10 Abstract

11 The necessity to reduce carbon emissions to mitigate climate change is accelerating the transition from fossil
12 fuels to renewable energy sources. Specifically, hydropower ~~in particular~~ has emerged as a prominent and safe
13 renewable energy source, but entails reservoir-triggered seismicity (RTS). This phenomenon causes
14 significant challenges for safe reservoir management. Irapé, in Brazil, is a prominent RTS site where
15 seismicity surged after reservoir filling, with a maximum event of magnitude 3.0 in May 2006, just six months
16 after the start of reservoir impoundment. Despite more than a decade has passed since the seismicity occurred,
17 the factors governing these earthquakes and their connection to subsurface rock properties remain poorly
18 understood. Here, we attempt to understand the potential causes of RTS at Irapé dam, which is the highest
19 dam in Brazil with 208 m, and the second highest in South America. Permeability and porosity measurements
20 of cylindrical cores from hard and intact rock samples which have been extracted near the RTS zone, by pitting
21 10 cm from the surface reveal a low-permeability rock. Porosity values range from 6.3 to 14.7%. Only three
22 out of the eleven tested samples present permeability ~~higher than~~ above the lowest measurable value of the
23 apparatus (0.002 mD), with the highest permeability being 0.0098 mD. The undrained response of the low-
24 permeability rock placed below the reservoir results in an instantaneous increase in pore pressure and
25 poroelastic stress changes due to elastic compression, which brings potential faults located below the reservoir
26 closer to failure conditions. According to our analytical calculations, the vertical loading caused by the
27 increase in 136 m of the reservoir-water level caused lead to a ~~0.54–~~ 0.61 MPa pore pressure buildup in
28 response to compression at the depth of the Magnitude 3.0 earthquake, i.e., 3.88 km, resulting in an increase

29 of ~~0.82~~ 0.75 MPa in the vertical effective stress and a ~~decrease~~ of ~~0.34~~ 0.48 MPa in the horizontal effective
30 stress. These changes resulted in an increase in the deviatoric stress that led to fault destabilization, causing
31 the RTS. The laboratory measurements and analytical calculations corroborate the hypothesis that the initial
32 seismic activity was induced by the undrained subsurface response to the reservoir loading at Irapé.

34 **1.Introduction**

35 Reservoir impoundment, deep underground mining, and fluid injection into and withdrawal from the
36 subsurface are some of the well-known causes of induced/triggered seismicity which have become a global
37 issue in the past few decades (McGarr et al., 2002; Foulger et al., 2018; Kivi et al., 2023). The understanding
38 and identification of these types of human-induced earthquakes is crucial in terms of environmental and
39 economic impact, as well as for socio-political and scientific discussion (Gonzalez et al., 2012; Vilarrasa et
40 al., 2019). Recently, the debate over potential induced or triggered nature of cases of felt seismicity has
41 intensified, such as the Oklahoma earthquakes of Mw 5.7 in 2011 and of Mw 5.8 in 2016 (Ellsworth, 2013;
42 Keranen et al., 2013; Yeck et al., 2017), Emilia, Italy, earthquakes of Mw 6.1 and 5.9 in 2012 (Cesca et al.,
43 2013a), Pohang, South Korea, earthquake of Mw 5.5 in 2017 (Grigoli et al., 2018; Kim et al., 2018), Lorca,
44 Spain, earthquake of Mw 5.1 in 2011 (González et al., 2012), and Castor, Spain, earthquake sequence of Mw
45 4.1 in 2013 (Cesca et al., 2014; Vilarrasa et al., 2021; Vilarrasa et al., 2022), to name a few. Apart from the
46 possibility of injuring people and damaging infrastructure, such earthquakes can have a negative public
47 perception leading to project cancellation (Boyet et al., 2023a).

48 The first reservoir-triggered seismicity (RTS) case was observed during the filling of Lake Mead at the
49 Hoover Reservoir (US) in the mid-1930s, with ~M4.0 (Carder 1945). Major worldwide RTS cases were
50 detected in the 1960s, such as the M6.1 Hsinenghiang (China) in 1962, Kariba (Zambia) M6.2 in 1963,
51 Kremasta (Greece) M6.3 in 1966, and Koyna (India) M6.3 in 1967 (Gupta, 2002). To date, over 150 RTS
52 cases have been documented (Wilson et al., 2017; Foulger et al., 2018). Studies to understand the triggering
53 mechanisms of RTS show that pore pressure changes in the order of a few tenth of MPa and the associated

54 poroelastic stress changes are sufficient to reactivate deep faults (Rice and Cleary, 1976; Simpson, 1976; Bell
 55 and Nur, 1978; Talwani and Acree, 1985; Roeloffs, 1988; Simpson et al., 1988).

56 RTS is generally controlled by the stress state, the geological and hydrogeological properties of the region,
 57 and the water-level changes at the reservoir. The perturbation caused by the changes in water-level results in
 58 the loading and/or unloading of the subsurface, which may respond in an undrained or drained way. An
 59 undrained response leads to an instantaneous pore pressure buildup that is proportional to the height of the
 60 reservoir load. In contrast, a drained response leads to pore pressure diffusion into the rock that causes
 61 progressive pore pressure build-up as the pressure front propagates into the rock (Table 1). In general, RTS
 62 magnitudes are smaller for undrained responses than drained ones (Simpson et al., 1988). The interactions and
 63 comprehensive analysis of these two responses are key to [understand the causes of RTS cases and eventually](#)
 64 [improve](#) the forecasting and mitigation of RTS hazard.

65 **Table 1.** The time-distribution types of responses to reservoir-triggered earthquakes (by Simpson, 1988)

Response type	Mechanism	Description	Main features	Cases
Instantaneous response	Instantaneous elastic response and undrained response due to reservoir loading	This type of RTS increases immediately after the initial impoundment of reservoir or changes rapidly after rapid changes in the water level.	Changes in water level have a strong correlation with the change of seismicity, this generally occurs around the reservoir area, and the earthquake magnitude is small, the majority of them are swarm seismicity.	Koyna , Monticello, Manico-3, Nurek, Kariba, Kremesta <i>Irapé (this paper)</i>
Delayed response	Increase of pore pressure caused by pressure diffusion through permeable rock below the reservoir	It is only after a period of reservoir impoundment that the seismicity changes continuously	No significant correlation between changes in water level and seismicity, the time delay is obvious, the magnitude is generally large, and the earthquake occurrence point is not limited.	Koyna, Aswan, Oroville

66
 67 The RTS cases are booming around the world, with Brazil being one of the concerned countries with 29 RTS
 68 cases to date (Sayão et al., 2020). The study of RTS in Brazil started in 1972 with the M3.7 at Carmo do
 69 Cajuru reservoir, southeast Brazil (Foulger et al., 2018). The largest recorded event, a M4.2 in 1974, caused

70 damage to several buildings without any fatalities and was associated with nearby reservoirs at Porto
71 Colombia and Volta Grande, both of which started damming in the early 1970s (Sayão et al., 2020).

