoon, a quasi-stationary subtropical rainfall band, by analysing and decomposing the moisture and moist static energy budgets into zonal-mean, stationary, and transient eddy contributions. Wills and Schneider (2015) used reanalysis data to understand spatial variations in global net precipitation via decomposition of the atmospheric moisture budget into the zonal mean, which accounts for 40% of the spatial variability in global $P - E$, and variations about the zonal-mean hydrological cycle, which explains the remaining 60%.

In this paper, we aim to fill the existing knowledge gap. More specifically, we examine the maintenance of the hydrological cycle in the Mediterranean using the 5th and latest generation ECMWF reanalysis (ERA5). Specific goals are: (1) to expose any climatological trends that might be present in the ERA5 dataset; (2) to assess the contribution of mean flow, transient, and stationary eddies to the maintenance of net precipitation in the annual and seasonal means over land and sea within the broad Mediterranean region.

The paper is organized as follows: We first describe data and methods in Section 2.1, with details on the moisture budget decomposition in Section 2.2 and moisture budget global and regional closure in Section 2.3. Results of our analyses for the annual and seasonal means are discussed in Sections 3.1 and 3.2, respectively. We summarize our results in Section 4 with some discussion of their relevance to future studies on climate change in the Mediterranean.

2 Data and Methods

2.1 ERA5

90 The atmospheric moisture budget of the Mediterranean region is studied using the atmospheric ERA5 reanalysis dataset, which currently covers the time period from 1940 to present. The ERA5 atmospheric archive provides global data that have been regridded to a reduced Gaussian grid with a horizontal resolution of $0.25^\circ \times 0.25^\circ$ ($\sim 27 - 28$ km), at 1-hourly temporal

resolution, and on 137 vertical levels up to the 0.01 hPa pressure level (Hersbach et al., 2020; Mayer et al., 2021). In this study, we use monthly averaged data on 37 uneven pressure levels as well as column-integrated mass-consistent atmospheric energy and moisture budget monthly data derived from 1-hourly ERA5 reanalysis data (Copernicus Climate Change Service, 2022) from 1979 to present archived by the [Copernicus Climate Data Store \(CDS\)](#). ERA5 publishes vertically integrated eastward and northward moisture fluxes as well as the divergence of the vertical integral of water vapor flux that employ mass-consistent horizontal wind fields (Copernicus Climate Change Service, 2022), which is what we employ in this study. It is worth mentioning that ERA5 also publishes moisture fluxes and associated divergence at hourly resolution, but these do not employ mass-consistent horizontal wind fields and are contaminated with numerical noise. While the high-frequency output would allow us to compute explicitly the transient eddy contribution, we decided against using these fluxes because they do not satisfy global properties such as having a zero global mean divergence and are affected by numerical noise (Gutenstein et al., 2021; Mayer et al., 2021).

The moisture budget calculations were done over the 1979 – 2020 time period; different subsets within this period were checked to test the robustness of the results. The primary objective of this study is to understand the role of moisture transport by stationary eddies and synoptic-scale eddies over a broad region of considerable orographic complexity, encompassing the Mediterranean Sea and adjacent land (roughly from -10°E to 40°E and from 30°N to 50°N). Notice how this includes regions not traditionally identified as belonging to the Mediterranean, but the focus on this broader box allows for the analysis of larger-scale patterns and possibly distinct behaviors of the Mediterranean with respect to other neighbouring areas. To eliminate noise on small spatial scales, monthly ERA5 data with the original resolution of $0.25^{\circ} \times 0.25^{\circ}$ were regridded to $1^{\circ} \times 1^{\circ}$ spatial resolution.

2.2 Atmospheric Moisture Budget Decomposition

We analyse the moisture budget of the Mediterranean region to evaluate the contributions from the mean flow, transient, and stationary eddies in the maintenance of the observed climatological net precipitation patterns in the annual and seasonal means over land and ocean. ERA5 provides data on pressure levels, and thus we study the budget in pressure coordinates. Given that P and E are the only fundamental sink and source of water vapor in an atmospheric column, (e.g., Wills and Schneider, 2015), under steady state, their difference must be equal to the convergence of water vapor flux (Trenberth et al., 2007):

$$P - E = -\nabla \cdot \langle \mathbf{u}q \rangle \quad (1)$$

where

$$\langle \cdot \rangle = \int_0^{P_s} \cdot \frac{dp}{g} \quad (2)$$

where $\langle \cdot \rangle$ represents a mass-weighted vertical integral, ∇ is the nabla operator on a sphere, \mathbf{u} is the horizontal wind vector, q is the specific humidity, P_s is the surface pressure and g is the gravitational acceleration. In this study, eleven pressure levels (1000 950 900 850 750 650 500 300 200 100 50 hPa) were used for the vertical integration.

Following previous studies (Seager et al., 2010; Wills and Schneider, 2015; D'Agostino and Lionello, 2020), we use
 125 Reynolds' decomposition to decompose fields into contributions from the time mean (with monthly averages shown by over-
 bars) and contributions from the transient eddies (shown by prime), such that $(\cdot) = \overline{(\cdot)} + (\cdot)'$. Further averaging in time, Eq. 1
 becomes:

$$\overline{P} - \overline{E} = -\nabla \cdot \langle \overline{\mathbf{u}} \overline{q} + \overline{\mathbf{u}'q'} \rangle \quad (3)$$

Here, the first term on the right is the moisture flux convergence (*MFC*) by the mean-flow contribution, and the second term
 130 is the MFC by the transient eddies. Climatological annual and seasonal averages of all terms are then computed and shown in
 Section 3.

We are interested in further decomposing the budget into zonal mean (shown by brackets) and variations from the zonal
 mean that represent the stationary components (shown by stars), such that $\overline{(\cdot)} = \overline{[\cdot]} + \overline{(\cdot)^*}$. With this further decomposition,
 the budget becomes:

$$135 \quad \overline{P} - \overline{E} = -\nabla \cdot \langle \overline{[\mathbf{u}][q]} \rangle - \nabla \cdot \langle \overline{\mathbf{u}^*q^*} + \overline{[\mathbf{u}]q^*} + \overline{\mathbf{u}^*[q]} \rangle - \nabla \cdot \langle \overline{\mathbf{u}'q'} \rangle \quad (4)$$

where

$$\overline{\mathbf{u}^*q^*} + \overline{[\mathbf{u}]q^*} + \overline{\mathbf{u}^*[q]} \equiv \overline{\mathbf{u}^\dagger q^\dagger} \quad (5)$$

In Eq. 4, the first term on the right is the MFC by the zonal-mean circulation, and the second term on the right is the total
 140 *MFC* by stationary eddies $\overline{\mathbf{u}^\dagger q^\dagger}$ (Eq. 5). Only the first of the three terms on the left hand side of Eq. 5 represents the contribu-
 tion from the classical (pure) stationary-eddy flux, $\overline{\mathbf{u}^*q^*}$, to the total *MFC*, which includes correlations of zonally anomalous
 circulations $\overline{\mathbf{u}^*}$ and zonally anomalous moisture $\overline{q^*}$. The other two terms are the cross terms, which capture interactions of
 stationary eddies with zonal means. Note how only the pure stationary-eddy term survives if one considers the global zonal
 mean (i.e., $\overline{[\mathbf{u}^*q^*]} \equiv \overline{[\mathbf{u}^\dagger q^\dagger]}$). While not contributing to the global zonal mean, the cross terms have, however, been shown to be
 very important at the regional scale (Kaspi and Schneider, 2013; Wills and Schneider, 2015).

