8 Abstract

9 Ozone depletion events (ODEs) occur every spring in the Arctic and have implications for the atmospheric
10 oxidizing capacity, radiative balance, and mercury oxidation. Here we comprehensively analyze ozone,
11 ODEs, and their connection to meteorological/air mass history variables through statistical analyses, back-
12 trajectories, and machine learning (ML) at Villum Research Station, Station Nord, Greenland from 1996 to
13 2019.

14 We show that the ODE frequency and duration peak in May followed by April and March, which is likely
15 related to air masses spending more time over sea ice and increases in radiation from March to May. Back-
16 trajectories indicate that, as spring progresses, ODE air masses spend more time within the mixed layer and
17 the geographic origins move closer to Villum. Positive trends in ODE frequency and duration are observed
18 during May (low confidence) and April (high confidence), respectively. Our analysis revealed that ODEs
19 are favorable under sunny, calm conditions with air masses arriving from northerly wind directions with
20 sea ice contact.

21 The ML model was able to reproduce the ODE occurrence and illuminated that radiation, time over sea ice,
22 and temperature were important variables for modeling ODEs during March, April, and May, respectively.
23 Several variables displayed threshold ranges for contributing to the positive prediction of ODEs vs Non-
24 ODEs, notably temperature, radiation, wind direction, time spent over sea ice, and snow on land. Our ML
25 methodology provides a framework for investigating and comparing the environmental drivers of ODEs
26 between different Arctic sites and can be applied to other atmospheric phenomena (e.g., atmospheric
27 mercury depletion events).

28

29

30 1. Introduction

31 Globally, ozone is an important constituent of the stratosphere but it also plays a central role in the
32 tropospheric chemistry. Due to ozone's radiative properties, such as absorption in both the ultraviolet (UV)
33 and infrared (IR) regions, it serves as an important short-lived climate forcer (SLCF). The absorption of
34 UV light by ozone also leads to the formation of an O^{1D} atom, which reacts with water vapor to form
35 hydroxyl (OH) radicals, the most crucial oxidant in the troposphere. Tropospheric ozone sources include in
36 situ photochemical formation from the catalytic reactions involving nitrogen oxides (NO_x) and volatile
37 organic compounds (VOCs), which are initiated by OH but dependent on the ratio between NO_x and VOCs
38 (Seinfeld and Pandis, 2016). Stratosphere-troposphere exchange (STE) represents another significant ozone
39 source (Monks et al., 2015). Sinks of ozone include dry deposition and reactions with NO_x, hydrocarbons,
40 and halogens as well as photolysis driven loss.

41 During winter and spring in the Arctic, long-range transport from the mid-latitudes and STE are
42 the major sources of ozone (Helmig et al., 2007a; Hirdman et al., 2010; Stohl, 2006). In the summertime
43 Arctic, low absolute humidity suppresses the formation of OH radicals and coupled with low primary
44 emissions of precursor species (VOCs and NO_x), in situ formation of ozone is limited (Ianniello et al., 2021;
45 Morin et al., 2008; Pernov et al., 2021). Dry deposition, photolysis, and reactions with halogens are the
46 dominant sinks while wet deposition is of less importance in the Arctic because of the low humidity and
47 the limited removal efficiency of ozone by precipitating snow/ice (Barten et al., 2021).

48 A phenomenon of the springtime Arctic, known as ozone depletion episodes (ODEs), involves the
49 rapid depletion of ozone due to catalytic reaction with halogen species (X or Y, representing Br, Cl, or I)
50 (Barrie et al., 1988; Simpson et al., 2007b, 2015; Skov et al., 2004). As shown in reactions (R) 1-6:

55
56 While ozone is catalytically destroyed by reactions R1 to R3, the number of available halogen
57 atoms is not increased. Multiphase reactions like the halogen explosion sequence (R1, R2, R4, R5, and R6)
58 accelerate halogen production, leading to high concentrations of ultra-reactive halogen species and causing
59 observed ODEs. These reactions require the presence of a frozen, heterogenous surface aided by high
60 acidity (Sander et al., 2006; Simpson et al., 2007b, 2015).

64
65 Moreover, ODEs occur simultaneously with atmospheric mercury depletion episodes (AMDEs)
66 (Schroeder et al., 1998), and the relative rate principle suggests that ODEs and AMDEs can be explained
67 by competing reactions of ozone and elemental mercury with Br atoms (Skov et al., 2004, 2020), which has
68 recently been demonstrated by direct measurements (Wang et al., 2019). The relative importance of ozone
69 removal by reactions with respectively Br and I atoms in spring is unclear (AMAP, 2015; Benavent et al.,
70 2022; Wang et al., 2019; Whaley et al., 2023). Recently, it was found that Br is the dominant oxidant during

71 spring, whereas I chemistry was active during the entire sunlight period (March to October) (Benavent et
72 al., 2022).

73 The sources for atmospheric halogens include sea spray aerosols, brine migration through sea ice
74 and the snowpack, blowing snow, and frost flowers (Simpson et al., 2007b, 2015) and the relative
75 importance of the halogen sources depends on the location and time. Sea-ice surfaces, aerosol, and frost
76 flowers have gained significant interest as halogen sources in earlier investigations. Later studies indicate
77 that frost flowers are of minor importance (Abbatt et al., 2012; Simpson et al., 2007a). Frieß et al. showed,
78 using trajectory analysis, that areas of first-year sea ice are correlated with high BrO levels (Frieß et al.,
79 2004), in agreement with later satellite observations for the Arctic (Bougoudis et al., 2020). First-year sea
80 ice is saltier than multi-year ice and therefore expected to be a greater source of halogens to the atmosphere,
81 however, studies have shown that both first- and multi-year ice are sources of halogens and ODEs (Bognar
82 et al., 2020; Peterson et al., 2019). Recycling of halogens on frozen heterogeneous surfaces such as sea salt
83 aerosols and snowpack are also important sources of halogens in polar regions (Custard et al., 2017; Frieß
84 et al., 2023; Peterson et al., 2017, 2018; Pratt et al., 2013; Raso et al., 2017).

85 Meteorologically, ODEs have been usually associated with sunny conditions and cold temperatures
86 (Simpson et al., 2015). High and low wind speeds have also been connected to ODEs, where high wind
87 speeds generate blowing snow (which are a source of halogens) (Blechschmidt et al., 2016; Bougoudis et
88 al., 2020; Choi et al., 2012; Frieß et al., 2011; Seo et al., 2020; Zhao et al., 2016) and low wind speeds are
89 associated with a stably stratified boundary layer, which confine reactants and oxidants in the lower most
90 atmosphere (Jones et al., 2009). High wind speeds can induce vertical mixing thus bring ozone rich air
91 masses to the surface and terminating ODEs and AMDEs (Moore et al., 2014). Halogen explosion events
92 and ODEs have also shown to be temperature dependent (Koo et al., 2012; Tarasick and Bottenheim, 2002).
93 This is likely connected to the need for an acidic, frozen heterogeneous surface (sea ice, snowpack, blowing
94 snow, and aerosols) required for halogen propagation (Burd et al., 2017; Jeong et al., 2022), although other
95 studies have not found such evidence (Halfacre et al., 2014; Jacobi et al., 2010).

96 Despite numerous studies and significant progress in understanding Arctic tropospheric ozone, the
97 dynamics of O₃ are still not yet fully understood (Simpson et al., 2015; Whaley et al., 2023) and significant
98 questions remain, including: What is the contribution of different halogen sources to ODEs such as sea ice
99 surfaces (multi- vs first-year ice), snowpack emissions, or recycling on aerosol particles? What are the
100 conducive meteorological conditions for ODEs? What is the contribution of halogen activation aloft vs
101 in the boundary layer? What is the relative importance of Br and I atoms to ODEs during spring?

102 The lack of full understanding of halogen dynamics and the connection to ODEs makes it very
103 important to address the external variables that influence and determine the observed ozone concentrations
104 especially during ODEs. In the present paper, the connection to meteorological and air mass history
105 variables is studied to cast light on the variables that control ODEs. This is achieved through statistical
106 analyses, back-trajectories, and machine learning (ML) applied to ODEs observed at Villum Research
107 Station, Station Nord in Northeast Greenland from 1996 to 2019.

108 2. Methods & Materials

109 2.1. Site description

110 Villum Research Station (Villum) is located on a small peninsula in North East Greenland (Fig. 1). The
111 station is located at the Danish military outpost Station Nord (81° 36' N, 16° 40' W, 24 m a.s.l.). Ozone
112 measurements were conducted at Flyger's Hut from 1995 to 2014 and at the Air Observatory from 2014 to
113 present. They are located a few hundred meters apart and 2 km south of the central complex of Station Nord

114 and upwind of the station the majority of the time (> 95 %). No significant differences in ozone levels were
115 observed when moving measurement locations.

116

117

118 **Figure 1.** Location of Villum Research Station (Villum). Mean sea-ice age for March, April, and May
119 2007-2019, were taken from the National Sea & Ice Data Center (Tschudi et al., 2019)
120 (<https://nsidc.org/data/nsidc-0611/versions/4>). Map background made with data from Cross-Blend-Hypso
121 (naturalearthdata.com). The mean sea-ice age for individual spring months closely resembled the spring
122 mean, therefore the spring mean is displayed for clarity.

123 2.2. Atmospheric measurements

124 Sample air was drawn into a 20 cm inner diameter (i.d.) electro-polished stainless-steel sampling line with
125 a protective inlet cap connected to a blower, where the ozone monitors sampled 0.8 L min^{-1} air. The setup
126 is constructed to avoid ice formation in the sample tube. Ozone is measured based on its absorption of UV
127 light at 254 nm. The original data was averaged to half hourly mean values and later reported to EBAS
128 (<https://ebas.nilu.no/>). Here we use 1-hour mean mixing ratios averaged from the native time resolution (15
129 min). The stability of the instruments is ensured by the addition of known concentrations of ozone from an
130 internal ozone generator traceable to a primary standard, in this way, although different instruments have
131 been employed, all use the same measurement and calibration methods, thus the measurements uncertainties
132 are estimated to remain unchanged. The Department of Environmental Science at Aarhus University is
133 accredited (EN 17025) to measure ozone but at Villum it is not possible to maintain the accreditation as the
134 visits to the station are not possible frequently enough. However, the instruments are operated as close as
135 possible to the accreditation procedures. To compensate for the deviations, two monitors are operated in
136 parallel. The uncertainty at a 95% confidence level (CL) is <7% for mixing ratios above 20 ppbv and 1.4
137 ppbv for mixing ratios below 20 ppbv (Skov et al., 2004, 2020).