72 The Irapé dam, located in the state of Minas Gerais, Brazil, is the highest dam in Brazil with about 208 m,
73 and the second highest in South America (França et al., 2010). The Irapé hydropower plant lies in the vicinity
74 of Jequitinhonha River. Seismicity started to increase immediately after the impoundment of the reservoir and
75 completion of the dam with the maximum event of M3.0 occurred on 14 May 2006, coinciding with the peak
76 water level of the dam. The significant magnitude of the earthquake and the early occurrence after-filling of
77 the reservoir impoundment has raised questions about the triggering mechanisms of this RTS. Understanding
78 these mechanisms is crucial for ensuring the safety of infrastructure around the Irapé reservoir and for the
79 local population.

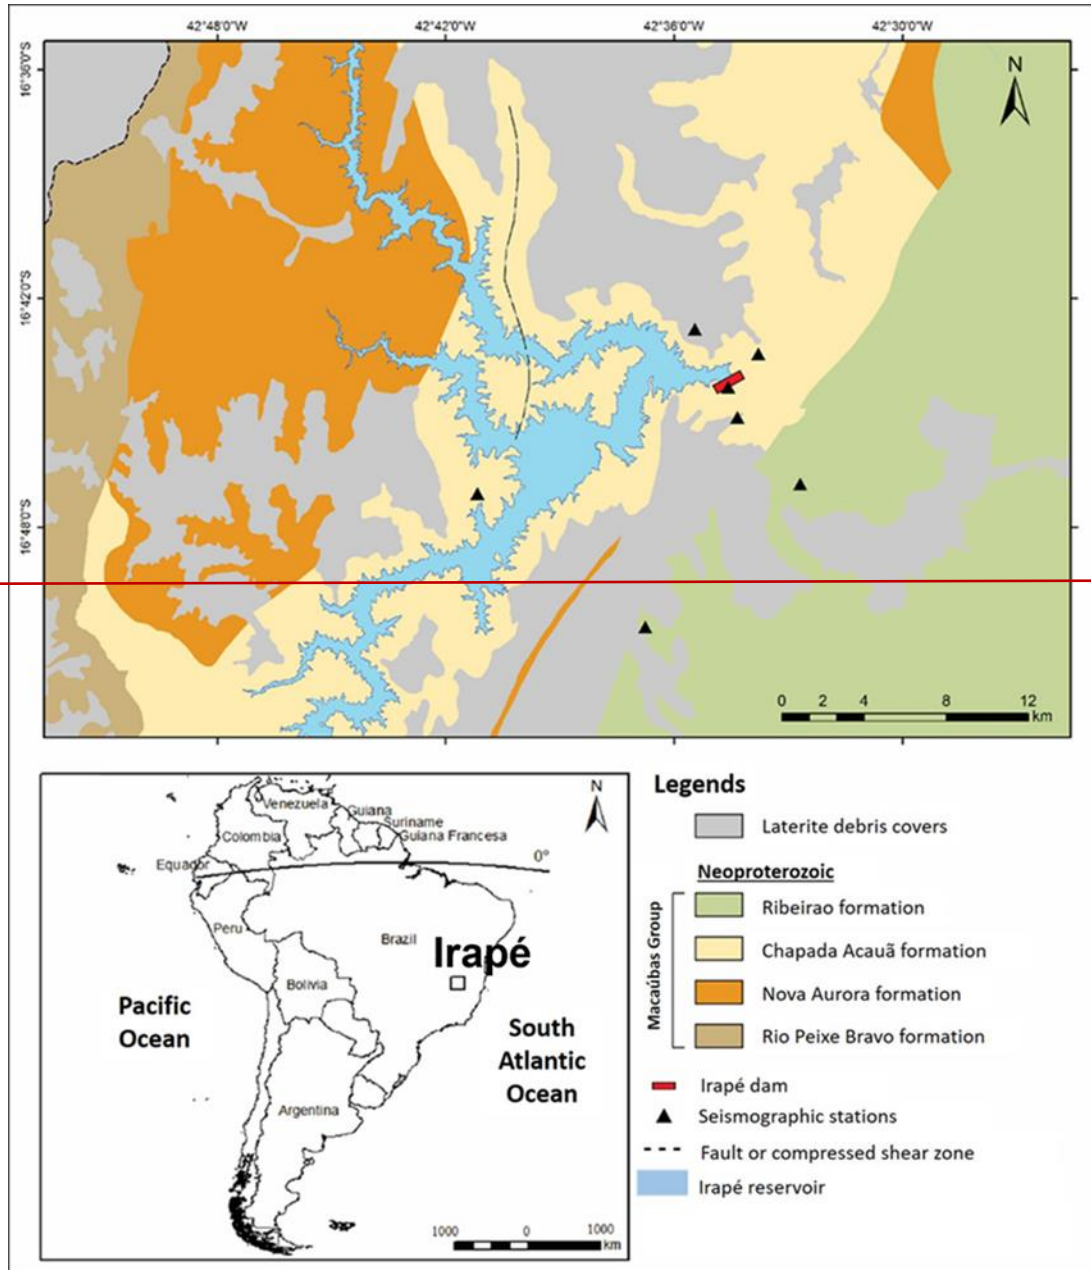

80 In this study, we aim to investigate the potential causes of the main RTS event at Irapé. We initially elaborate
81 on the geological setting and rock characteristics in the vicinity of the reservoir. We explain the characteristics
82 of the RTS at Irapé, including the temporal evolution of the seismicity, which occurred in the short period
83 from December 2005 to May 2006 and the location of the main event based on the local velocity model. Then,
84 we present the performed permeability and porosity tests of cylindrical cores from hard and intact rock
85 samples, which have been extracted near the RTS zone to identify and describe the primary role of porosity
86 and permeability. We perform analytical calculations to estimate [the](#) pore pressure and poroelastic stresses in
87 response to the highest water level of the reservoir filling and the time [it](#) would take for the pore pressure
88 diffusion front to reach the depth of the main event. We present evidence that the cause of RTS at Irapé was
89 the undrained response of the subsurface to reservoir impoundment.