145 Several studies have pointed out the inevitable introduction of errors in the analyses of the vertically integrated moisture
 budget, which results in possibly non-zero residuals (e.g., Seager and Henderson, 2013; Wills and Schneider, 2015; Minallah
 and Steiner, 2021). Differentiation approximations, spatial and temporal discretization, and vertical interpolation all contribute
 to information loss and errors. For these reasons, we compute all other terms explicitly, but estimate the transient-eddy term
 implicitly as the moisture budget residual, that is:

$$150 \quad \nabla \cdot \langle \overline{\mathbf{u}'q'} \rangle = -(\overline{P} - \overline{E}) - \nabla \cdot \langle \overline{[\mathbf{u}][q]} \rangle - \nabla \cdot \langle \overline{\mathbf{u}^*q^*} + \overline{[\mathbf{u}]q^*} + \overline{\mathbf{u}^*[q]} \rangle \quad (6)$$

It is crucial to note that in our decomposition, following Byrne and O'Gorman (2015), we took the divergences of the vertically
 integrated fields in the zonal and meridional direction rather than vertically integrating the moisture flux divergence fields.
 The latter introduces an extra term related to the surface-pressure gradient that does not appear in our decomposition. This
 approach allows a further breakdown of the mean flow into contributions from moisture convergence and advection. See the

155 proposed methodology in Seager et al. (2010, 2014a, b); Wills and Schneider (2015); D’Agostino and Lionello (2020) for further information. To quantify which components in Eq. 4 have a bigger contribution to the zonal-mean pattern of $P - E$ within the Mediterranean, following Wills and Schneider (2015), we write the zonal sector-mean moisture budget as the:

$$\{\overline{P}\} - \{\overline{E}\} = -\{\nabla \cdot \langle [\bar{\mathbf{u}}][\bar{q}] \rangle\} - \{\nabla \cdot \langle \bar{\mathbf{u}}^{\dagger} \bar{q}^{\dagger} \rangle\} - \{\nabla \cdot \langle \bar{\mathbf{u}}' \bar{q}' \rangle\} \quad (7)$$

where $\{\cdot\}$ denotes an average in longitude over the broad Mediterranean region (that is, from -10°E to 40°E).

160 2.3 Atmospheric Moisture Budget Closure

Before delving into maintenance of the Mediterranean moisture budget, we analyse the closure of the global moisture budget in ERA5, that is, we explore if and to what extent globally averaged P is equal to globally averaged E in the 1979 – 2020 period under consideration. Fig. 1, which shows the evolution of these two quantities averaged globally and annually, reveals a few concerning results. Firstly, globally averaged P always exceeds globally averaged E by an average value of 0.045 mm/day over the 1979 – 2020 period, suggesting there exists an artificial moisture sink in ERA5. Secondly, the imbalance between the two fields does not remain constant over time but decreases significantly after 1995. In particular, while the excess of globally averaged P over globally averaged E is about 0.083 mm/day in the 1979 – 1995 period, it decreases to 0.015 mm/day after 1995. Previously, Mayer et al. (2021) reported analogous results from ERA5, with residual values of about 0.03 mm/day in the 1985 – 2018 period and of about 0.02 mm/day in the 2000 – 2018 period. Similar discontinuities in precipitation from ERA5 and other global reanalyses have been reported in Scoccimarro et al. (2024) and attributed to the progressive addition of satellite data sources (Diniz and Todling, 2020).

While for our purposes a closed moisture budget would be desirable, but not strictly necessary, improvements over time introduce trends in both E and P that appear unrealistic and might not reflect observed changes. Specifically, from the mid-1990s, E increases more drastically than P , and this seems to be the main change that results in a better balance (Hersbach et al., 2020). This highlights how extreme caution should be taken when analysing any trend in quantities related to the ERA5 moisture budget.

If we now consider the moisture budget averaged over the Mediterranean region, $P - E$ is negative on the annual average. This highlights the known characteristics of this basin: the Mediterranean Sea acts as a source of moisture, supporting both local recycling and precipitation over neighboring land regions. A negative MFC (i.e., divergence of moisture flux) must balance the net evaporation (negative $P - E$), which is what we see in Fig. 2. However, as was the case for the global mean, the regional moisture balance is not closed, especially in the first 10 years of the time period under consideration. MFC, with a climatological annual mean value of -0.503 mm/day, exceeds $P - E$, with a climatological annual mean value of -0.367 mm/day. There is a decreasing trend in $P - E$ from 1979 to 2020, which is due to an increasing trend in E and a rather steady P (not shown). Yet, there seems to be no statistically significant trend in MFC. All in all, the budget over the Mediterranean is not strictly closed, and the imbalance is larger over land (Fig. 2b). Mirroring what was seen at the global scale, the closure of the regional moisture budget improves over time, with a decreasing imbalance between $P - E$ and MFC (Fig. 2a).

Figure 1. Temporal evolution of globally and annually averaged P and E in the 1979 – 2020 period.

What can we conclude about hydroclimate changes in the Mediterranean region in the past 40 years, according to ERA5? Can we trust the signal? While it is possible to choose different time windows and find some trends, the “artificial jumps” in global P and E from ERA5 make it difficult to extract any meaningful trends or changes in the hydroclimate, because of remaining inconsistencies in large scale budgets of moisture and energy (Hersbach et al., 2020; Allan et al., 2020; Mayer et al., 2021). We hence caution against the use of ERA5 for trend identification and attribution. However, like other reanalysis products, it remains a very useful tool to study mechanisms responsible for the maintenance of climatic patterns both at the global and regional scales, as we do in this study.

3 Results

3.1 The Annual Mean Mediterranean Moisture Budget

We begin by analysing how the long-term, annually averaged moisture budget over the Mediterranean region is maintained in ERA5 in the zonal sector-mean and we then explore the spatial patterns of all relevant terms. The zonal sector-mean decomposition of the moisture budget, following Eq. 7, in our analysis region is shown in Fig. 3. Similarly to what is seen in the global zonal mean (e.g., Wills and Schneider, 2015), the zonally averaged net precipitation in the Mediterranean region transitions from net evaporation to net precipitation at around 43°N , slightly poleward of the globally zonally averaged value of 37°N (not shown). Transient eddies are primarily responsible for the associated poleward moisture transport by diverging moisture from the lower midlatitudes and converging it to the higher latitudes. Note how the net precipitation minimum at 35°N coincides with the transient-eddy moisture flux divergence maximum around the same latitude band. While smaller in magnitude, total stationary eddies and the mean meridional circulation provide net moisture flux divergence at all latitudes. South of 32°N ,