138 To quantify the frequency and the duration of ODEs, the parameter ‘ozone depletion hour’ was
139 defined as an hour during which the average ozone mixing ratio was below 10 ppbv, following the definition
140 used by other studies (Halfacre et al., 2014; Koo et al., 2012; Tarasick and Bottenheim, 2002; Yang et al.,
141 2020). In total, 6605 ODE hours were detected. To account for ozone mixing ratios exceeding 10 ppbv
142 during a single hour which was part of a larger depletion event, hours that were below 15 ppbv and the
143 previous and subsequent hours were below 10 ppbv were also classified as ODEs. This resulted in 57
144 additional hours being classified as ODEs, which brings the total number of ODEs to 6662, although this
145 addition criteria did not affect the results of this study.

146 **2.3. Meteorological variables**

147 Meteorological data were collected at or near the ozone measurement sites. From 1996 to 2014
148 measurements of temperature, relative humidity, wind speed, and wind direction were obtained through the
149 Danish Meteorological Institute’s weather station located within Station Nord (Jensen, 2022). From 2014
150 to 2020, measurements of temperature, relative humidity (RH), wind speed, wind direction, and solar
151 radiation were obtained from an automatic weather station located ~44 m from the Air Observatory.

152 Observations of solar radiation only started in 2014 and input data for ML models require no
153 missing data. To overcome this absence of measurements before 2014 and extend the input dataset for the
154 ML model to 2007, we supplemented observations with ERA5 reanalysis data (Hersbach et al., 2020).
155 ERA5 output of “shortwave solar radiation downwards” was used, which is the amount of shortwave
156 downwelling solar radiation (including both direct and diffuse radiation) that reaches the Earth’s surface
157 on a horizontal plane.. This is the ERA5 equivalent of the output of a pyranometer with a radiation spectrum
158 of 0.2–4 μm (Hogan, 2015). ERA5 originally provided data as an accumulated value in J m^{-2} but was
159 converted to W m^{-2} by dividing the original values by one hour in seconds (3600). Data are on a $0.25^\circ \times$
160 0.25° spatial resolution and an hourly temporal resolution. These data were only used to substitute missing
161 data after 2014 and as a replacement for the absence of measurements before 2014 and were not included
162 in the evaluation of the statistical analysis of ODEs and meteorological variables. This approach was only
163 implemented for the machine learning model and not for the statistical analysis of meteorological variables.
164 A comparison of solar radiation measured at Villum and ERA5 data after 2014 is shown in Fig. S8. Overall,
165 ERA5 agrees quite well with observations, with a Spearman rank correlation coefficient of 0.974, although
166 ERA5 slightly underestimates with a slope of 0.881 (Fig. S8), which is common for ERA5 in the Arctic
167 (Pernov et al., 2024). ERA5 data were corrected using the slope of the observation-model comparison to
168 avoid changepoints in the time series, which could affect the results of the machine learning model.

169 **2.4. Back trajectory analysis**

170 Air mass back trajectories were calculated via the HYSPLIT trajectory model (Draxler and Hess, 1998;
171 Rolph et al., 2017; Stein et al., 2015). Trajectories of 168-hour length were calculated, arriving at 50 m
172 above ground level, for every hour from 2007 to 2019. The trajectory starting height of 50 m was selected
173 as a compromise between capturing air masses that are representative of our sampling site due to very low
174 boundary layers in the Arctic (Gryning et al., 2023) and avoiding trajectories intercepting the surface, which
175 can produce unrepresentative trajectories (Stohl, 1998). The trajectory length was chosen to avoid the
176 uncertainty associated with extremely long trajectory calculations, while capturing the entire geographic
177 extent of ODE air masses. This trajectory length of one week roughly corresponds to the longest observed

178 ODE at Villum during the study period (~6.5 days, Sect. 3.1) and is shorter than the longest observed ODE
179 at a land-based station (9 days at Alert by Strong et al. (2002)). Previous studies have shown that ODE air
180 masses can extend over great distances in the Arctic (Halfacre et al., 2014; Peterson et al., 2017), therefore
181 we selected a trajectory length of one week to fully investigate the air mass history of ODEs. Other studies
182 have used shorter (Bognar et al., 2020; Frieß et al., 2023) or longer (Bottenheim and Chan, 2006; Begoin
183 et al., 2010; Simpson et al., 2018) trajectory lengths than one week. Trajectories were calculated based on
184 meteorological files from the NCEP/NCAR Reanalysis Data, which has a resolution of 2.5°
185 latitude/longitude (Kalnay et al., 1996). The mixed layer height for each step of each trajectory was output
186 by the HYSPLIT model. Only trajectories corresponding temporally to available ozone measurements were
187 used in this study. To analyze the geographic origins of ODEs, a concentric grid centered around the
188 location of Villum, consisting of 2° × 4° (latitude x longitude) grid cells, was constructed. The normalized
189 trajectory frequency for each grid cell was calculated by counting the number of trajectory steps that were
190 below the mixed layer height and intersecting each grid cell. This was normalized by the total number of
191 trajectory steps that were below the mixed layer over all grid cells and multiplied by 100%. This
192 methodology has been utilized by previous studies to systematically analyze the geographic origins of air
193 masses (Dall'Osto et al., 2017, 2018; Frieß et al., 2023; Heslin-Rees et al., 2020; Pernov et al., 2022).

194 For each trajectory, a surface-type footprint analysis was performed. The underlying surface types
195 used for the surface footprint type analysis were produced by the National Oceanic and Atmospheric
196 Association/National Environmental Satellite, Data, and Information Service (NOAA/NESDIS) Interactive
197 Multisensor Snow and Ice Mapping System (IMS) developed under the direction of the Interactive
198 Processing Branch (IPB) of the Satellite Services Division (SSD). The altitude at each step along the
199 trajectory was compared to the height of the mixed layer. Steps were classified as being above the mixed
200 layer (AML) if the trajectory altitude was above this height. If the trajectory altitude was below this height,
201 then the underlying surface type (land without snow, sea, sea ice, or snow on land) was recorded using a
202 polar stereographic map of the Northern Hemisphere classified into 1024×1024 24 km grid cells. It is
203 important to note that grid cells classified as sea ice likely contain snow on the surface, although the satellite
204 products used in this study does not differentiate between bare sea ice and snow-covered sea ice, likely due
205 to the similar spectral signatures between sea ice and snow (U. S. National Ice Center, 2008). We opted to
206 keep the original labels from the satellite product for this analysis, as we cannot make any definitive
207 statements about the presence of snow on top of sea ice. The reader should keep this in mind when
208 interpreting the results. The time spent over different surfaces is expressed as a percentage of the total
209 trajectory length.

210 **2.5. Trend analysis**

211 A trend analysis of ODE frequency, duration, and start/end/range of ODE days for March, April, and May
212 was performed. The Mann-Kendall test was used to determine the presence of a statistically significant (SS)
213 trend (Kendall, 1948; Mann, 1945) and the Theil-Sen slope estimator was used to calculate the magnitude
214 of the trend slope (Sen, 1968; Theil, 1950) via the 3PW algorithm from Collaud Coen et al. (2020). The
215 3PW algorithm tests for autocorrelation present in the time series, as this can affect the results of the Mann-
216 Kendall test, however, no SS autocorrelation was detected therefore these data were not prewhitened.

217 **2.6. Machine learning modeling**

218 In this study, we utilize a supervised, binary classification form of machine learning (ML) to investigate
219 the dynamics of ODEs. The target variable used was the binary label of ODE or Non-ODE, defined as
220 ozone mixing ratios above or below 10 pbbv, respectively. The explanatory variables used in the ML model
221 were the meteorological and air mass history variables (RH, wind direction, wind speed, temperature,
222 radiation, pressure, time air masses spent over snow on land, time air masses spent over sea ice, and time
223 air masses spent above the mixed layer). Below we describe the missing data imputation, the machine
224 learning model, hyperparameter tuning, the ML explainability approach employed, and model evaluation
225 metrics.

226 Before input into the ML model, missing data were imputed since ML models require no missing
227 data in the input files. We imputed missing data using the median value for the hour of the day for that day
228 of the year. For instance, if a value is missing for hour 12 on the 90th day of the year then this value was
229 imputed using the median of all values from hour 12 on the 90th day of the year from the entire dataset. This
230 imputation approach allows us to account for changes occurring from early to late spring as well as diurnal
231 changes, which would otherwise be overlooked if only using a single median for the spring months. This is
232 especially important for variables that drastically change over this short period (e.g., temperature, RH, solar
233 radiation). Table S1 lists the percentage of missing data before imputation for each variable. Wind speed
234 and direction exhibited the highest percentage of missing data, with both missing ~21 %, therefore data
235 imputation shouldn't adversely affect the results of the ML model. No feature engineering (standardization
236 or normalization) was applied prior to modeling since the initial evaluation metrics were deemed
237 sufficiently accurate. No temporal information (Julian day, day of year, hour of day) was included in the
238 input variables.

239 The XGBoost model was selected as the model used in this study due to its accuracy, computational
240 efficiency, and ability to handle collinearity amongst the input variables, which is important for
241 meteorological variables. XGBoost is an ensemble machine learning algorithm using the gradient-boosting
242 methodology on individual decision trees (which are weak learners) and then builds multiple decision trees
243 that are sequentially added (Chen and Guestrin, 2016). This allows for the previous tree's errors to be
244 learned by the next tree, therefore reducing the loss function while obtaining the best prediction. A
245 regularized model formalization is used in the XGBoost model to improve computational efficiency and
246 prevent over-fitting. The xgboost package (v1.6.2) was used and all ML modeling was implemented in a
247 Python environment (v3.10.2).

248 Hyperparameter tuning is an essential part of ML which ensures optimal model performance. We
249 utilized a Bayesian approach for exploring the optimum hyperparameter configuration, implemented
250 through the Optuna (Akiba et al., 2019) library (v3.0.3). The hyperparameters included, the range of values
251 explored, and the optimum values are listed in Supplementary Table 2. This study employed a stratified
252 70/30 train/test split ratio, meaning the test set contained the same proportion of positive labels (i.e., ODEs)
253 as the entire dataset. The purpose of the training set is for the model to learn how to model the data and the
254 test set is used to evaluate the model's performance on unseen data. The objective of the hyperparameter
255 tuning procedure is to maximize the mean recall score using 10-fold cross-validation. Cross validation
256 involves splitting the training data in 10 equally sized folds (or groups), training the model using nine folds
257 and testing the model using the remaining fold. This was repeated 10 times to use each fold as a test set
258 once. The final evaluation metrics were averaged using the arithmetic mean to select the optimal
259 hyperparameters and make an overall evaluation of the model performance. Tuning was performed for 1000

260 trials and the best hyperparameters were selected. Hyperparameter values were sampled using the Tree-
261 structured Parzen Estimator (TPE) algorithm (Bergstra et al., 2011) and trials were pruned using the
262 Hyperband pruner (Li et al., 2018). The final set of hyperparameters was selected based on the compromise
263 between overall performance (high recall scores) and agreement between the training and test set evaluation
264 metrics using 10-fold cross-validation (prevention of over-fitting).