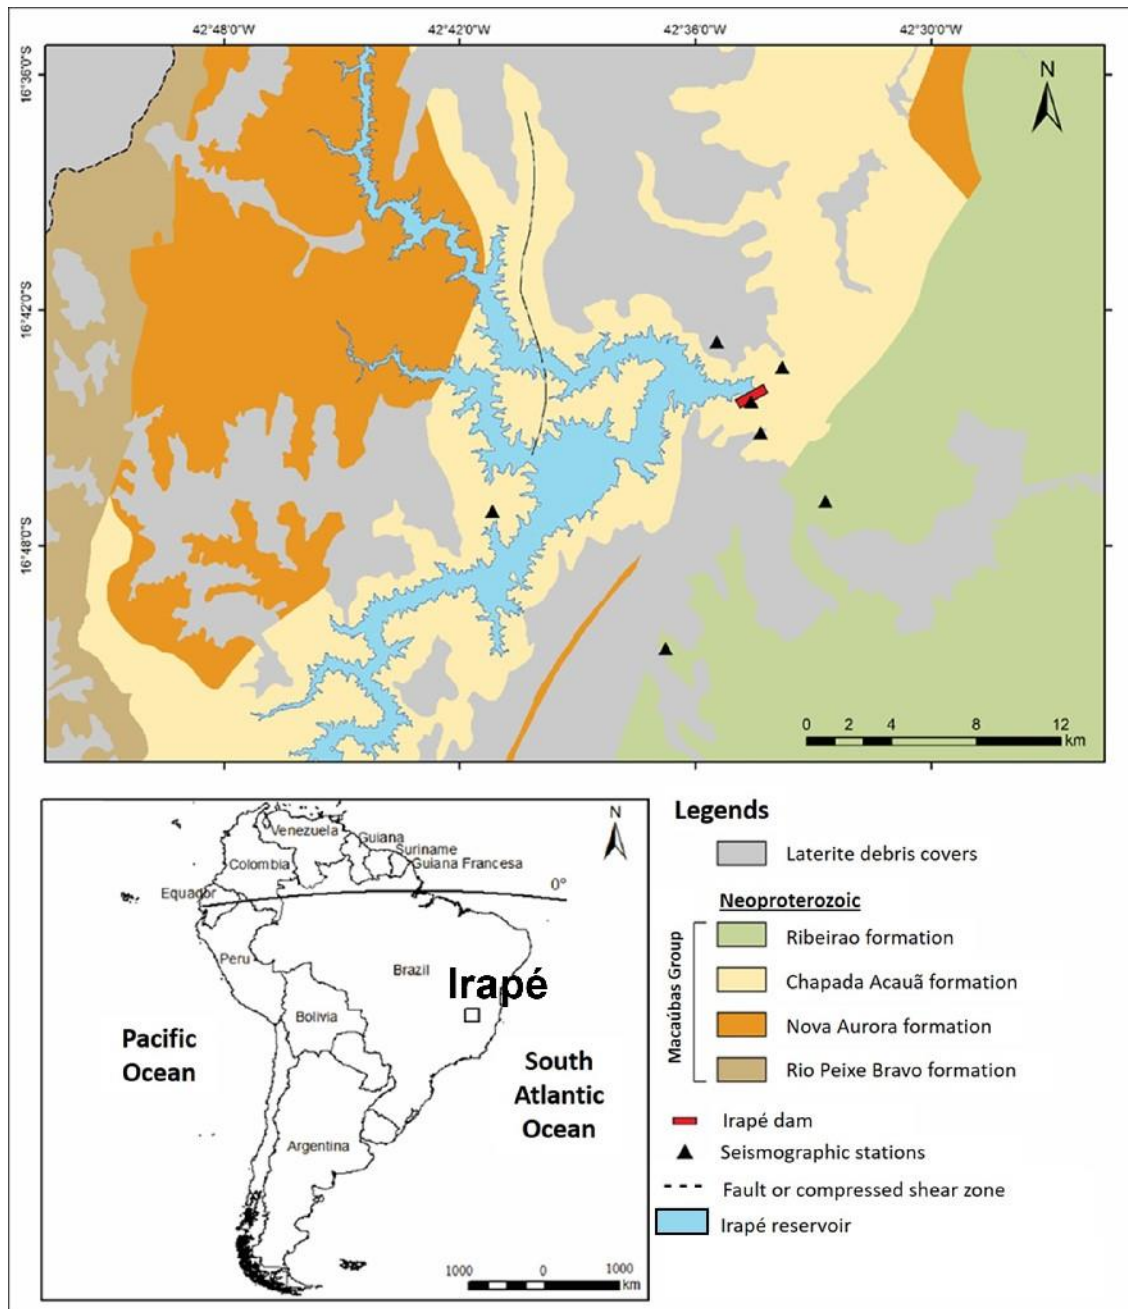

90 **2. Geological setting and RTS at Irapé**

91 **2.1 Geological setting**

92 The area of Irapé is located within the domain of the Pre-Folding Belt Cambrian Araçuaí, which is oriented
93 approximately in a north-south direction and defines the eastern part of the São Francisco Craton in the State
94 of Minas Gerais (Almeida, 1977). Approximately 80% of the reservoir area in Irapé corresponds to the

95 Chapada Acauã Formation. The Chapada Acauã Formation, which has been investigated near the Irapé Shear
96 Zone (Araujo et al., 2010), consists of carbonaceous mica-schist rocks, locally with pyrite, garnet, or graphite
97 (Lima, 2002). This rock is intensely deformed, characterized by the formation and rotation of quartz sub-
98 grains and the migration of grain edges (Araujo et al., 2010). ~~It~~ This formation is characterized by typical
99 passive margin sedimentation and is associated with sediment deposition in the Macaúbas Basin along with
100 the Nova Aurora Formation (Silva et al., 2014). ~~To the east of the Chapada Acauã formation,~~ The Ribeirão da
101 Folha Formation is found to the east of the Chapada Acauã formation, consisting of mica shales, quartzite,
102 and cal-silicates rock (Figure 1).