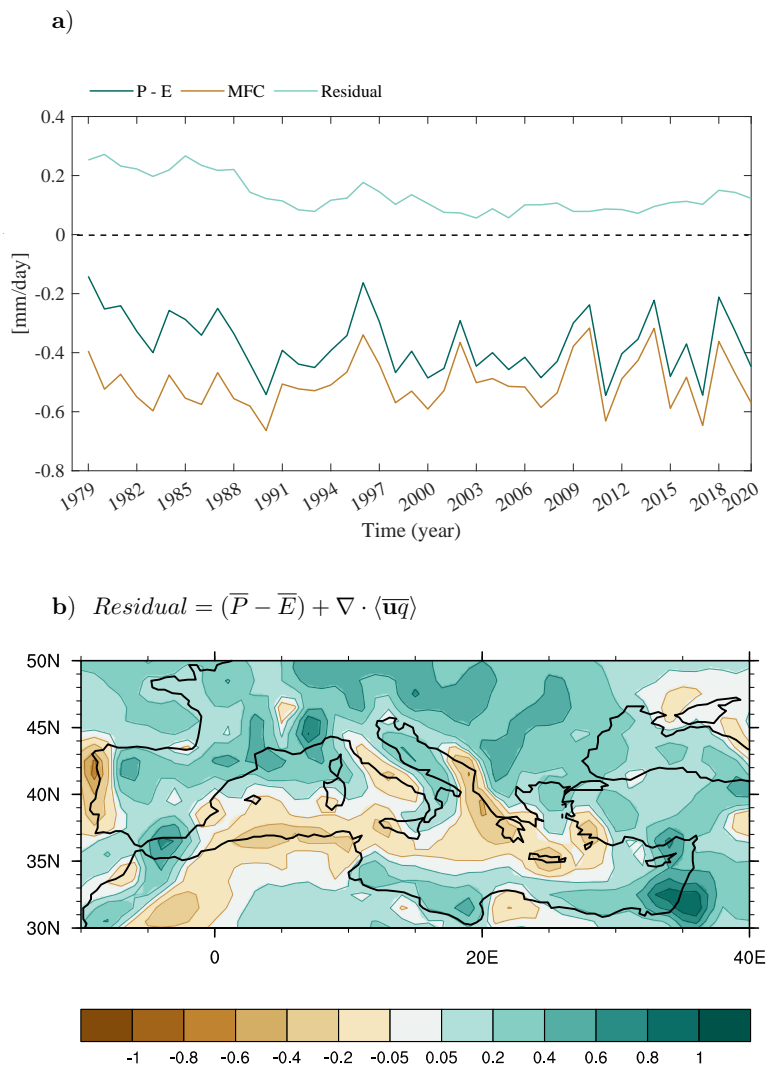

Figure 2. Annual mean moisture budget components in the Mediterranean region from ERA5 in the 1979 – 2020 period: (a) temporal evolution of $P - E$ (green line), total moisture flux convergence (MFC , brown line), and the difference between the two (residual, cyan line), (b) time-averaged spatial variations of the imbalance between $P - E$ and total MFC in millimeters per day.

Figure 3. Sector-mean annually averaged (ANN) components of the Mediterranean moisture budget in the 1979 – 2020 period from ERA5. Each curve is smoothed in latitude using a 3-point running average filter.

205 their combined effect is large enough to more than offset the moisture flux convergence by transient eddies and to maintain net evaporation on the southern edge of the Mediterranean region.

While illustrative of the role that different atmospheric circulations play in meridional moisture transport and the resulting zonally averaged net precipitation patterns, the zonal-mean analysis hides large zonal variability and land-sea contrast and possibly obscures the role of zonally varying circulations in their maintenance. The spatially varying moisture budget and its
210 components are hence shown in Figs. 4 and 5.

All northern Mediterranean land areas, such as the Iberian Peninsula, France, the Alps, the Balkans, and Turkey, have an excess of P over E (Fig. 4c). Annually averaged positive net precipitation is particularly strong in high-topographic regions (the Alps and Balkans). In agreement with previous work, over the Mediterranean Sea, E exceeds P , confirming how this ocean basin acts as an evaporative body for the surrounding land masses. Evaporation appears particularly dominant in the
215 eastern Mediterranean Sea, due to both strong near-surface winds (at 900 hPa) and warm sea surface temperatures (SST s, see Fig. 6). Evidently, the sea is divided into two distinct parts: the northern (western) part with colder SST s, and the southern (eastern) part with warmer SST s.

According to ERA5, positive $P - E$ over all land regions surrounding the Mediterranean Sea, with the exception of northern Africa, is predominantly maintained by the sub-monthly transient-eddy moisture flux that converges over these regions

220 moisture originating from the sea (Fig. 4f). The mean flow partially counteracts the wetting tendency of the transient eddies
over land regions, with the exception of northern Africa, and reinforces it over the ocean, except for the Adriatic Sea (Fig. 4e).
Over northwestern Africa, where the time-mean flow is convergent, the transient eddies are strongly divergent, which points
to the opposing behaviour of the two phenomena leading to negligible net precipitation in the region. This counterbalancing
contribution by the mean flow and transient eddies is consistent with earlier work based on the previous generation of the
225 ECMWF reanalysis, ERA-Interim, (Seager et al., 2014a), giving us confidence in the robustness of our results.

The time-mean moisture flux convergence can be further decomposed into contributions by the zonally averaged circulation
and the stationary eddies. The long-term averaged zonal-mean circulation, dominated by the mean meridional circulation,
results in divergence of moisture from the subtropical southern edge of the Mediterranean region (from 30°N to 36°N, Fig. 4g).
Everywhere else in the region, the contribution by the zonal-mean moisture flux is negligible, revealing how moisture flux and
230 the associated convergence by stationary eddies dominate the time-mean flow, pointing to the immense impact of land-sea
contrast and variations about the zonal mean on the hydrological cycle in the Mediterranean region.

As mentioned before, the total stationary-eddy moisture flux arises from three different components that contain stationary
terms (see Eq. 5). We are particularly interested in knowing which component, if any, contributes the most to the hydrological
cycle of the region. According to ERA5, pure stationary eddies, $-\nabla \cdot \langle \bar{\mathbf{u}}^* \bar{q}^* \rangle$, converge moisture over the Mediterranean land
235 region as well as the sea, except for the southwestern Mediterranean (Algeria) and western Black Sea (see Fig. 5a). The
transport of zonally symmetric moisture by the zonally anomalous circulation, $-\nabla \cdot \langle \bar{\mathbf{u}}^* [\bar{q}] \rangle$, results in moisture divergence
from the Mediterranean region, including the Mediterranean Sea, with the exception of northwest Africa, northern Italy, and
the Adriatic Sea (Fig. 5b). The divergence seems to be the strongest over the eastern Mediterranean, where the zonal variations
in circulation are the largest. These patterns primarily mirror patterns of the zonally anomalous lower-level wind divergence
240 (not shown).

The transport of zonally anomalous moisture by the zonally symmetric circulation, $-\nabla \cdot \langle [\bar{\mathbf{u}}] \bar{q}^* \rangle$, yields a different result:
convergence of moisture over the Mediterranean Sea, northern Africa, and western Black Sea, and divergence over the western
Mediterranean (i.e., the Iberian Peninsula, Morocco, etc.), Corsica, the Tyrrhenian Sea, and Turkey (Fig. 5c).

In sum, the total stationary-eddy moisture flux arises firstly from a strongly divergent zonally anomalous circulation and
245 secondly from pure stationary eddy moisture flux convergence (see Fig. 3). The contribution from the zonally-anomalous
atmospheric water vapor to the hydrological cycle of the Mediterranean region, though convergent, plays a smaller role than
the other two components.

3.2 Seasonal Cycle

We analyse the seasonality of the hydroclimate in the Mediterranean region using four seasons expressed as DJF (December
250 to February), MAM (March to May), JJA (Jun to August), and SON (September to November). Here we focus primarily on
the solstice seasons, DJF and JJA, both showing zonal averages in the Mediterranean sector (Figs. 7) and spatial patterns of all
relevant terms (Fig. 8 for DJF and Fig. 9 in JJA). Interested readers can find similar analyses for the shoulder MAM and SON
seasons in Appendix A.