265 We employed SHapley Additive exPlanations (SHAP) values (Lundberg and Lee, 2017) which are
266 based on Shapely values (Shapley, 1953), to assess the effect of the input variables on the model output.
267 The SHAP approach is a model-agnostic methodology designed to assess input variable importance based
268 on coalitional game theory (Molnar, 2022), where input variables are treated as “players” in a “game”
269 (model framework) and SHAP aims to assess the players’ contribution to the “payout” (model output). For
270 each observation, the SHAP value represents an input variable’s marginal contribution over the mean model
271 output when considering all possible combinations of the input variables. SHAP values can be positive or
272 negative, with positive values indicating a variable is more likely to contribute to an observation being
273 predicted as an ODE while negative values mean a variable is more likely to contribute to an observation
274 being labeled as a Non-ODE. It is important to note that SHAP values do not represent how well the input
275 variables explain the behavior of our target variable in the natural environment but how well these variables
276 explain the behavior of our target variable in our model, therefore SHAP values represent purely statistical
277 relationships. SHAP can produce both local and global explanations contrary to other commonly used input
278 variable importance methods (e.g., split count, gain, permutation importance) that only produce an estimate
279 of global importance (Lundberg et al., 2019). The global importance for each feature is calculated as the
280 mean of the absolute SHAP values for said input variable which gives an overview of the most important
281 variables, however, this does not account for the relationship between the SHAP and input value (positive
282 or negative relationship, linear or non-linear). Therefore, we assessed the relationship between the SHAP
283 and ambient values by discretizing the ambient values into fifteen equally spaced bins and calculated the
284 median and 25th/75th percentiles for each bin. These two approaches allow for the evaluation of the overall
285 global importance as well as the relationship between ambient and SHAP values for each input variable.
286 The SHAP approach was applied via the shap package (v0.41.0).

287 The ML model was evaluated using common metrics for a classification model, namely accuracy,
288 recall, and Area Under Curve Receiver Operating Characteristics (AUC ROC). The accuracy is the fraction
289 of correctly labeled data, both positive (ODEs) and negative (Non-ODEs), compared to the total number of
290 data points (sum of ODEs and Non-ODEs) and ranges from 0 to 1. In other words, accuracy is the fraction
291 of correctly predicted observations regardless of label (ODE vs Non-ODE). The recall (also defined as the
292 true positive rate or sensitivity) is the fraction of correctly identified positive labels (ODEs identified by the
293 ML model) compared to the total number of positive labels (total number of ODEs) and ranges from 0 to
294 1. In other words, recall is the fraction of ODEs correctly predicted. The ROC curve displays the
295 performance of a classification model across different decision thresholds and is represented by a plot of
296 the true positive rate versus the false positive rate. The AUC ROC is the area underneath the ROC curve
297 and evaluates how well a model can discriminate between positive and negative labels across all decision
298 thresholds (0.5 is the default threshold used in this study). The AUC ROC ranges from 0 to 1, with 0.5
299 representing random chance and 1 representing a perfect model. The accuracy gives an overview of the
300 model performance for both labels (ODEs vs Non-ODEs), recall gives the model performance only for
301 positive labels (ODEs), and AUC ROC evaluates the model performance over different decision thresholds,

302 together, these three metrics give a comprehensive view of the model's performance. These metrics were
303 implemented using the scikit-learn package (v1.0.2).

304

305 **3. Results**

306 **3.1. Overview of ozone and ozone depletion events**

307 The seasonal cycle of ozone mixing ratios with the daily median, minimum/maximum, and interquartile
308 range for each day of the year is shown in Fig. 2a. During winter (December-February), ozone mixing
309 ratios are elevated and slightly increase from January to March, displaying maximum daily median ozone
310 values in February. During spring (March-May), ozone mixing ratios are highly variable with daily
311 minimum values reaching 0 ppbv and maximum values observed in April. During summer (June-August),
312 ozone mixing ratios begin to decrease in late June, remain low during July, and begin increasing in August.
313 During autumn (September-November), ozone mixing ratios continue to increase and begin to return to
314 wintertime values in October. A seasonal histogram of ozone mixing ratios is displayed in Fig. 2b. For
315 winter, autumn, and summer, ozone values are normally distributed with the highest averages experienced
316 in winter > autumn > summer. Spring experiences a non-parametric distribution and the highest and lowest
317 observed values as explained above.

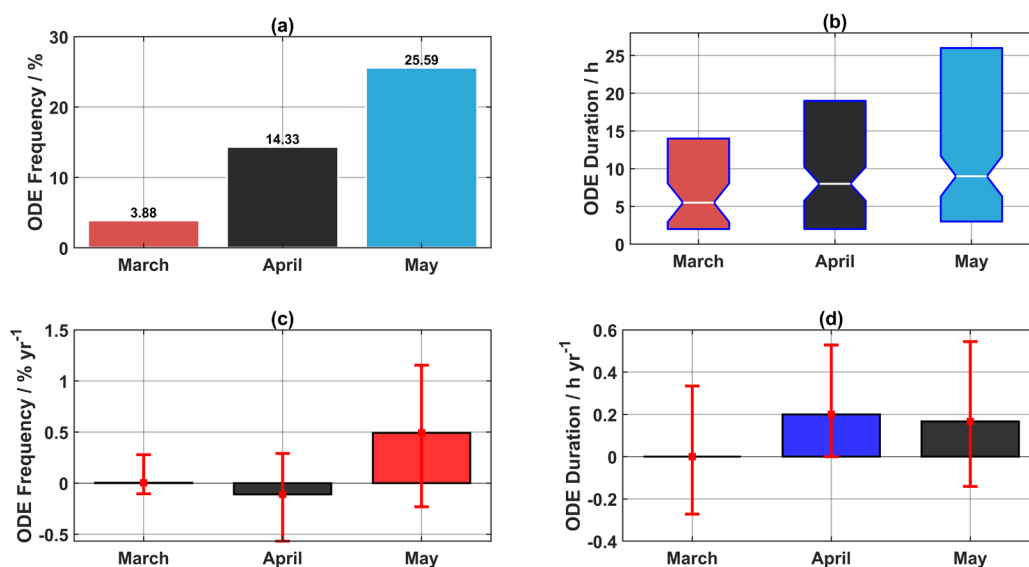

318
319 **Figure 2. Overview of the seasonal cycle and seasonal distribution. (a)** Seasonal ozone cycle of the daily
320 median (red line), minimum/maximum (light blue shading), and interquartile range (blue shading) and **(b)**
321 histograms of ozone by season (winter in blue: December-February, spring in cyan: March-May, summer
322 in red: June-August, and autumn in grey: September-November).

323 An overview regarding the frequency and duration of ODEs at Villum is shown in Fig. 3a and b,
324 respectively. ODEs were formally defined in this study as a hourly mean observation with an ozone mixing
325 ratio below 10 ppbv (Halfacre et al., 2014; Koo et al., 2012; Tarasick and Bottenheim, 2002; Yang et al.,
326 2020). The frequency is calculated as the percentage of ODE hours relative to the number of available
327 hourly observations during a month over the study period. The ODE duration is defined as the number of
328 consecutive hours that were classified as ODEs. ODEs are most frequently observed during May, followed
329 by April and March (Fig. 3a). The increase in the ODE frequency from March to April (10.45 %) is similar
330 to the increase from April to May (11.26 %). The distribution (median and interquartile range) of the ODE
331 duration for the spring months is shown in Fig. 3b. The most common duration of ODEs is 1-2 hours, with
332 longer ODEs more often occurring in May. The longest ODE occurred during May and lasted 155 hours
333 (~6.5 days). For comparison, the longest ODE observed at a ground-based Arctic station was at Alert,
334 Canada and lasted for 9 days (Strong et al., 2002). Over the central Arctic Ocean, Bottenheim et al. (2009)
335 observed an ODE lasting from April 21 to May 23, 2007. ODEs lasting less than 8 hours occurred ~50 %

336 of the time. ODEs lasting more than one (two) day(s) occurred 21 and 9 % of the time, respectively.
 337 Interestingly, the median of ODE duration between any of the spring months is not significantly different
 338 (Fig. 3b). The median ODE duration increases from March (5.5 h) to April (8 h) to May (9 h), while the
 339 interquartile range increases more drastically from March to May (Fig. 3b). The diurnal ODE frequencies
 340 for each spring month is displayed in Fig. S2, only minor variability is displayed which is most evident
 341 during April.

342 To investigate changes in the frequency and duration of ODEs, a temporal trend analysis was
 343 performed for 1996-2019. Temporal trends of ODE frequency and duration for each month are displayed
 344 in Fig. 3c and d, respectively. The slopes of the trends are displayed as boxes (colored by p-value range)
 345 with the 95th % confidence intervals (CI) as the red error bars. For ODE frequency, no SS trends at the 95th
 346 % CL were detected, although May is SS at the 85th % CL ($p = 0.14$) with a slope [lower CI, upper CI] of
 347 0.49 [-0.23, 1.2] % yr⁻¹. The only SS trend for ODE duration at the 95th % CL ($p = 0.039$) is during April,
 348 with a positive trend of 0.2 [0, 0.53] h yr⁻¹. Temporal trends in the start, end, and range of ODE days for
 349 each year were also examined to investigate any changes in the ‘ODE season’. The first ODE was defined
 350 as the first day of the year with an ozone measurement < 10 ppbv, the last ODE day was defined as the last
 351 day of the year with an ozone measurement < 10 ppbv, and the range of the ODE days was defined as the
 352 difference between the last ODE day of the year and the first ODE day of the year. The results are shown
 353 in Fig. S3, and no SS trends at the 95th % CL were found.