104

105 **Figure 1.** Geological map of Irapé reservoir and surrounding area

106 **2.2 Background on the reservoir-triggered seismicity at Irapé**

107 The Irapé reservoir covers an area of 137.8 km² with a reservoir volume of 5.964 km³. The dam was
 108 constructed on the Jequitinhonha River, filling the reservoir to a maximum height of 137 meters (Figure 1 and
 109 Table 2). The dam area was monitored by a three-component seismic network at three stations prior to [three](#)

110 3 years of its impoundment, which started on 7 December 2005. These stations did not detect any seismicity
 111 before the impoundment (Chimpliganond et al., 2007).

112 **Table 2.** Characteristics of the main RTS event at Irapé (França et al., 2010)

Dam height (m)	Length (m)	Volume (km ³)	Max. reservoir water depth (m)	Reservoir area (km ²)	Seismicity type	Date	Magnitude (mR)	Io (MMI)	ΔT (yr)
208	540	5.964	137	137.8	Initial	14 May 2006	3.0	III-IV	0.5

113 *ΔT : interval time (years) since the start of filling/impoundment; MMI: modified Mercalli Intensity*
 114 *scale, mR: magnitude Regional.*

115 Microearthquakes started to be detected just one day after the impoundment began, exceeding 300
 116 microearthquakes by October 2006. The largest event occurred on 14 May 2006 with a M3.0 that was felt at
 117 the reservoir area [at a](#) depth of 3.88 km (Chimpliganond et al., 2007; França et al., 2010). The seismicity
 118 occurred within a small area, with epicentres in the lake and its nearby margins (less than 3 km from the
 119 narrow lake), close to the dam axis. [The epicenters are distributed from 0 to 11.4-km depth, showing a](#)
 120 [progressive increase in depth \(see Table S1\).](#) The evident temporal correlation between the start of the
 121 reservoir impoundment and the occurrence of seismicity [leads us to investigate](#) a causative relationship
 122 (Figures 2 and 3). The spatial distribution of the epicentres also suggests the hypothesis that this is another
 123 case of RTS of the initial response type.

124

125

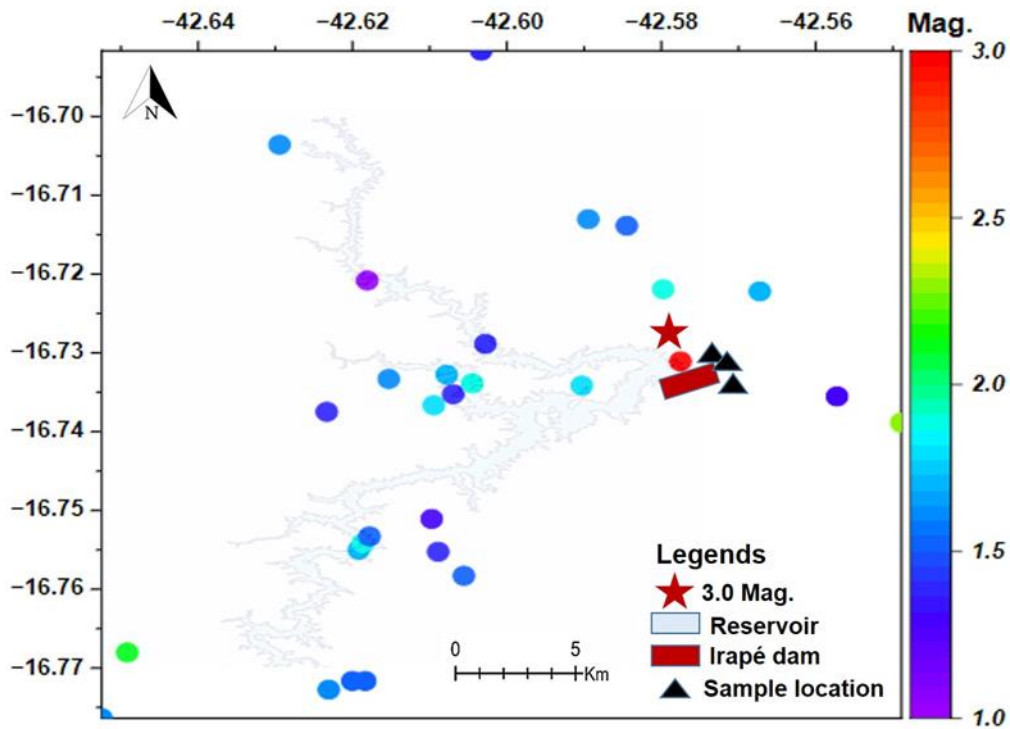

126

127

128 **Figure 2.** Temporal evolution of RTS at Irapé by ten days. Number of events during December 2005 to May
129 2006 (histogram) at Irapé and average water elevation above the mean sea level (blue line) are illustrated. The
130 red star indicates the time when the main and largest event occurred, M3.0 on 14 May 2006 (modified from
131 Silva et al., 2014).

132 The events were analysed using the program Seismic Analysis Code (Goldstein and Snoke, 2005), in which
133 the arrival of the P and S waves and the polarity are considered. The hypocentre location of the events that
134 were recorded by three stations was computed with the program HYPO71 (Lee and Lahr, 1975). The analysis
135 of seismograms went through a double-checks routine (Silva et al., 2014). [The local monitoring station](#)
136 [presented operational challenges, which resulted in positional uncertainty of seismic events \(Silva et al.,](#)
137 [2014\). The velocity model that was used to locate the seismic events was based on a deep seismic refraction](#)
138 [survey in combination with local geological interpretations and studies of the crustal structure in south-eastern](#)
139 [Brazil \(Assumpção et al., 2002b\).](#)

140
141 **Figure 3.** RTS Distribution in the initial period with location and magnitude (see colour scale), the red star is
142 the main event felt near the dam and black triangles denote the samples location.