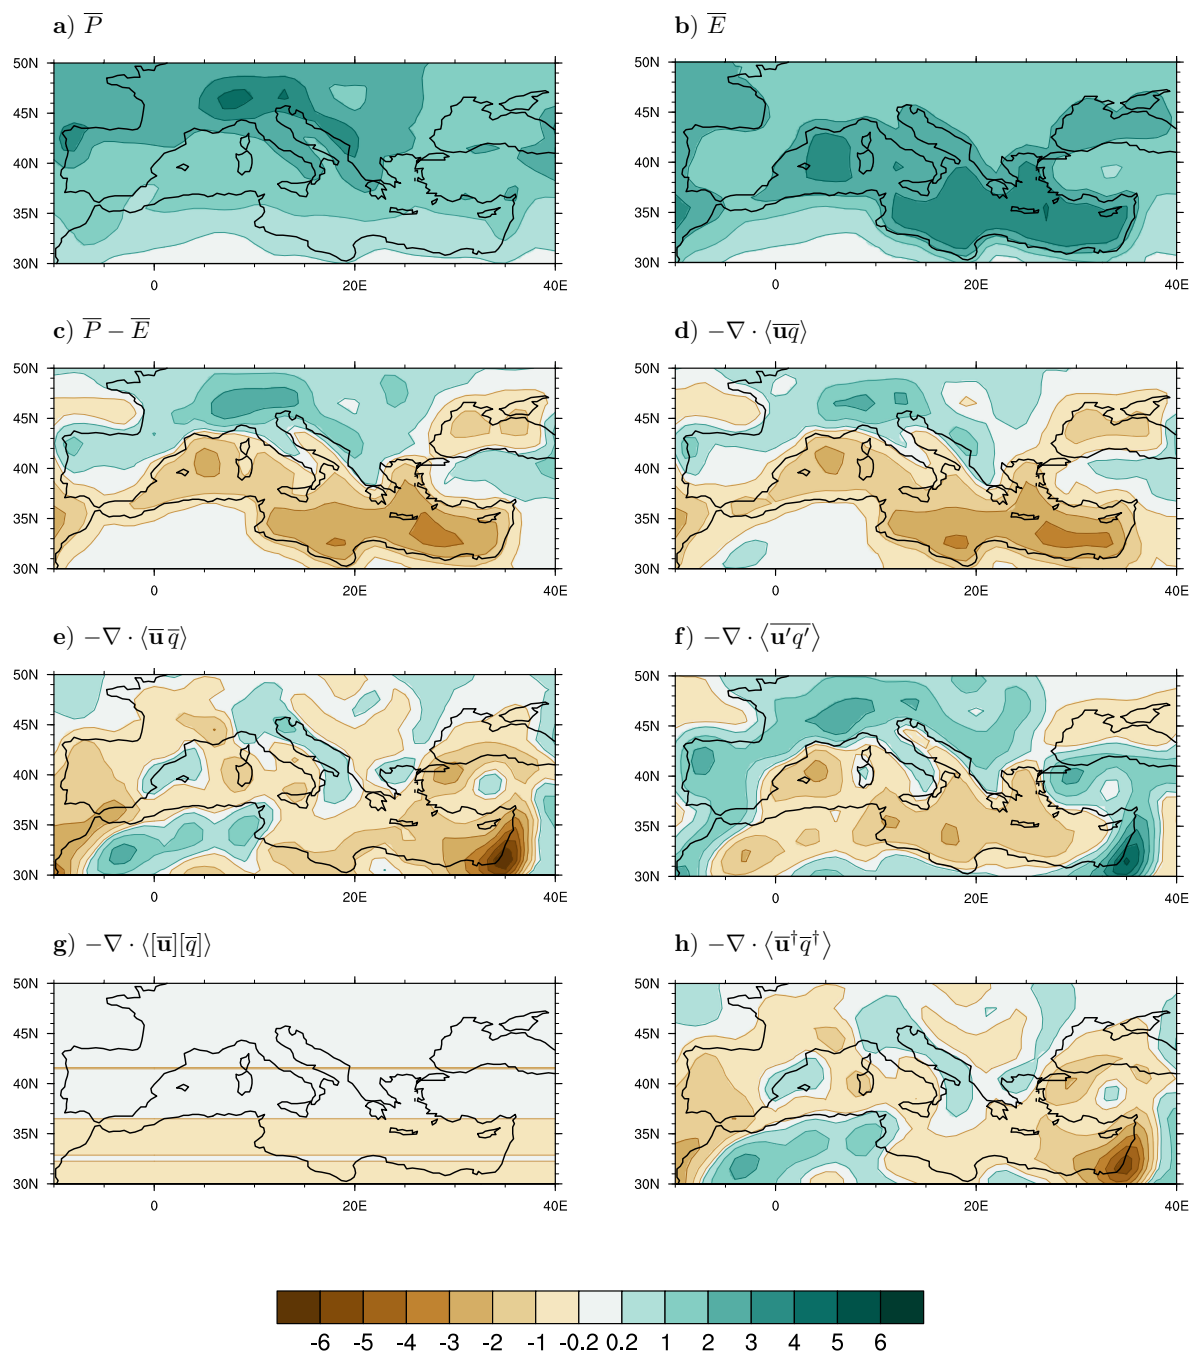

Figure 4. Annual mean climatological Mediterranean moisture budget in the 1979 – 2020 period from ERA5: (a) P , (b) E , (c) $P - E$, (d) total MFC , and contributions by the (e) monthly mean flow, (f) transient eddies, (g) zonal-mean circulation, and (h) total stationary eddies. All fields are smoothed using a 3×3 point smoothing filter. Units are in millimeters per day.

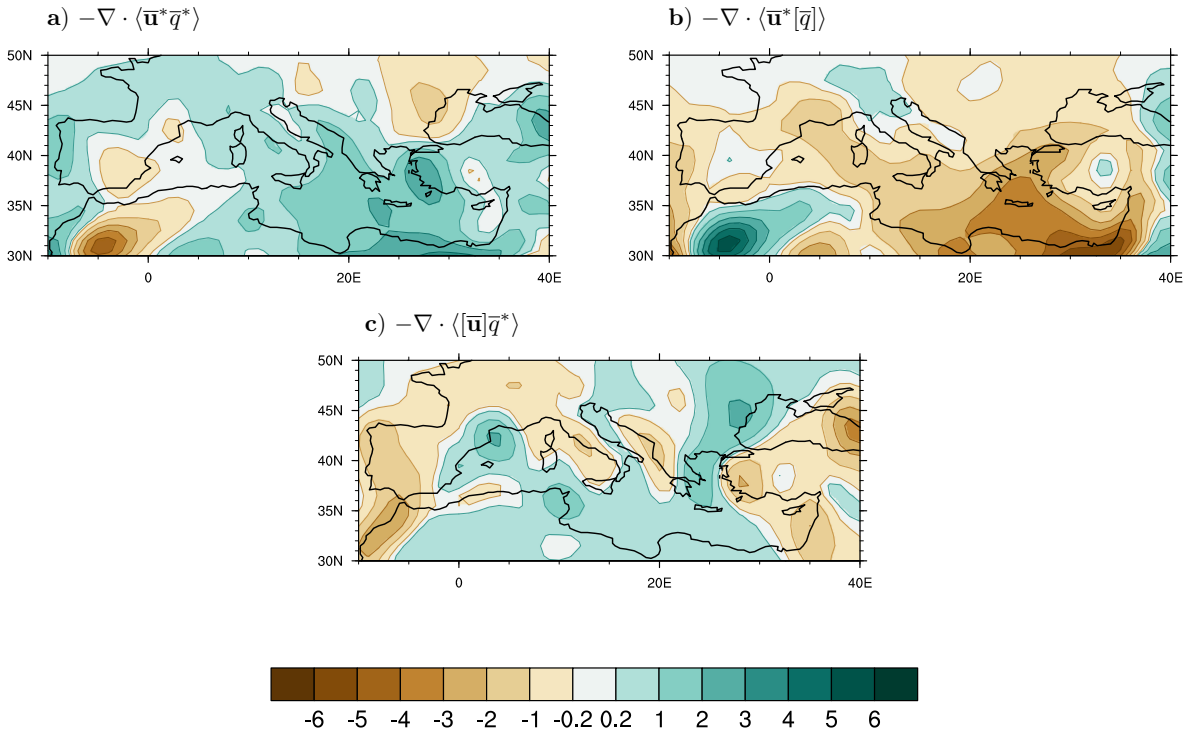

Figure 5. Contributions to the annual mean climatological $P - E$ within the Mediterranean region in the 1979 – 2020 period from ERA5: (a) pure stationary eddies, (b) zonally anomalous circulation, and (c) zonally anomalous water vapor. Units are millimeters per day. All fields are smoothed using a 3×3 point smoothing filter. Units are in millimeters per day.