354
 355 **Figure 3.** Overview of ozone depletion events including (a) bar plots of the frequency of ODEs color-coded
 356 by month, (b) boxplots of ODE duration (the white line represents the median, the colored boxes represent
 357 the interquartile range, the medians of boxes whose notches do not overlap differ with 95% confidence),
 358 (c) trends in ODE frequency, and (d) trends in ODE duration for March, April, and May. The blue, red, and
 359 black bars in (c) and (d) represent trends that are significant on the >95th, >85th, and <85th % CLs,
 360 respectively. The red error bars represent the 95th % confidence intervals (CI) of the slope. The p-values for
 361 ODE frequency in March, April, and May are 0.54, 0.75, and 0.14, respectively. The p-values for ODE
 362 duration in March, April, and May are 0.85, 0.04, and 0.41, respectively.

363

364 3.2. Statistical relationships of ODEs with meteorological/air mass history variables

365 The relationships between the ODEs, ozone mixing ratios, and meteorological/air mass history variables
366 were investigated. This was accomplished by grouping the meteorological variables into bins and summing
367 the number of ODE hours for each bin which were normalized by the total number of hours within the same
368 bin and the median ozone mixing ratio for each bin was calculated for each month separately. The results
369 are shown in Figure 4, the distribution (median and interquartile range) of these variables for ODEs and
370 Non-ODEs are displayed in Fig. 5, and wind roses for ODEs and Non-ODEs for the spring months are
371 displayed in Fig. S5. It should be noted that this analysis simply considers the statistical relationship
372 between a given meteorological variable and ozone/ODEs and not the causal relationship. All available
373 data for a given meteorological parameter collocated with ozone measurements was used in this analysis.
374 It should be kept in mind that the air mass history variable, time spent over sea ice, does not give information
375 about the presence of snow cover and only if the underlying surface was classified as sea ice or not.

376 For RH, during March, the lowest median ozone mixing ratio and highest normalized ODE hours
377 are mainly confined in the 65-90 % range (midpoints 68-88 %) (Fig. 4a), while lower median ozone mixing
378 ratios occur at higher RHs, which are infrequent. During April and May, lower median ozone mixing and
379 higher normalized ODE hours are observed at higher RH values (75-90 %, midpoints 78-88 %) (Fig. 4a).
380 There is little difference between the distribution for RH when comparing ODEs and Non-ODEs during
381 March, while for April and May, consistently higher RH is observed during ODEs (Fig. 5a).

382 For wind direction, there is a clear effect of northerly wind directions during all spring months,
383 with the lowest median ozone mixing ratios and highest normalized ODE hours occurring in the 315°-45°
384 sector (Fig. 4b). Wind roses for each spring month show a lack of northerly winds for Non-ODE periods
385 and wind more frequently arriving from the north and northwest during ODE periods (Fig. S5).

386 For wind speed, during March, there is little effect on ozone mixing ratios and the normalized ODE
387 hours display no discernable pattern across the range of wind speeds (Fig. 4c). The distribution of wind
388 speeds shows a higher median during ODEs compared to Non-ODEs (Fig. 5b). During April, the median
389 ozone mixing ratios show little variation with wind speed although the normalized ODE hours show a
390 tendency for ODEs to occur more often at higher wind speeds (midpoints 9-15 m s⁻¹), however, these values
391 seldomly occur (Fig. 4c). The distribution of wind speeds during ODEs in April is shifted towards higher
392 values compared to Non-ODEs (Fig. 5b). During May, a clearer picture for the effect of wind speed is
393 presented; median ozone mixing ratios and normalized ODE hours show two modes, one at low wind speeds
394 and one at high wind speeds, although it should be noted that the mode at higher wind speeds (midpoints
395 15-18 m s⁻¹) seldomly occurs (Fig. 4c). Interestingly, during May, the distribution of wind speeds was lower
396 for ODEs compared to Non-ODEs (Fig. 5b).

397 For temperature, median ozone mixing ratios show a slight decreasing pattern for colder
398 temperatures during March and April. The normalized ODE hours showed a slight increase with colder
399 temperatures during March although for April values increased from freezing, peaked in the -25 to -20 °C
400 range (midpoint -22.5 °C), and decreased thereafter (Fig. 4d). During May, median ozone shows a stark
401 decrease with colder temperatures and the normalized ODE hours sharply increases with decreasing

402 temperatures. The -25 to -20 °C bin (midpoint -22.5 °C) displayed the lowest median ozone mixing ratios
403 and the largest normalized ODE hours during May (Fig. 4d). The distribution of temperatures is similar for
404 ODEs compared to Non-ODEs during March and April while ODEs in May experience substantially colder
405 temperatures compared to Non-ODEs (Fig. 5c).

406 For solar radiation, there are large differences in the magnitude between different spring months.
407 During March, median ozone mixing ratios (normalized ODE hours) experienced a minimum (maximum)
408 in the 100 to 150 W m⁻² range (midpoint 125 W m⁻²). The distribution of solar radiation values is
409 substantially higher during ODEs in March compared to Non-ODEs and the medians are significantly
410 different on the 95th % CL (Fig. 5d). During April, median ozone mixing ratios display a decrease from the
411 lowest bin to the 50 to 100 W m⁻² bin (midpoint 75 W m⁻²), afterwards they plateau until the 300 to 350 W
412 m⁻² bin (midpoint 325 W m⁻²), and finally decrease afterward and the normalized ODE hours displayed a
413 similar, yet opposite, pattern (Fig. 4e). During May, median ozone mixing ratios are consistently < 22 ppbv
414 across the range of solar radiation values (Fig. 4e). The normalized ODE hours display a maximum in the
415 0 to 50 W m⁻² bin (midpoint 25 W m⁻²) although these values seldomly occur), and display similar values
416 afterward.

417 For pressure, during March and April, there is little variation in the median ozone mixing ratios
418 and normalized ODE hours, however, during May, there is a clear dependency of lower (higher) median
419 ozone mixing ratios (normalized ODE hours) with higher values of atmospheric pressure (Fig. 4f).
420 Interestingly, the distribution of pressure during ODEs is substantially higher compared to Non-ODEs for
421 each spring month, with median values being significantly different on the 95th % CL (Fig. 5e).

422 For time spent over sea ice, every spring month displays a decreasing (increasing) pattern of median
423 ozone mixing ratios (normalized ODE hours) with increasing time spent over sea ice (Fig. 4g), which
424 supports the results shown earlier for ODEs corresponding to northerly wind directions (Figs. 4b and S5).
425 Trajectories during all spring months consistently spent more time over sea ice during ODEs compared to
426 Non-ODEs (Fig. 5f).

427 For the time air masses spent over snow on land, no clear impact on median ozone mixing ratios is
428 observed for March and April, while May displays higher ozone mixing ratios for 90-100 % of time spent
429 over snow on land (Fig. 4h). During each spring month, the normalized ODE hours displays no discernable
430 pattern over the range of time spent over snow on land (Fig. 4h). Interestingly, the distribution of time spent
431 over snow on land during ODEs is consistently lower compared to Non-ODEs for each spring month and
432 the median is significantly different at the 95th % CL (Fig. 5g).