143 Velocity models were adopted based on a deep seismic refraction survey in combination with local
144 geological interpretations and studies of the crustal structure in south-eastern Brazil to locate seismic events
145 in the Irapé area (Assumpção et al., 2012). The local velocity model consists of a superficial 4.8 km-thick
146 layer with a P-wave velocity (V_p) of 4.5 km/s, representing the mica-schist to graphite-schist rocks from
147 surface, and a second layer from schist to crystalline basement rocks with a thickness of 11.2 km with P-wave
148 velocity (V_p) of 6 km/s (Marshak et al., 2006; Silva et al., 2014).

149 The repetition of a structural trend in the NE-SW direction originates from the geological and geophysical
150 structuring of the crust (Silva et al., 2014). The stress regime in the Irapé region has been estimated to be a
151 normal faulting stress regime. The accuracy of the focal mechanisms remains a subject of debate due to the
152 low quality of the seismic data recorded by analogue seismograms and uncertainties associated with the
153 velocity model. Consequently, the focal mechanisms of the May 14, 2006, M3.0 earthquake have not been
154 resolved yet (Silva et al., 2014).

155 **3. Materials and methodology**

156 We inspected the Irapé site and surrounding areas as well as the outcrops. The dam area is surrounded by
157 mica-schist rock, which is shiny, ranging from blackish to medium grey in colour, with foliated, fine to
158 medium-grained textures. According to the local velocity model, there is a superficial layer that is 4.8-km
159 thick, representing mica-schist to graphite-schist rocks at the surface. Below that, there is a second layer that
160 is 11.2-km thick, consisting of crystalline basement rock. Measurements from these samples are crucial for
161 understanding the estimated permeability beneath the subsurface in the context of the main event, which
162 occurred at a depth of 3.88 km (França et al., 2010). Since the epicenter of the main event was located about
163 1 km away from the dam, we collected bulk rock samples from different locations around the dam, as well as
164 nearby outcrops, by digging pits that were 0.10-m deep.

165 **3.1 Laboratory experiments**

166 We have extracted cylindrical core samples perpendicular to the bedding planes of mica-schist rock. We
167 have performed tests on three sets of samples, with a total of 11 core samples, of hard and intact samples

168 because the rest of the samples were fragile and fractured during the coring from bulk samples (Table 3). The
169 retrieved cylindrical plugs have a length ranging from 3.8 to 5.0 cm and a diameter of 2.50 cm, which meets
170 the International standard criteria (Core Lab) to measure core plug samples by Ultra-Pore 300 and Ultra-Perm
171 610 (Figures 4).

172

173

174 **Figure 4.** The three sets of mica-schist rock samples (1, 2, and 3) after cylindrical coring from bulk samples
175 (\perp coring of cylindrical plugs has been done by loading perpendicular to the bedding planes).

176 We conduct porosity measurements using the Ultra-Pore 300, which is manufactured by Core Lab Instruments
177 in Texas, USA. The Ultra-Pore 300 is a gas expansion helium pycnometer specifically designed for
178 determining the grain volume or pore volume of both core plug and full-diameter samples. To achieve this,

179 we utilized matrix cups designed for samples with diameters ranging from 2.5 to 3.8 cm, equipped with a
180 Setra 204 transducer rated for pressures ranging from 0 to 1.72 MPa. We determined the pore volume using
181 the nitrogen gas (N₂) expansion technique (API,1998; Ceia et al., 2019).

182 We measure the intrinsic permeability of rock samples using Ultra-Perm 610 Permeameter. This precision
183 equipment, which controls backpressure, maintains a constant rate or mean pressure at 0.69 MPa. Before
184 testing, samples are cleaned with soxhlet equipment and toluene, followed by drying in an oven. The
185 permeability measurements included a permeameter, nitrogen source, stopwatch, a core holder, a bubble tube,
186 and a digital calliper. The core holder is pressurized to 3.45 MPa confining pressure using compressed air.
187 The bubbles passing through a burette are timed, and outflow gas volume is recorded. The permeability is
188 calculated using Darcy's law, considering core dimensions. Hard rock core samples, like mica-schist, require
189 long stabilization times due to the low permeability.

190 3.2 Analytical calculations of undrained pore pressure and stress changes

191 Reservoir impoundment causes an undrained effect in the subsurface that manifests as ~~an~~ instantaneous pore
192 pressure and stress changes below the reservoir (Skempton, 1954). The change in the vertical stress, $\Delta\sigma_v$,
193 equals the weight of the water level rise [assuming an extensive reservoir](#). The horizontal stress, assuming
194 [oedometric](#) conditions, changes [because of the increase in the vertical stress and](#) ~~proportionally to the un-~~
195 [drained](#) pore pressure changes as (Rutqvist, 2012)

$$196 \quad \Delta\sigma_h = \alpha \frac{(1-2\nu)}{(1-\nu)} \Delta p, \quad (1)$$

197

$$198 \quad \Delta\sigma_h = \frac{\nu}{(1-\nu)} (\Delta\sigma_v) + \alpha \frac{(1-2\nu)}{(1-\nu)} \Delta p \quad (1)$$

191 where $\Delta\sigma_h$ is the horizontal stress change, α is Biot's coefficient, ν is Poisson's ratio and Δp is the pore
 192 pressure change. Additionally, in an isotropic and homogeneous poroelastic material subject to un-
 193 drained conditions, the change in pore pressure resulting from a change in stress can be computed as
 194 (e.g., Rice and Cleary, 1976; Cocco and Rice, 2002)

$$195 \quad \Delta p = \frac{B}{3} \Delta\sigma_{kk}, \quad (2)$$

196 where $\Delta\sigma_{kk} = \Delta\sigma_v + 2\Delta\sigma_h$, $\Delta\sigma_{kk}$ is the [mean](#) stress change and B is the Skempton's coefficient of
 197 mica-schist rock (Roeloffs, 1988). [Here we adopt the sign criterion of geomechanics, i.e., compressive](#)
 198 [stresses are positive](#). Equations (1) and (2) constitute a system of two equations with two unknowns. Its
 199 resolution yields the undrained pore pressure change as

$$200 \quad \Delta p = \frac{B}{3} \frac{\Delta\sigma_v}{\left(1 - \frac{2B\alpha(1-2\nu)}{3(1-\nu)}\right)}. \quad (3)$$