According to Fig. 7a, the dominant term in the maintenance of the sector-mean Mediterranean hydroclimate, $\{\bar{P}\} - \{\bar{E}\}$, during DJF is the convergent transient storm systems, $-\{\nabla \cdot \langle \bar{\mathbf{u}}' \bar{q}' \rangle\}$. In this season, the divergent zonally-anomalous circulation term, $-\{\nabla \cdot \langle \bar{\mathbf{u}}^* [\bar{q}] \rangle\}$ is opposed by the convergent pure stationary eddies, $-\{\nabla \cdot \langle \bar{\mathbf{u}}^* \bar{q}^* \rangle\}$, and the zonally anomalous water vapor term, $-\{\nabla \cdot \langle [\bar{\mathbf{u}}] \bar{q}^* \rangle\}$. The total stationary-eddy term, $-\{\nabla \cdot \langle \bar{\mathbf{u}}^\dagger \bar{q}^\dagger \rangle\}$, therefore, has very little impact in the zonal-mean hydrological cycle during this season due to the opposing behaviours of the three contributing stationary-eddy terms.

In summer (Fig. 7b), the divergent zonally anomalous circulation term dominates the budget and more than counterbalances the convergent pure stationary eddies, leading to negative $\{\bar{P}\} - \{\bar{E}\}$ in the region. Note how this term is four times as strong in JJA than in DJF (note the different x-axis ranges in Fig. 7a, 7b and Fig. A3). Interestingly, the divergent zonal-mean flow, $-\{\nabla \cdot \langle [\bar{\mathbf{u}}] \bar{q} \rangle\}$, plays a secondary role during both DJF and JJA. Nevertheless, compared to JJA, this term causes a slightly larger drying tendency in the southern Mediterranean region during DJF.

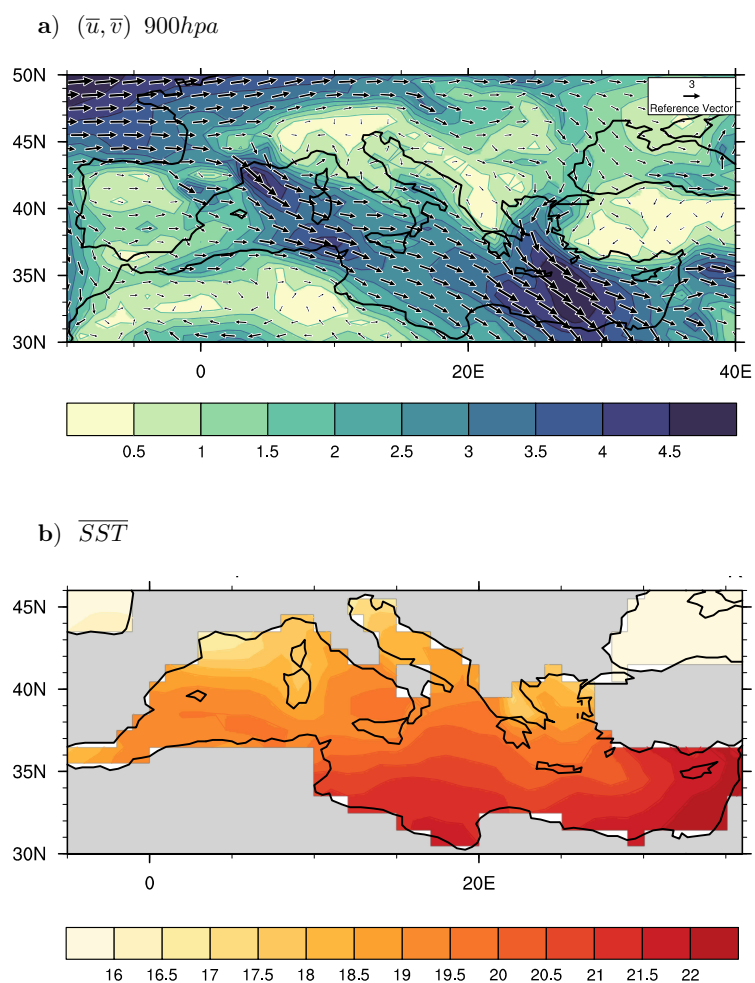

Figure 6. The climatological annual mean (a) horizontal winds at 900 hPa in meters per second, and (b) SST in degrees Celsius, in the 1979 – 2020 period from ERA5.