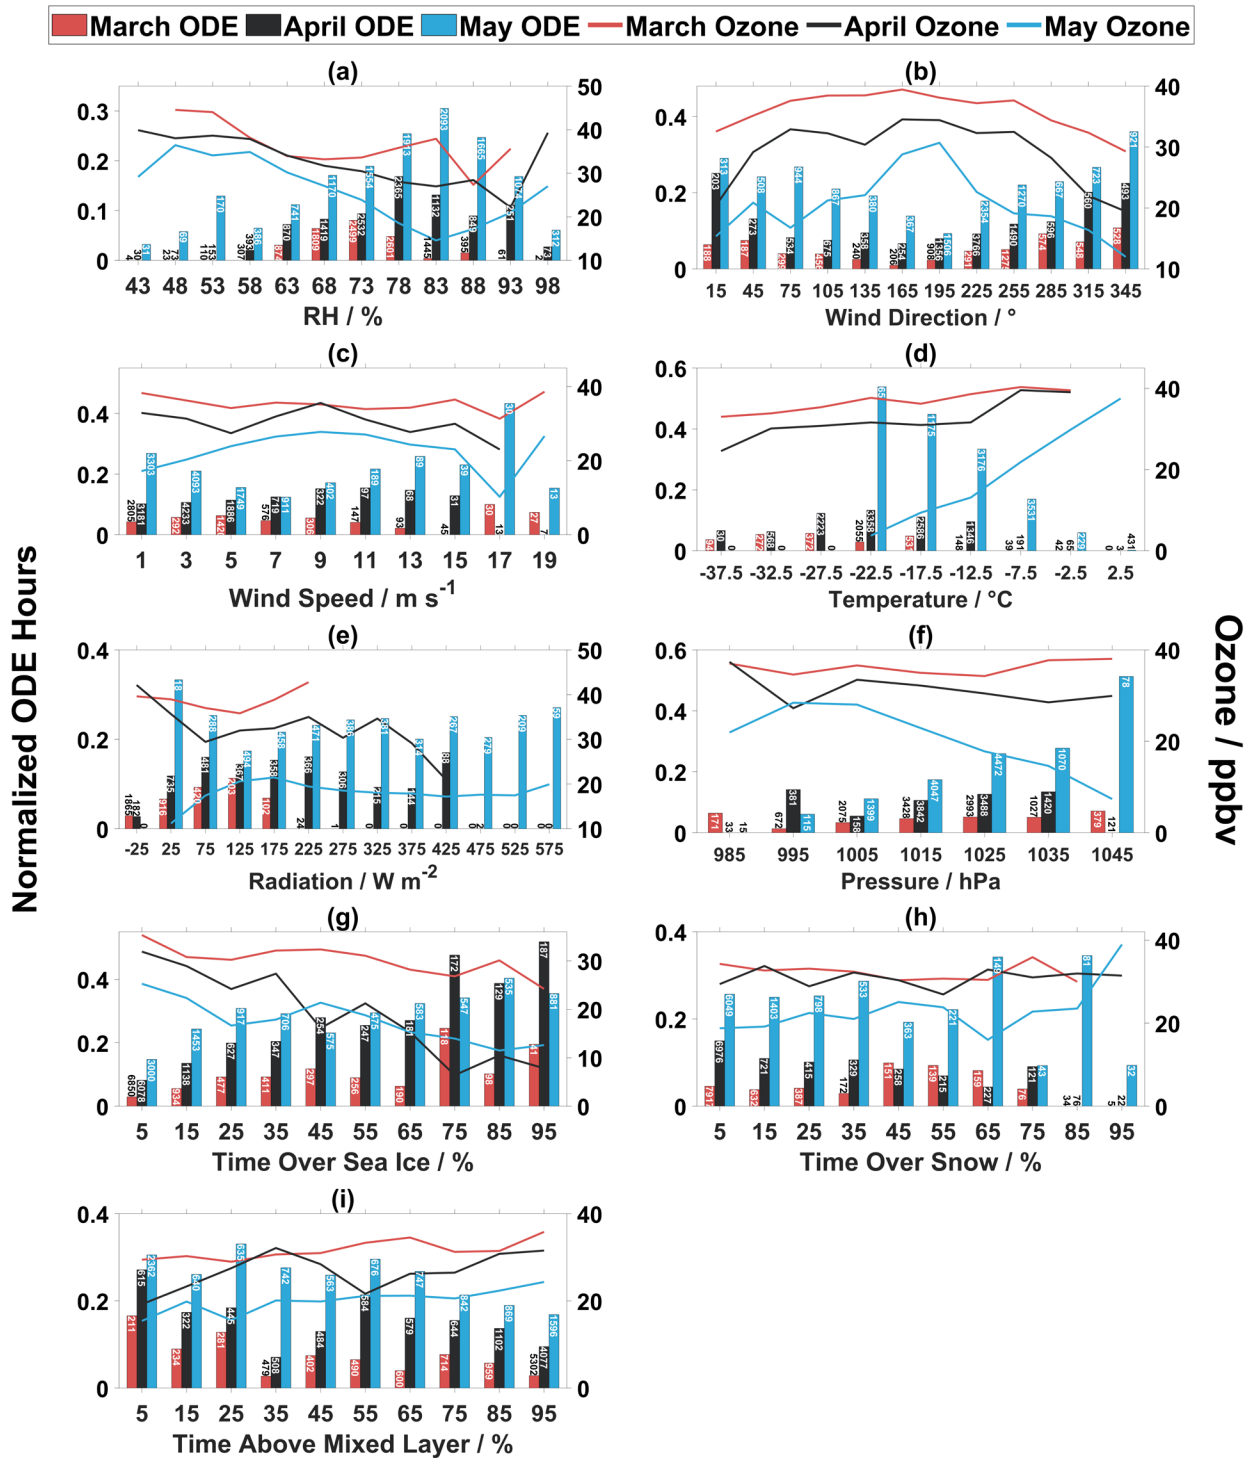

433 For time spent above the mixed layer (i.e., free troposphere), each spring month displays a similar
434 pattern, with a general tendency of decreasing (increasing) ozone mixing ratios (normalized ODE hours)
435 with less time spent above the mixed layer (Fig. 4i). The distribution of time spent above the mixed layer
436 for ODEs is consistently lower than for Non-ODEs and the median is significantly different at the 95th %
437 CL (Fig. 5h).

438

439

440

441

442

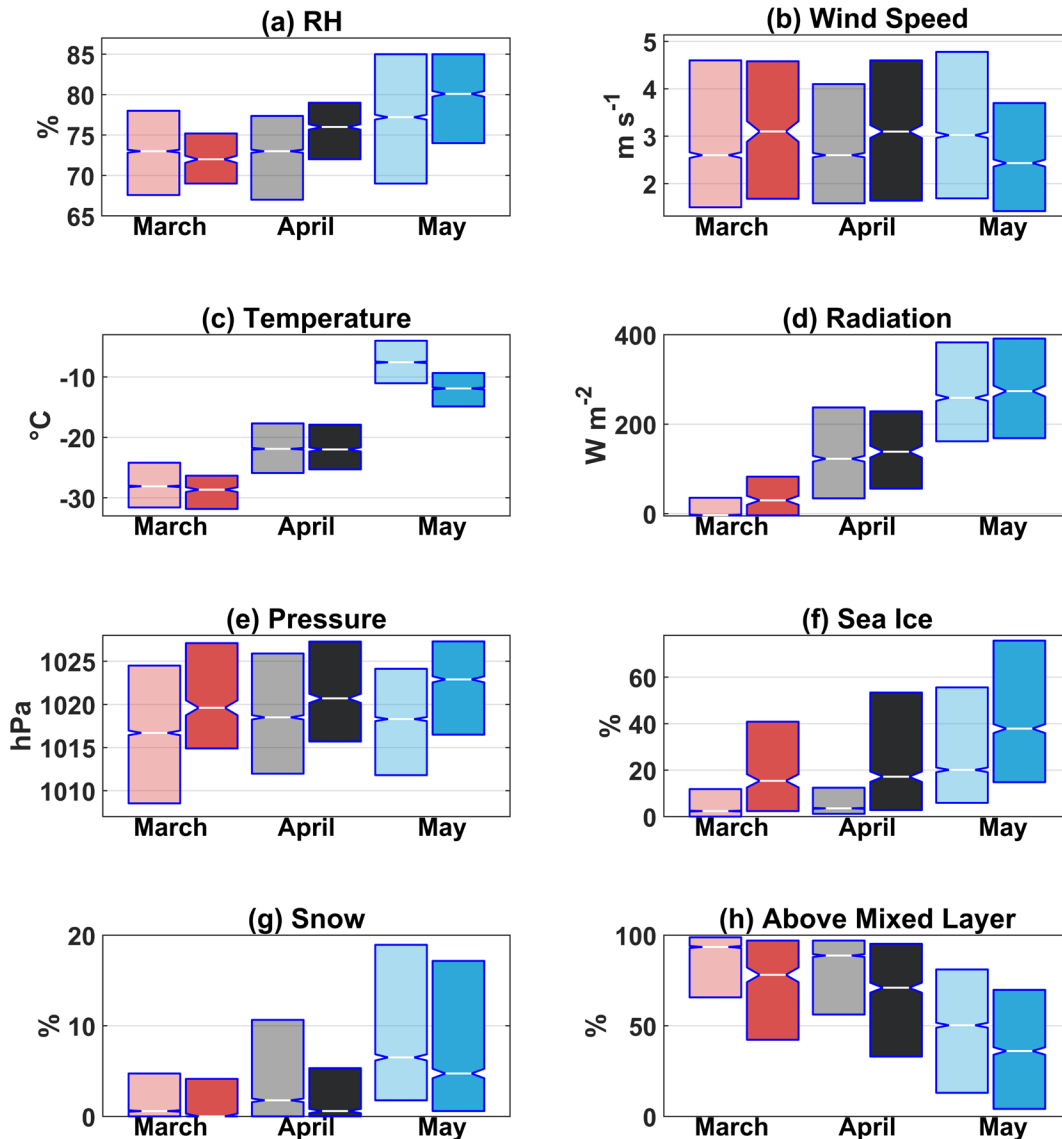

443 **Figure 4.** Median ozone and normalized ODE hours binned in predefined intervals of (a) RH, (b) wind

444 direction, (c) wind speed, (d) temperature, (e) radiation, (f) pressure, time air masses spent over (g) sea ice,

445 (h) snow on land, and (i) time above the mixed layer for March, April, and May. The number associated with each bar represents the number of total observations in that bin. All available data for each variable
 446 with each bar represents the number of total observations in that bin. All available data for each variable
 447 collocated with ozone measurements was used, resulting in different years used for each variable, with the
 448 minimum number of years included being 5 for radiation.

449

450

451

452 **Figure 5.** Distribution of meteorological and air mass history variables during the spring months for ODEs
 453 (dark colors) and Non-ODEs (light colors) including (a) RH, (b) wind speed, (c) temperature, (d) radiation,
 454 (e) pressure, (f) time over sea ice, (g) time over snow on land, and (h) time above the mixed layer. The line

455 in the middle of the box represents the median, the boxes represent the interquartile range, and the medians
456 of boxes whose notches do not overlap differ with 95% confidence. For a description of how the time spent
457 over different surface types is calculated see the methods section. All available data for each variable
458 collocated with ozone measurements was used, resulting in different years used for each variable, with the
459 minimum number of years included being 5 for radiation.