201

$$202 \quad \Delta p = \frac{B}{3} \frac{(1+\nu)\Delta\sigma_v}{\left(1-\nu - \frac{2B}{3}(\alpha-\nu-2\alpha\nu)\right)}. \quad (3)$$

203 **3.3 Analytical calculations of the time at which the pore pressure diffusion front reaches the** 204 **depth of the earthquake**

205 The advancement of the pore pressure front within the subsurface is controlled by diffusivity

$$206 \quad D = \frac{k\rho g}{\mu S_s} \quad (4)$$

207 where, D is diffusivity, k is the intrinsic permeability, ρ is water density, g is gravity, μ is water viscosity,
 208 and S_s is the specific storage coefficient. The time at which the pore pressure front reaches a certain
 209 distance r is given by

$$210 \quad t = \frac{r^2}{D} \quad (5)$$

211 **4.Results**

212 **4.1 Porosity and permeability measurements**

213 The results of our laboratory measurements are provided in Table 3. These data are subject to meas-
214 urement uncertainties inherent to the experimental equipment used according to the standard procedure.
215 Laboratory measurements of samples of mica-schist reveal a low permeability (Table 3 and Figure 6).
216 The maximum permeability is 0.0098 mD, but most of the samples present a permeability lowest meas-
217 urable value of the apparatus, i.e., ~~lower than~~ 0.002 mD. Such permeability is in the range of low-
218 permeability rock, which act as a barrier to flow. Most of the samples have a porosity between 6 to
219 10%, except for two with higher porosity. The low permeability of mica-schist could be explained by
220 the fact that the larger pores are not well connected (Figure 5). In general, there is no correlation between
221 permeability and porosity (Figure 6).

222
223 **Figure 5.** Megascopic representation of samples IR-2 b, c, and IR-3b showing pores that are not well-
224 connected.

225 **Table 3.** Location of samples with permeability and porosity data from measured cores

226

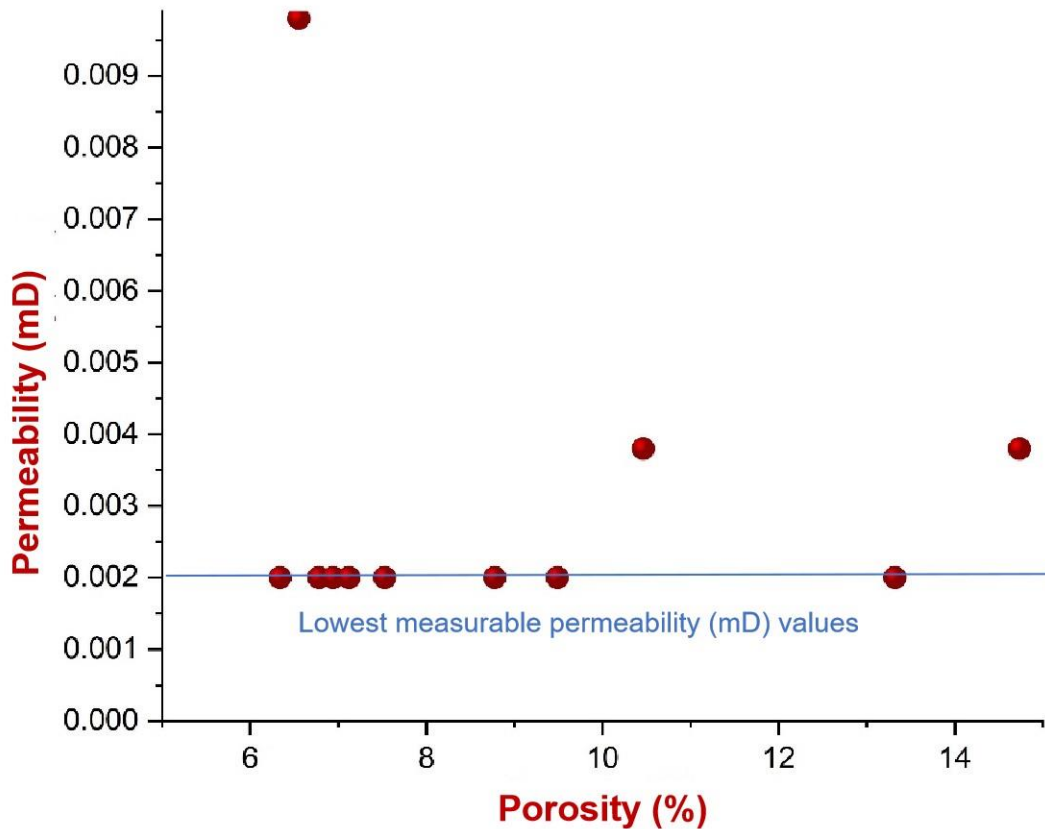

Location (lat., long.)	Sample Numbers	Permeability (mD)	Porosity (%)
16.73872, 42.57680	IR-1a	<0.002	7.5
	IR-1b	<0.002	6.8
	IR-1c	<0.002	8.8
	IR-1d	0.0098	6.6
16.74038, 42.57652	IR-2a	<0.002	9.5
	IR-2b	0.0038	10.5
	IR-2c	0.0038	14.7
16.72438, 42.56316	IR-3a	<0.002	6.9

227

Experiments loaded perpendicular to bedding plane (\perp)

228

229

230 **Figure 6.** Porosity-permeability relation of mica-schist rock samples.

231 **4.2 Undrained response of rock: changes in pore pressure and stress**

232 The 136 m of water level increase at the time of the M3.0 earthquake resulted in an increase in the
 233 vertical stress of 1.36 MPa. To compute the pore pressure change caused by the reservoir impoundment,
 234 the Biot coefficient, Skempton’s B coefficient and Poisson’s ratio of mica-schist are needed (Eq. (3)).
 235 Since such measurements are not available, we adopt the values of Opalinus Clay because it is a similar
 236 rock to mica-schist ([both are shales primarily composed of quartz minerals](#)). Thus, we assume
 237 Skempton’s B coefficient of 0.92, undrained Poisson’s ratio of 0.39 and Biot’s coefficient of 1. With
 238 these values, the resulting pore pressure change is ~~0.54~~ [0.61 MPa](#). Consequently, the horizontal stress
 239 change is of ~~0.1.09~~ [MPa](#) (Eq. (1)). These pore pressure and stress changes result in [an increase in the](#)
 240 vertical effective stress of ~~0.82~~ [0.75](#) MPa and ~~a in the~~ horizontal effective stress ~~decrease~~ of [0.48](#) MPa,
 241 increasing the deviatoric stress in more than ~~+~~ [0.25](#) MPa.