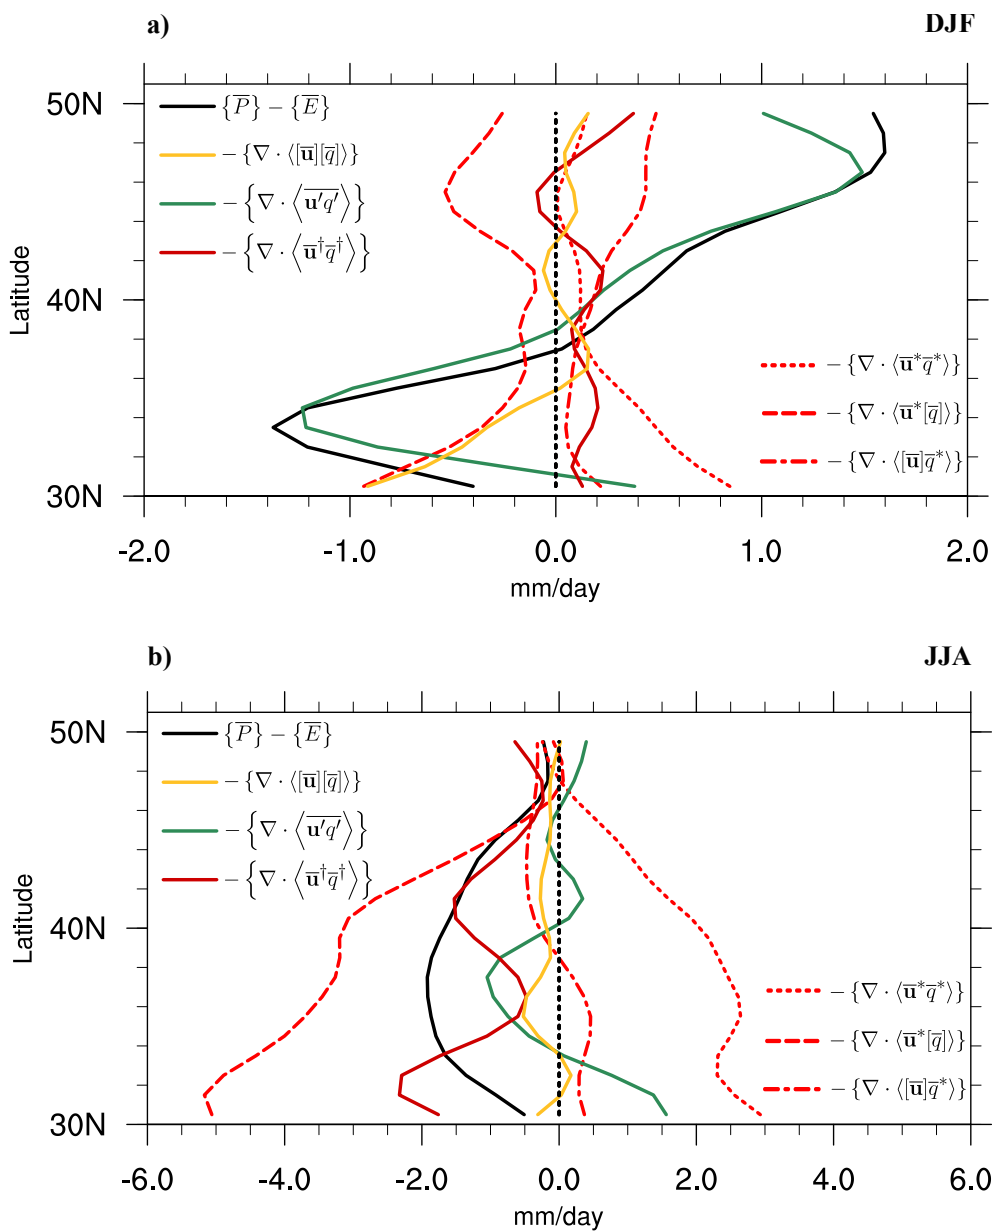

Figure 7. Sector-mean components of the Mediterranean moisture budget in the 1979 – 2020 period from ERA5 during (a) DJF and (b) JJA. Each curve is smoothed in latitude using a 3-point running average filter. Note the difference in the x-axes.

The spatial variations of the Mediterranean moisture budget and its components in DJF and JJA are shown in Fig. 8 and Fig. 9, respectively, which clearly highlight the strong seasonal signal, by which the net flux of fresh water (i.e., $P - E$, panels a) is the most positive during DJF and the most negative during JJA. According to ERA5, and in agreement with previous work, the transient eddies provide the moisture flux convergence needed to balance the positive $P - E$ over all Mediterranean land regions during winter (Fig. 8d). It can be seen that the Mediterranean region experiences a strong land-sea contrast due to transient winter storms, with wet conditions over land and dry conditions over the sea itself. During summer, the signal appears more varied, with transient eddies contributing to moisture flux divergence over the Mediterranean Sea and certain land regions such as northwestern Africa, northern Italy and southern Turkey, and contributing to moisture flux convergence in other regions such as northern land regions surrounding the sea and northern Turkey. (Fig. 9d).

The zonal-mean flow leads to subsidence and minor moisture divergence in the Mediterranean during both seasons: in DJF, it is the southern Mediterranean that undergoes mild divergence (Fig. 8c), while during JJA, it is the central and northern Mediterranean that undergo mild moisture divergence and drying (Fig. 9c).

Finally, focusing on the contributions by stationary eddies, we see how the total stationary eddies are generally weaker during DJF than JJA, when in fact, all the terms involving stationary eddies are very pronounced (Fig. 9f, 9g, 9h). During JJA, the total stationary-eddy moisture flux causes intense drying in the Mediterranean, except in northwest Africa, the Alps, and a region extending from eastern Spain to western south France (Fig. 9e). Transports of zonal-mean moisture by the zonally anomalous circulation and by the pure-stationary eddies have larger magnitudes than the term related to zonally anomalous moisture (Fig. 9f, 9g, 9h), with mostly opposing tendencies: while the zonally anomalous circulation strongly diverges moisture away from the region, except for northwest Africa, the Iberian Peninsula and the Alps (Fig. 9g), the pure stationary-eddy moisture flux mediates the resulting dry climatic conditions through moisture convergence over the region, except northwest Africa (Fig. 9f). Northwest Africa appears to be an exception in both cases: the moisture flux convergence by the zonally-anomalous circulation is offset by the divergent pure stationary eddies.

4 Conclusion and Discussion

We investigated the maintenance of the atmospheric branch of the Mediterranean hydrological cycle within the ERA5 reanalysis via extended decomposition of the atmospheric moisture budget into contributions from the mean meridional circulation, stationary and transient eddies.

Starting from analysing the closure of the global moisture budget, we conclude that the global budget, averaged over land and ocean, is not closed. P consistently exceeds E , indicating that there is an artificial sink of moisture in ERA5. From the mid-1990s, the imbalance between the two fields is reduced, but this introduces unrealistic jumps in P and E , making it difficult to utilize this data for trend analyses and hydroclimate change studies. Hence, we recommend extra caution when analysing trends in quantities related to the ERA5 moisture budget. In the Mediterranean region, the budget is also not closed, and in fact, the annual mean value of the residual between net precipitation and moisture flux convergence is 0.136 mm per day, but also shows