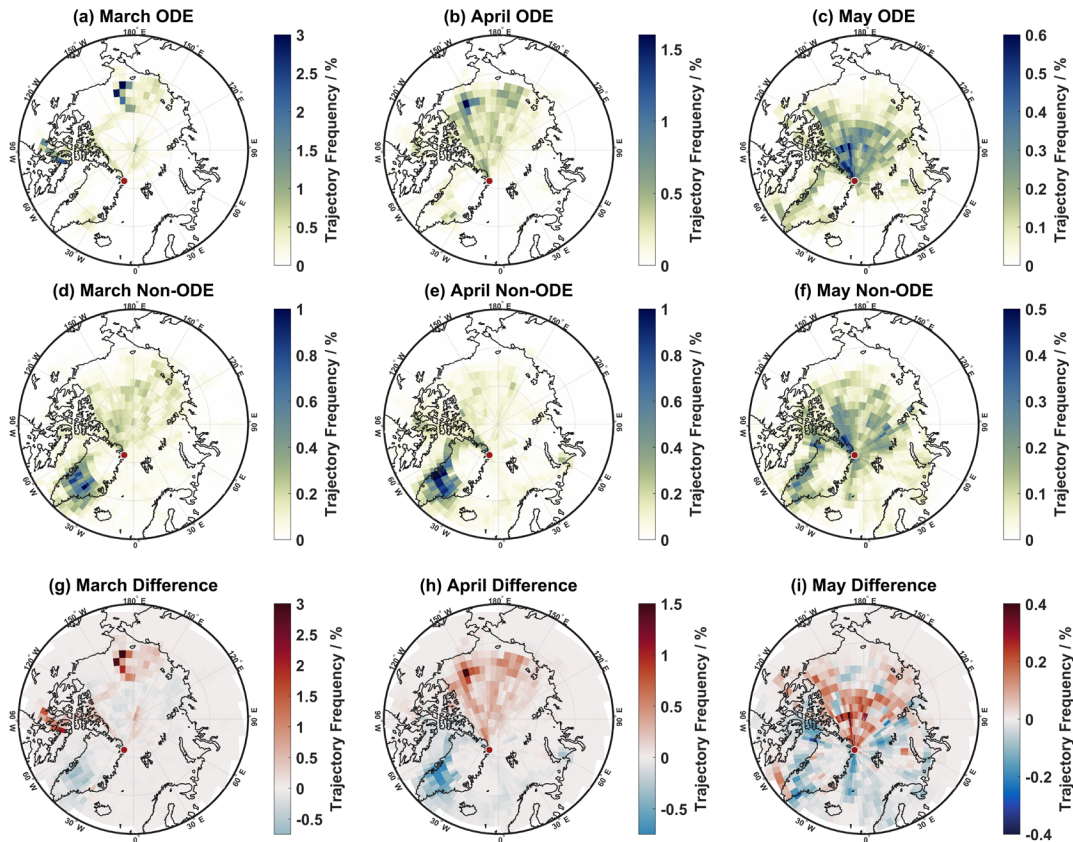

460

461 **3.3. Air mass history of ODEs**

462 To understand the air mass origin of ODEs and Non-ODEs, source regions were investigated through
463 trajectory frequency maps (see Methods Sections for details). Figure 6 displays the trajectory frequency for
464 only steps below the mixed layer for ODE hours (Fig. 6a-c), Non-ODE hours (Fig. 6d-f), and the difference
465 between ODE and Non-ODE hours (Fig. 6g-i) for each spring month. Air masses arriving at Villum have
466 been shown to predominantly reside above the mixed layer (~75 %) during March and April whilst during
467 May this value decreases to ~50 % (Pernov et al., 2022), hence the smaller air mass footprint for March
468 and April. During March, the main source regions for ODE air masses appear to be the Chukchi Sea while
469 for Non-ODE air masses the main source region is Greenland with a minor contribution from the central
470 Arctic Ocean (Fig. 6a and d). The difference between these trajectory frequency maps during March reveals
471 ODE air masses are spending relatively more time over in the Chukchi Sea and Canadian Archipelago and
472 less time over Greenland (Fig. 6g). During April, ODE air masses are originating from the central Arctic
473 Ocean and especially the Beaufort and Chukchi Seas while Non-ODE air masses are arriving from the
474 central Arctic Ocean and Greenland (Fig. 6b and e). The difference between ODEs and Non-ODE air
475 masses during April shows the ODEs are preferentially coming from the central Arctic Ocean (Beaufort
476 and Chukchi Seas) and are spending comparatively less time over Greenland (Fig. 6h). During May, ODE
477 air masses experience the most time over the central Arctic Ocean with a minor contribution from the west
478 coast of Greenland which is similar to the source regions of Non-ODE air masses although with increased
479 contribution from Greenland (Fig. 6c and f). The difference between May ODE and Non-ODE trajectory
480 frequencies shows the central Arctic Ocean is the main source region for ODE air masses and Non-ODE
481 air masses are related to more southerly regions (Fig. 6i).

482

483

485

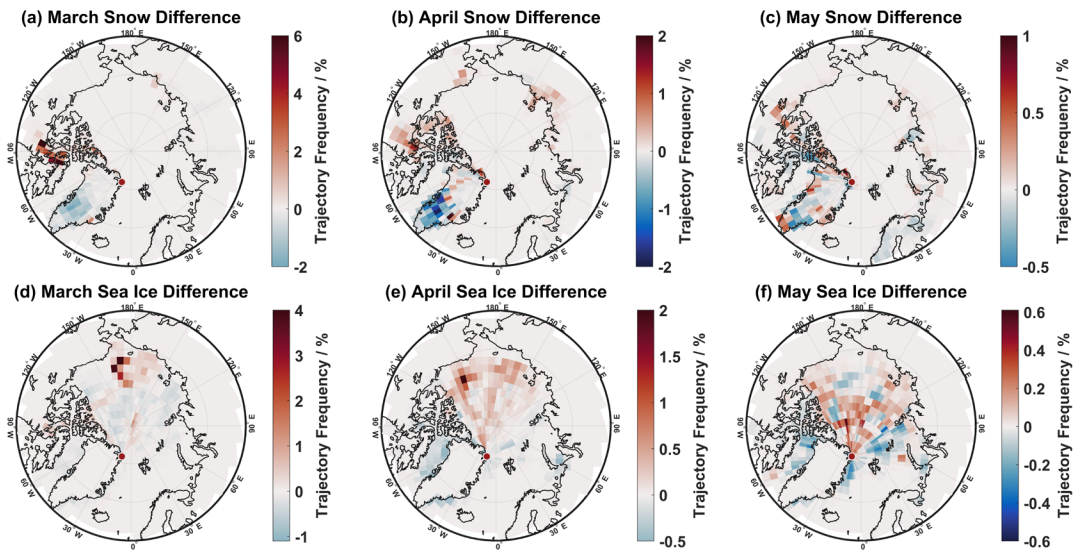

486 **Figure 6.** Trajectory frequency maps for trajectory steps below the mixed layer for (a-c) March, April, May
 487 ODEs, (d-f) March, April, May Non-ODEs, and (g-i) difference between ODE and Non-ODE trajectory
 488 frequencies during March, April, and May at Villum (indicated by the red and white circle).

489

490 To investigate the geographic extent of the different surface types experienced during ODEs and
 491 Non-ODEs, the trajectory frequencies for steps below the mixed layer and over sea ice and snow on land
 492 during ODEs and Non-ODEs were also calculated, the frequencies are displayed in Figs. S6 and S7,
 493 respectively, while the difference is displayed in Fig. 7. For brevity, only the difference between ODE and
 494 Non-ODE trajectory frequencies for each spring month will be discussed. The air mass history variable,
 495 time spent over sea ice, does not give information about the presence of snow cover and only if the
 496 underlying surface was classified as sea ice or not.

497 During March, ODE trajectory steps over snow on land preferentially arrive from the Canadian
 498 Archipelago whilst they arrive less often from Greenland compared to Non-ODEs (Fig. 7a). Trajectory
 499 steps over sea ice during ODEs in March arise from the Chukchi Sea and less often arrive from the central
 500 Arctic Ocean compared to Non-ODEs (Fig. 7d). During April, ODE trajectory steps over snow on land
 501 display a similar pattern to March (Canadian Archipelago) although now with minor contributions from
 502 other continental regions (Greenland, Alaska, and Siberia) compared to Non-ODE air masses (Fig. 7b).

503 Trajectory steps over sea ice during ODEs in April preferentially arrive from the Beaufort and Chukchi
 504 Seas and less often from Baffin Bay compared to Non-ODEs (Fig. 7e). During May, ODE trajectory steps
 505 over snow on land preferentially arrive from the Canadian Archipelago, similar to March and April, but
 506 now with increased contributions from Greenland compared to Non-ODEs (Fig. 7c). Trajectory steps over
 507 sea ice during May ODEs more often arrive from the central Arctic Ocean and less often from more
 508 southerly areas (Baffin Bay, Greenland Sea, and Barents Sea) compared to Non-ODEs (Fig. 7f).
 509 Interestingly, certain areas of the central Arctic Ocean experience more trajectory steps over sea ice during
 510 Non-ODEs compared to ODEs (Fig. 7f), this is likely due to the central Arctic Ocean being a common
 511 source area for air masses below the mixed layer during May (Fig. S7), however, the results point to the
 512 central Arctic Ocean overall being a major source region for ODEs during May.

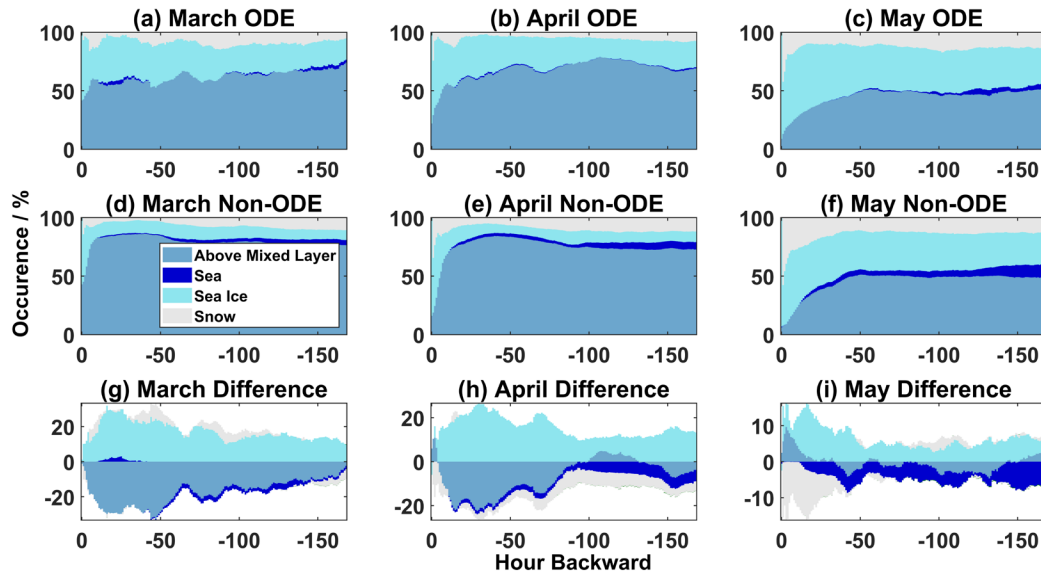

513
 514 **Figure 7.** Difference between ODE and Non-ODE trajectory frequencies for (a-c) trajectory steps below
 515 the mixed layer and over snow on land during March, April, May and for (d-f) trajectory steps below the
 516 mixed layer and over sea ice during March, April, May at Villum (indicated by the red and white circle).

517
 518 The above analysis investigated the geographic extent and surface types experienced by ODE and
 519 Non-ODE air masses, although does not give any temporal information. To further investigate the temporal
 520 relationships between ODEs and air mass history, the relative occurrence of each surface type (sea, sea ice,
 521 or snow on land) and time spent above the mixed layer for each hourly step backward along the trajectories
 522 were calculated. Figure 8 shows the results of this analysis for ODEs on the top (a-c), Non-ODEs in the
 523 middle (d-f), and the difference between ODEs and Non-ODEs on the bottom row (g-i).

524 For ODEs during March and April, air masses spend a similar amount of time above the mixed
 525 layer and over sea ice. However, during March, trajectories experience slightly more time spent over snow
 526 on land and the sea and during April begin their descent later along the trajectory compared to March (Fig.
 527 8a and b). During May, ODE trajectories spend less time above the mixed layer and more time over sea ice,

528 sea, and snow on land compared to March and April (Fig. 8c). For Non-ODEs during March and April a
 529 similar picture is presented, air masses spent a majority of the time above the mixed layer, followed by sea
 530 ice, snow on land, and sea, and the occurrence of each surface type is relatively constant throughout the
 531 length of the trajectory until they begin their descent into the boundary layer (Fig. 8d and e). For Non-ODEs
 532 during May, different air mass history conditions are presented compared to March and April. Air masses
 533 no longer spend a majority of the time overall above the mixed layer (45 % on average) and start to descend
 534 later along the trajectory compared to March and April (Fig. 8f). Instead, air masses experience increased
 535 time below the mixed layer and over sea ice and snow on land with minor increases in time spent over the
 536 sea. The time air masses spend over snow on land is relatively constant throughout the trajectory length
 537 until air masses start to descend. This pattern for Non-ODEs largely reflects the typical air mass history for
 538 the spring months observed at Villum (Pernov et al., 2022). The difference in the occurrence of each surface
 539 type between ODEs and Non-ODEs reveals ODE air masses experience more time over sea ice and less
 540 time above the mixed layer during March and April (Fig. 8g and h). Air masses experience more time over
 541 snow on land during ODEs compared to Non-ODEs when contrasting March and April, while less time
 542 over the sea is experienced during April compared to March (Fig. 8g and h). During May, the main
 543 differences between ODEs and Non-ODEs are more time over sea ice and less time over the sea and snow
 544 on land, interestingly, there is little difference between time spent above the mixed layer except for several
 545 hours before arrival at Villum when ODEs air masses experience more time above the mixed layer (Fig.
 546 8i).