242 **4.3 Pressure diffusion along mica-schist**

243 The measured intrinsic permeability of mica-schist is in the order of 10^{-18} m^2 (Table 3). Assuming a
244 specific storage coefficient in the order of $1.05 \times 10^{-6} \text{ m}^{-1}$, diffusivity (Eq. (4)) results in $9.5 \times 10^{-6} \text{ m}^2/\text{s}$.
245 Taking into account that the depth of the M3.0 earthquake occurred at 3.8 km, the time at which the
246 pore pressure front would reach this depth by diffusion (Eq. (5)) is in the order of 50,000 years by
247 assuming the absence of fractures.

248 **5. Discussion**

249 RTS has been the focus of many studies, but the origin and development of RTS are still unclear in
250 many cases (Gupta et al., 2016; Arora et al., 2018). There is a general consensus that there are two main
251 triggering mechanisms (Simpson et al., 1988). On the one hand, low-permeability rock has an undrained
252 response to the water-level changes of the reservoir, which acts as a loading, instantaneously increasing
253 pore pressure and causing poroelastic stress changes deep underground (Chen and Talwani, 2001;
254 Vilarrasa et al., 2022; Raza et al., 2023). On the other hand, in the presence of permeable rock or a
255 permeable fracture network, pore pressure diffuses downwards, which may eventually trigger an
256 earthquake if a critically stressed fault becomes pressurized (Talwani and Acree, 1985).

257 At Irapé, the low-permeability of the rock below the reservoir, i.e., mica-schist with permeability in
258 the order of 10^{-18} m^2 or lower, hinders pore pressure diffusion. Given that the hypocentre was located at
259 3.88 km depth, the pressure propagation front would take in the order of 50,000 years to start
260 pressurizing the depth at which the earthquake was nucleated. Even assuming that the presence of
261 fractures enhanced the rock permeability by three orders of magnitude, which would be the upper limit
262 of observed permeability enhancement of low-permeability rock at the field scale (Neuzil, 1986), the
263 pressure front would take 50 years to reach 3.88 km depth. The permeability enhancement due to the
264 presence of fractures could become larger in crystalline than in clay-rich rock, reaching an increase of
265 up to five orders of magnitude (Bondarenko et al., 2022). Such high permeability enhancement caused
266 by fractures is not feasible in clay-rich rock like mica-schist because of its ductility and low dilatancy
267 angle, which prevents fractures from becoming open pathways. At Irapé, the necessary permeability of
268 the rock to reach the depth of the largest earthquake within 0.5 years, i.e., the delay of the earthquake
269 with respect to the start of impoundment, would be of 10^{-13} m^2 , five orders of magnitude higher than

270 the actual permeability of mica-schist. Such high permeability enhancement is deemed unlikely [for](#)
271 [mica-schist](#).

272 Considering the load caused by the water-level rise in the reservoir of 136 m, the low-permeability
273 mica-schist experienced an undrained response, with subsequent poroelastic stress and pore water
274 changes. We have estimated these changes analytically, finding a vertical effective stress increase of
275 ~~0.82~~ [0.75](#) MPa, a horizontal effective stress [increase](#) of [0.48](#) MPa, and a pore pressure increase of ~~0.54~~
276 [0.61](#) MPa. Given the normal faulting stress regime at Irapé, these changes cause an increase in the
277 deviatoric stress that could destabilize faults in the subsurface. These changes in pore pressure and stress
278 levels provide valuable insights into the dynamic behaviour of the geological formation and are crucial
279 considerations in understanding the reservoir response to alterations in reservoir water levels. We
280 contend that the rapid loading of the reservoir weakens this fault because of the undrained stress and
281 pore pressure changes (Figure 7).

282 In addition, the megascopic representation of core samples in the configuration of the physical
283 evidence illustrates that rock can exhibit relatively high porosities and low permeability when their
284 pores are not well-connected (Figure 5). Thus, mica-schist may present preferential lateral fluid
285 migration at depth, following the foliation direction. The surface rock beneath the Irapé reservoir is
286 highly metamorphosed and [despite having high porosity, the rock presents](#) low permeability. Therefore,
287 pore pressure diffusion is disregarded as the potential cause triggering the seismicity at Irapé.

288

289

290 **Figure 7.** Schematic description of the mechanism of RTS at Irapé, indicating the effect of the weight
 291 of the reservoir water volume due to undrained response in low-permeable mica-schist rock (the
 292 background photo was taken in the field from an outcrop at Irapé).