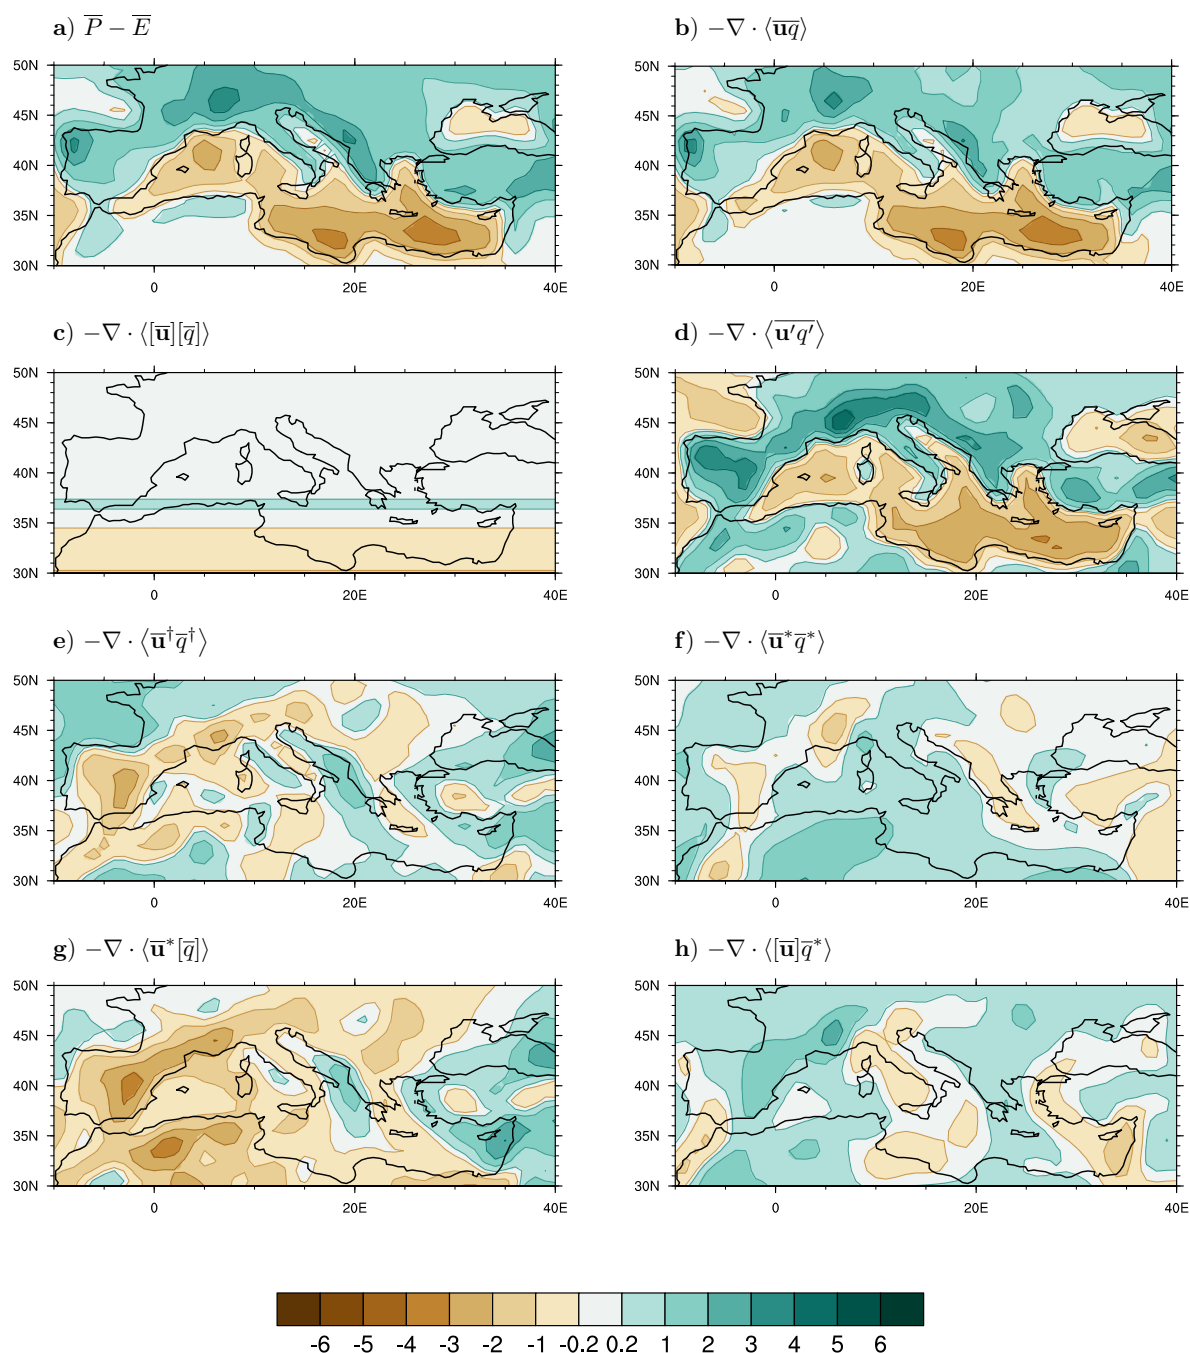

Figure 8. December-February (DJF) climatological Mediterranean moisture budget in the 1979 – 2020 period from ERA5: (a) $P^v E$, and (b) Total MFC , (c) zonal-mean circulation, (d) transient eddies. (e) total stationary eddies and its components due to (f) pure stationary eddies, (g) zonally anomalous circulation, and (h) zonally anomalous moisture. All fields are smoothed using a 3×3 point smoothing filter. Units are in millimeters per day.