547
 548 **Figure 8.** The occurrence of each surface type trajectories experienced in the previous 168 hours backward
 549 for (a-c) ODEs, (d-f) Non-ODEs, and (g-i) the difference between ODEs and Non-ODEs for March, April,
 550 and May. Note the differences in the y-axis scale for (g-i).

551

552 **3.4. Machine Learning Modelling of ODEs**

553 The statistical analysis of ODEs, meteorological variables, and air mass history variables examines
 554 the relationships between ozone/ODEs and each variable individually and does not consider interactions
 555 between, nor does it give any information about which variables are most important for ODEs. To address
 556 this shortcoming and quantitatively investigate the most important variables for ODEs and how they affect
 557 ODEs, we utilized an ML model in our analysis (see Methods section for further details).

558 The evaluation metrics of the ML for all spring months combined and individual months are
 559 displayed in Table 1. We use three common metrics for evaluating a binary classification ML model:
 560 accuracy, recall, and AUC ROC (Area Under Curve Receiver Operating Characteristics). Briefly, accuracy
 561 is the fraction of correctly predicted observations regardless of label (ODE vs Non-ODE), recall is the
 562 fraction of ODEs correctly predicted, and AUC ROC evaluates how well a model can discriminate between
 563 positive and negative labels across all decision thresholds for binary classification (see Sect. 2.6 for a
 564 detailed description of the evaluation metrics). In general, the ML model can accurately reproduce ODEs
 565 over all spring months combined as evidenced by how all three metrics are close to unity (their maximum
 566 value). However, when evaluating the results on an individual monthly basis, there is an increase in the
 567 recall metric and decrease in the accuracy and AUC ROC from March to May (Table 1), which is likely
 568 connected to the increasing occurrence of ODEs from March to May. With increased ODE occurrence, the
 569 recall metrics would increase as positive labels (ODEs) are more likely to be identified when they occur
 570 more often and the accuracy and AUC ROC metrics would decrease with the increased occurrence of
 571 positive labels due to a concurrent increase in number of incorrectly labeled ODEs. The ML model is also
 572 free from over-fitting given the close agreement between the train and test sets. Overall, this ML model is
 573 sufficiently accurate, robust, and suitable for the investigation of ODEs.

574

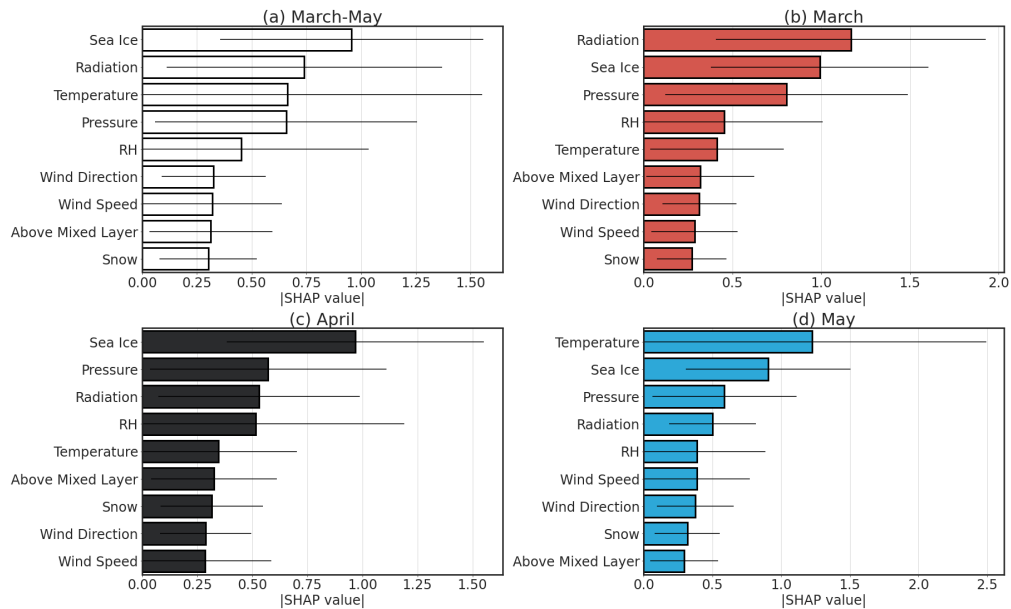

575 **Table 1.** Evaluation metrics of the ML model for the spring months, together and individually. AUC ROC
 576 stands for Area Under Curve Receiver Operating Characteristics. For each metric, the top value represents
 577 the mean of the 10-fold cross-validation score and the value below in parenthesis represents the standard
 578 deviation (see Sect. 2.6 for a description of cross-validation). The shaded column represents the test set
 579 evaluation metrics for clarity. The accuracy gives an overview of the model performance for both labels
 580 (ODEs vs Non-ODEs), recall gives the model performance only for positive labels (ODEs), and AUC ROC
 581 evaluates the model performance over different decision thresholds, together, these three metrics give a
 582 comprehensive view of the model's performance. The three metrics range from 0 (worst) to 1 (best).

	March-May		March		April		May	
	Train	Test	Train	Test	Train	Test	Train	Test
Accuracy	0.886 (0.007)	0.870 (0.010)	0.964 (0.005)	0.955 (0.010)	0.909 (0.013)	0.870 (0.017)	0.858 (0.013)	0.809 (0.026)
Recall	0.811 (0.028)	0.738 (0.034)	0.608 (0.070)	0.504 (0.128)	0.770 (0.044)	0.642 (0.078)	0.896 (0.024)	0.856 (0.047)
AUC ROC	0.936 (0.008)	0.905 (0.012)	0.954 (0.019)	0.911 (0.042)	0.939 (0.014)	0.865 (0.034)	0.944 (0.010)	0.897 (0.021)

583

584 The most important variables in the ML model are explored using SHAP values (Lundberg and
 585 Lee, 2017). The SHAP approach is designed to estimate the importance of each input variable to the model
 586 output based on coalitional game theory (Molnar, 2022) (see Sect. 2.6 for a more detailed description).
 587 SHAP values represent the marginal contribution of each input variable to the model output, or in other
 588 words: how each observation for each variable affects the model’s prediction. SHAP values can be positive
 589 or negative, with positive values indicating a variable is more likely to contribute to an observation being
 590 predicted as an ODE while negative values mean a variable is more likely to contribute to an observation being
 591 labeled as a Non-ODE. The SHAP methodology can produce both local and global explanations. The global
 592 importance gives an overview of the most important variables to the model output. The local
 593 importance of each observation can give information about the relationship between the SHAP and input
 594 values (positive or negative relationship, linear or non-linear), or in other words how does the model output
 595 vary over the range of input values.

596 The mean (\pm standard deviation) SHAP values for each variable during all spring months and
 597 individual months is displayed in Fig. 9. The most important variables overall are time spent over sea ice,
 598 radiation, temperature, pressure, and RH, which are the top variables during all spring months combined
 599 and each month individually, although the order differs slightly, while wind direction, wind speed, time
 600 spent above the mixed layer, and time spent over snow on land are consistently ranked near the bottom
 601 (Fig. 9a-d). During March, the most important variables are radiation, time spent over sea ice, and pressure
 602 (Fig. 9b). During April, time spent over sea ice, pressure, radiation, and RH are indicated as the most
 603 important variables (Fig. 9c). During May, the most important variables are temperature, time spent over
 604 sea ice, pressure, and radiation (Fig. 9d).

605
 606 **Figure 9.** Overall importance of each feature in the ML model during (a) all spring months combined, (b)
 607 March, (c) April, and (d) May. The bars represent the mean of the absolute SHAP value while the lines
 608 represent the standard deviation.

609

610 While the overall importance of each variable in the ML model gives information about which
611 variable has the largest influence on the model output, it does not give information about the nature of the
612 relationship between the SHAP and ambient values for each variable (i.e., how the model output (SHAP
613 values) vary over the range of input values). Here, ambient values refer to the observed values of each
614 variable i.e., the input data into the ML model. We binned the ambient values of each variable into fifteen
615 equally spaced bins and calculated the median SHAP value for each bin, as displayed in Fig. 10. A similar
616 figure is presented in Fig. S9 which shows each month as its own subpanel with the 25th and 75th percentiles
617 included and Figure S10 shows all spring months combined with the 25th and 75th percentiles included.
618 Overall, the results largely agree with the results of the statistical analysis but reveal unique information
619 about each variable during each month and how it affects the model prediction of ODEs. Notably, the
620 presence of certain threshold ranges where the relationship between ambient and SHAP values differs above
621 and below this range. The ranges reported here indicate the lower and upper bin limits for one or more bins.

622 Ambient values of RH are normally distributed in each month and the median SHAP values are
623 negative for RHs below the mode of the distribution and near zero for above-average RH values (Fig. 10a).
624 This indicates that when RH is below average it has a negative effect on the model prediction of ODEs (i.e.,
625 the model is more likely to predict a Non-ODE) and above average RH values have little effect on the
626 model output.

627 Ambient values of wind speed are usually low at Villum ($< 5 \text{ m s}^{-1}$), with values rarely exceeding
628 11 m s^{-1} , and median SHAP values are only positive for the lowest bin during April and May (Fig. 10b).
629 With higher values of wind speed, the median SHAP values are mostly negative except for the 13-19 m s^{-1}
630 range during May and only the 17 m s^{-1} bin during March, although these high speeds rarely occur.

631 For temperature, the ambient values are normally distributed in each month, and interestingly, a
632 threshold value for temperature is observed during all months, with negative median SHAP values observed
633 in the (-10 to -13 °C bin (midpoint of -12 °C) and values centered around zero towards lower temperatures
634 (Fig. 10c).