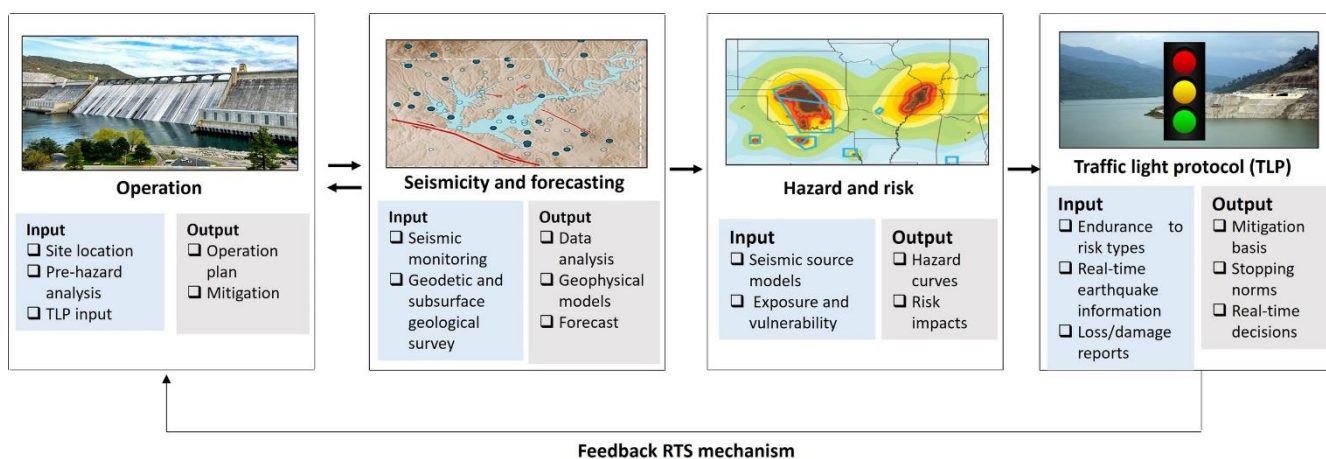

293 The regional geology at the eastern part of the São Francisco Craton in the State of Minas Gerais
294 follows a N-S direction (Almeida, 1977). Silva et al. (2014) also mentioned that the repetition of a
295 structural trend in the NE-SW direction originates from the geological and geophysical structuring of
296 the crust. This trend makes it feasible to assume the existence of a N-S vertical mature fault that could
297 become destabilized by small changes in the effective stress. An association of such seismicity with the
298 shear zone along reservoir /lineaments suggests the reactivation of such faults under the influence of
299 reservoir impoundment.

300 Mitigation of the risk of RTS requires knowledge of the physical mechanisms that may trigger
301 seismicity. Thus, it is crucial to a thoroughly characterization of the site-by-to measure rock physical
302 properties is crucial. Analytical and numerical solutions should integrate the physics of the problem,
303 ~~such as~~ in particular, poromechanics to assess both the undrained response of the subsurface to reservoir
304 impoundment and pore-pressure diffusion. Such models should include the rock layers below the
305 reservoir down to the crystalline basement and their characteristics, including features like faults.
306 Before the construction of the dam, the hazard of triggering moderate to large earthquakes should be
307 estimated, to disregard locations with high probability of RTS. This estimation requires knowing the
308 hydro-mechanical properties of the rock layers, i.e., permeability, porosity, stiffness, and strength, as
309 well as the design parameters of the dam, i.e., height for potential future projects. Note that at Irapé, the
310 porosity and permeability measurements have not been done until now, but should have been done prior
311 to the design of the dam. The successful management of RTS requires an interdisciplinary approach
312 combining concepts of hydrogeology, geomechanics and seismology.

313 ~~Finally, to address and manage RTS risks, the traffic light protocol (TLP) is being employed. In general,~~
314 ~~TLP initiates the green light as the primary approach allowing operations without restrictions, the yel-~~
315 ~~low light as the point to activate mitigation measures, and the red light as the point necessitating regu-~~
316 ~~latory intervention. The efforts have also begun by linking the configuration of TLPs with risk-oriented~~
317 ~~measures, infrastructure harm, and the likelihood of loss or damages while adapting them to real time~~
318 ~~data. The occurrences that may ensure after an operation are crucial, given their substantial impact on~~
319 ~~standard risk management. Nevertheless, these methodologies can be revolved around by assessment~~

320 ~~of events succeeding in the conclusion of an operation. The utilization of physics based models holds~~
 321 ~~promising by illustrating and projecting anticipated seismic activity, enabling the anticipation of future~~
 322 ~~warnings and risks, and build up the information for operational adjustments and for future mitigation~~
 323 ~~(Boyet et al., 2023b) (Figure 8).~~

324 To address and manage RTS risks, the Traffic Light Protocol (TLP) should be employed (Figure 8). A
 325 TLP is a tool that assists decision makers to decide how to operate the dam to minimize risks. The TLP
 326 has three levels of operation: (1) a green light that allows operations to proceed without restrictions, (2)
 327 a yellow light that requires to activate mitigation measures, and (3) a red light that urges to stop opera-
 328 tion Efforts have been made regarding the incorporation of real-time data with the application risk-
 329 oriented measures to prevent infrastructure damage and nuisance to the local community. Incorporating
 330 in TLP the two types of RTS, i.e., immediate events induced by the undrained response of the subsurface
 331 to water-level changes, and delayed seismicity induced by pore pressure diffusion, is crucial. To this
 332 end, the utilization of physics-based models is promising since they are capable of anticipating seismic
 333 activity, enabling operational adjustments for future mitigation of RTS risk (Boyet et al., 2023b) (Figure
 334 8).

335
 336
 337 **Figure 8.** Reservoir operations and impoundment are strategically designed to reduce the risk of RTS.
 338 Monitoring seismic and geophysical activities yields information for predictive earthquake models. The
 339 catalogues of earthquakes and source/origin models are applicable in the assessment of hazard and risk.

340 These assessments of risk and hazard can guide the development of a traffic light protocol (TLP), func-
341 tioning as a dynamic decision module during operations. The display of each box shows the classifica-
342 tions of input data (blue boxes) and output results (grey boxes).

343 Regarding the mitigation approaches for RTS within the framework of a TLP, the effectiveness of an
344 operator heavily relies on the efficiency of mitigation strategies implemented at the yellow-light stage.
345 Ideally, these strategies would proficiently diminish seismic risks and hazards, ultimately circumvent-
346 ing the red-light scenario that terminates the operation. Thus, TLPs can be one major strategy and strong
347 decision-making tool for operators to minimize the risk of RTS for future developments of dams.

348 **6. Conclusions**

349 We have analysed RTS at Irapé to discern the cause of the triggered seismicity. The measured low
350 permeability of the rock at Irapé disregards pore pressure diffusion as the triggering mechanism and
351 suggests that the M3.0 RTS was triggered by the undrained response of the subsurface to reservoir
352 impoundment. Analytical calculations estimate that pore pressure increased by ~~0.54~~ 0.61 MPa in
353 response to an increase of 136 m in the reservoir-water level. The resulting vertical effective stress
354 increased by 0.75 ~~0.82~~ MPa and the horizontal effective stress ~~decreased by 0.34~~ 0.48 MPa. Thus, the
355 deviatoric stress would increase in a normal faulting stress regime, like the one at Irapé, destabilizing
356 the fault and causing RTS. Both laboratory measurements and analytical calculations support the
357 hypothesis that the initial seismicity was triggered by the undrained response of the subsurface to the
358 loading of the reservoir at Irapé. This study ~~also~~ suggests that the occurrence of such earthquakes may
359 be avoided by thorough site characterization and carefully ~~manipulating~~ management of the reservoir
360 loading following TLPs that mitigate RTS risk.

361 **Data availability**