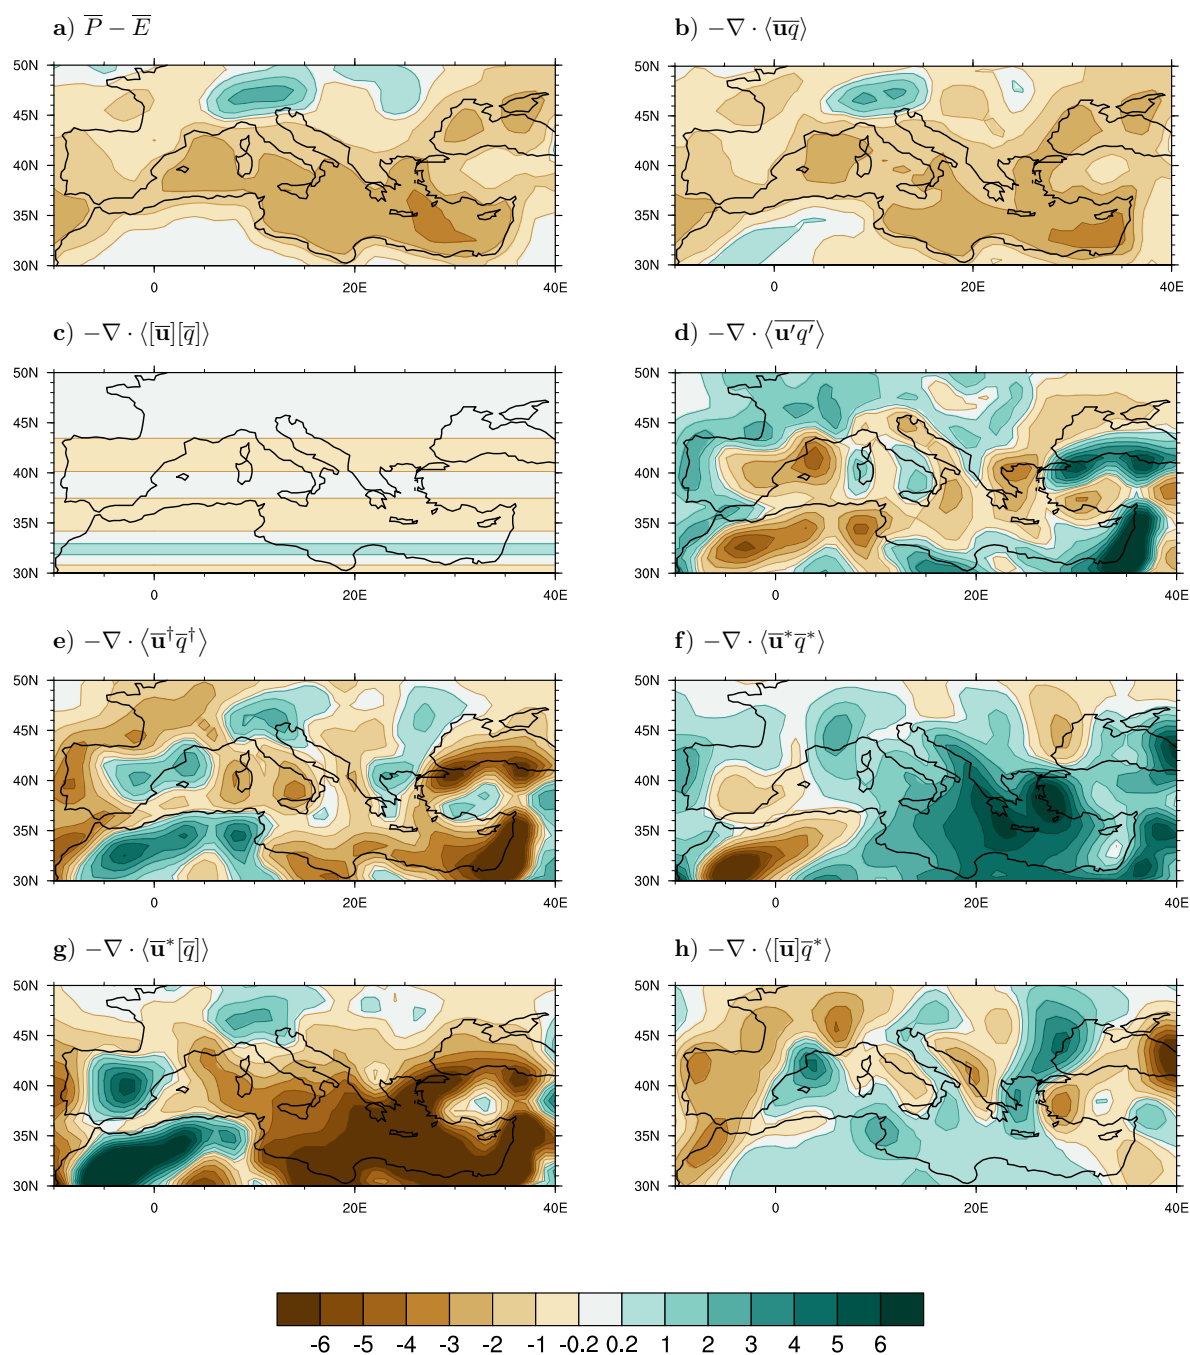

Figure 9. June-August (JJA) climatological Mediterranean moisture budget in the 1979 – 2020 period from ERA5: (a) $P - E$, and (b) Total MFC , (c) zonal-mean circulation, (d) transient eddies. (e) Total stationary eddies and its components due to (f) pure stationary eddies, (g) zonally anomalous circulation, and (h) zonally anomalous moisture. All fields are smoothed using a 3×3 point smoothing filter. Units are in millimeters per day.

an improvement in the most recent decades. While a closed budget would be desirable, it does not prevent the assessment of how different circulations help maintain the net precipitation patterns, which is the goal of the analyses presented here.

Our findings on the maintenance of the hydrological cycle in the Mediterranean region confirm previous work that has shown how, in the long-term annual mean, the transient eddies are the dominant pathway by which moisture originating from the Mediterranean Sea converges over all surrounding land regions, except northwestern Africa. The convergent transient eddies are opposed by the divergent time-mean flow. We further decompose the time-mean flow into contributions from the zonal-mean flow and variations about the zonal mean. According to ERA5, the long-term, annually averaged mean meridional circulation causes mild subsidence and moisture divergence in the southern Mediterranean, but is negligible everywhere else in the region. This highlights how the time mean divergence primarily arises from zonally varying circulations and moisture patterns, and their covariation. Among all stationary eddy terms, the divergence of zonally symmetric moisture by the zonally anomalous circulation is dominant, partly compensated for by the pure stationary eddy term that converges moisture in the region.

In winter, positive net precipitation over land regions is primarily sustained by transient storms, which converge moisture originating from the Mediterranean Sea over the surrounding land masses. Stationary eddies are weaker in this season, and are not large enough to counteract the influence of the transient eddies. In summer, the strengthened divergent stationary eddies dominate the hydrological cycle. This leads to net evaporation over both sea and land in the Mediterranean region, with the exception of the Alps. While pure stationary eddies provide moisture convergence, they are opposed and offset by the divergence of zonally symmetric moisture by the zonally anomalous circulation.

By showing some of the essential features of the Mediterranean hydrological cycle as well as the role of different circulations on the maintenance of $P - E$ within the region in the annual, seasonal, and zonal means, our findings might help shed further light on to future changes in the Mediterranean and the resulting impacts on water resources. In particular, by exposing the explicit role of zonally anomalous circulations, they add one additional piece to the complex puzzle of the hydroclimate change in the region. Expansion of the subtropical dry zones in association with the projected expansion of the Hadley cell and the midlatitude jet (e.g., Lu et al., 2007; Lucas et al., 2014; Grise and Davis, 2020) is often invoked as implicated in the projected increased aridification in the Mediterranean under greenhouse gas forcing, even if mechanisms remain debated (e.g., Staten et al., 2020). The importance of zonally anomalous descent and lower-level diverging wind patterns for the maintenance of the climatological net precipitation patterns emerging from our study, however, suggests that the strength of the response cannot simply be explained in terms of zonally invariant processes and that dynamical changes in stationary eddies might be among the factors making the Mediterranean region a “hot and dry” spot for global climate change. The extent to which the associated dynamics is well captured and projected to change by state-of-the-art climate models will be the topic of future studies.

Appendix A

Contributions from each term to the sector-mean Mediterranean moisture budget in the 1979 – 2020 period during spring (MAM), and autumn (SON) are shown in Fig. A1. During both MAM and SON, the region features positive $\{\bar{P}\} - \{\bar{E}\}$ in its

northern part and negative $\{\bar{P}\} - \{\bar{E}\}$ in its southern part (Fig. A1a, A1b). As shown in section 3.2, the same pattern is also
330 evident for the zonal-mean Mediterranean hydroclimate during DJF (Fig. 7a), in contrast to the widespread negative $\{\bar{P}\} - \{\bar{E}\}$
over all latitudes within the region in summer. During spring, the divergent stationary-eddy moisture flux arises mainly from
the divergence of zonal-mean moisture by the zonally anomalous circulation, which is partially opposed by convergent pure
stationary eddies (Fig. A1a). While having little impact on the zonal-mean hydroclimate of the region, during spring the mean
meridional circulation causes moisture flux divergence (convergence) south (north) of $\sim 36^\circ\text{N}$. During autumn, instead, the
335 mean meridional circulation causes strong subsidence and divergence at all latitudes within the region (Fig. A1b). In both
seasons, the overall $P - E$ patterns are primarily explained by the transient eddies, which converge to higher latitudes moisture
originating from lower latitudes.

The spatial patterns of all terms for MAM and SON are shown in Fig. A2 and Fig. A3, respectively. During spring, the
northern Mediterranean land regions, such as the Alps and the Balkans, experience an excess of P over E (Fig. A2a). According
340 to ERA5, the mean meridional circulation has its weakest contribution to the region's hydroclimate in this season (Fig. A2c).
As seen in winter, overall transient eddies diverge moisture from the sea and converge it over the surrounding land regions,
with the exception of northwestern Africa (Fig. A2d). The total stationary eddies tend to reinforce the transient-eddy tendency
over the sea, but oppose it over land (Fig. A2e), with the largest contribution arising from the zonally anomalous circulation
term (Fig. A2g). Over the Mediterranean Sea, the transports of zonally anomalous moisture by the zonally symmetric flow
345 and by pure stationary eddies cause convergence and wet conditions, which partially oppose the divergence due to the zonally
anomalous circulation (Fig. A2f, A2h).

During autumn, all northern Mediterranean land regions have strong excess of P over E (Fig. A3a). The divergent mean
meridional circulation causes a widespread drying tendency over the central and southern parts of the region, and is at its
strongest (Fig. A3d). The total stationary eddy term is still primarily explained by the zonally anomalous circulation term,
350 but unlike all other seasons, this term causes strong divergence only over the Eastern Mediterranean and in fact results in
moisture convergence over Italy, and the Adriatic and the Tyrrhenian Seas (Fig. A3e). Over the eastern Mediterranean, the
divergent zonally anomalous circulation term is opposed by moisture convergence by the pure stationary-eddy and the zonally
anomalous moisture components (Fig. A3f, A3h).

Code and data availability. ERA5 data are available from the Copernicus Climate Data Store (). Codes developed for the analyses and
355 resulting data are available upon request.

Author contributions. SB conceived this study, RT performed the analyses, RDA provided some of the codes, and all authors discussed the
results. RT and SB wrote the manuscript with helpful feedback from RDA.