635 The distribution of radiation during each month is skewed towards lower values and a threshold
636 value for positive median SHAP values is also displayed for this variable as well. At values below the 112
637 to 153 W m^{-2} bin range (midpoint 133 W m^{-2}) radiation makes a negative contribution to the model output
638 and at values above this bin range it contributes positively and the relationship appears to be nearly linear
639 (Fig. 10d).

640 For pressure, the ambient values are all normally distributed in each month. Similar to RH, the
641 relationship between ambient and SHAP values is negative for below-average ambient values, although,
642 for above-average ambient values, the median SHAP value is only positive for the next several bins and
643 becomes negative at very high values of pressure (which rarely occurs though) (Fig. 10e).

644 The most common wind direction at Villum is from the southeast, as observed in previous studies
645 (Nguyen et al., 2016), although only northerly wind directions (288° to 72° bins) exhibit positive median
646 SHAP values (Fig. 10f). This observation is congruent with the statistical analysis of wind direction (Fig.
647 4b) and the origin of ODEs being the central Arctic Ocean (Figs. 6 and 7).

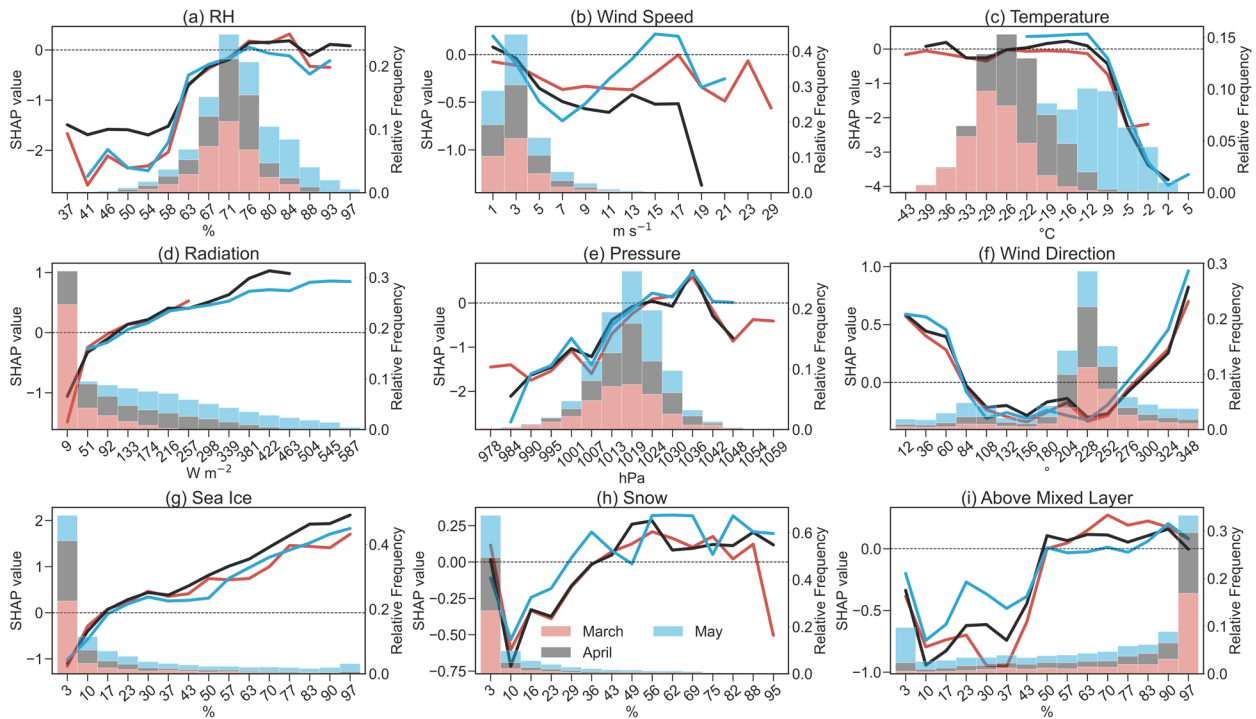

648 The distribution of time air masses spend over sea ice is skewed towards lower values for all three
649 spring months and only during May do values above 50 % occur regularly. The relationship between
650 ambient and SHAP values for time spent over sea ice is almost linear, with higher values of time spent over
651 sea ice increasing the likelihood of an ODE occurring (Fig. 10g). A threshold value for average positive
652 SHAP values for time spent over sea ice is observed at 13 to 19 % bin range (midpoint 17 %) and
653 interestingly, only after 30 % of the time spent over sea ice does the average relationship begin to differ for
654 each month, although still follows a linear pattern indicating a slightly different sensitivity towards exposure
655 to sea ice and ODEs.

656 For time spent over snow on land, the distribution is more skewed towards lower values when
657 compared to time spent over sea ice. The relationship between ambient and SHAP values for time spent
658 over snow on land is complex and non-linear (Fig. 10h). The mode of time spent over snow on land is also
659 the lowest value and appears to have little effect on the model output, however, the second most often
660 occurring bin for time spent over snow on land shows a strongly negative effect. After the third bin, SHAP
661 values increase almost linearly and on average become positive at 32-39 % bin range (midpoint 36 %)
662 during March and April and 26 to 32 % bin range (midpoint 29 %) during May. During all spring months,
663 the SHAP values reach a plateau around 56 % of time spent over snow on land, after which, increasing time
664 spent over snow on land has little effect on the model prediction of ODEs (Fig. 10h).

665 The relationship between ambient and SHAP values for time spent above the mixed layer shows
666 negative contributions until a threshold range of 46 to 53 % (midpoint 50 %) is reached after which slightly
667 positive is observed (Fig. 10i).

668

669

670

671 **Figure 10.** The relationships between SHAP and ambient values for (a) RH, (b) wind speed, (c),
 672 temperature, (d) radiation, (e) pressure, (f) wind direction, time air masses spent over (g) sea ice, (h)
 673 snow on land, and (i) time above the mixed layer for each month. Fifteen equally spaced bins were calculated for
 674 each variable, and the median of the SHAP values was computed for each bin, as represented by the colored
 675 lines. The value listed on the x-axis is the midpoint of each bin. The colored bars represent a histogram of
 676 the ambient values for each month. The relative frequency of each histogram bin for each variable is
 677 displayed on the right axis. The legend is the same for the colored lines and bars.

678

679

680 4. Discussion

681 4.1. Overview of ozone and ozone depletion events

682 Overall, the seasonal cycle of ozone at Villum displays a similar pattern observed at other coastal High
683 Arctic sites that experience ODEs (Barrie et al., 1988; Eneroth et al., 2007; Law et al., 2023; Schroeder et
684 al., 1998; Whaley et al., 2023), with elevated values during winter, highly variable and minimum values
685 during spring, low values during summer, and increasing values during the autumn. The elevated values
686 during winter are due to the efficient transport of anthropogenic pollution from the mid-latitudes (Stohl,
687 2006), descending air masses bringing ozone-rich air into the boundary layer (Hirdman et al., 2010), and
688 inefficient removal mechanisms (absence of sunlight, reduced dry deposition due to a stably stratified
689 atmosphere, snow coverage, and minimal wet scavenging). The minimum values observed during spring
690 are due to ozone depletion events (ODEs) (Helmig et al., 2007a; Simpson et al., 2007b) caused by reactions
691 with halogen species (Simpson et al., 2015; Yang et al., 2020). The maximum ozone values occurring in
692 April are likely due to the maximum transport efficiency of anthropogenic pollution from the mid-latitudes
693 during this period (Stohl, 2006) as well as stratospheric intrusions of dry, ozone-rich air (Helmig et al.,
694 2007b; Liang et al., 2009).

695 The ODE frequency and duration display an increasing pattern from March to May which is likely
696 due to air masses spending more time within the mixed layer and over sea ice coupled with increased
697 amounts of radiation, as these variables are all important for ODEs (Fig. 9) and show a similar seasonal
698 progression from March to May (Fig. 5). The geographic origin of ODEs within the mixed layer also shows
699 a seasonal progression from March to May, with sources being more distant during March and progressively
700 moving closer to Villum during April and May (Figs. 6 and 7). The ODE frequency at Zeppelin follows a
701 similar season progression with ODEs occurring more often in late spring compared to early spring (Solberg
702 et al., 1996; Zilker et al., 2023).

703 The ODE frequency and duration trends are positive during May ($0.49 [-0.23, 1.2] \% \text{ yr}^{-1}$, $>85^{\text{th}}$ %
704 CL) and April ($0.2 [0, 0.53] \text{ h yr}^{-1}$, $>95^{\text{th}}$ % CL), respectively (Fig. 3). There appears to be no SS trends in
705 the start, end, or range of ODE days for any spring month (Fig. S3). SS positive trends in ODE frequency
706 of $0.54 [\pm 0.26]$ (slope $[\pm 95 \% \text{ CI}]$) have been observed at Utqiagvik (formerly known as Barrow), Alaska
707 only during March over the period 1973-2010 (Oltmans et al., 2012). A tendency for positive ODE
708 frequencies trends throughout the lowest level of ozonesonde measurements has also been observed at
709 Canadian Arctic sites at Alert ($0.19 [\pm 0.53] \% \text{ yr}^{-1}$, 1987-2020), Eureka ($0.79 [\pm 0.83] \% \text{ yr}^{-1}$, 1991-2020)
710 and Resolute ($0.60 [\pm 0.30] \% \text{ yr}^{-1}$, 1966-2020) (Law et al., 2023; Tarasick and Bottenheim, 2002), which
711 are similar in magnitude to the positive trend observed in this study. These positive trends in ODE
712 frequencies around the Arctic and the trends in ODE frequency and duration at Villum could be connected
713 to multiple causes: an increase in springtime tropospheric BrO in the Arctic as observed from satellites
714 (Bougoudis et al., 2020), the increase in Arctic sea salt aerosol due to multi-year ice being replaced with
715 first-year ice (Confer et al., 2023), changing transport patterns (Heslin-Rees et al., 2020; Koo et al., 2014),
716 increasing frequency of re-freezing leads (Yang et al., 2020), or increasing salinity of surface snow which
717 release halogen compounds to the atmosphere (Peterson et al., 2018; Pratt et al., 2013; Simpson et al.,
718 2005). Further research is required to elucidate the underlying causes of these trends as well as the positive
719 trends in ozone mixing ratios observed at Villum (Law et al., 2023).

720

721

722 4.2. Dynamics of ODEs in relation to meteorological variables and air mass history

723 Our investigation into the dynamics of ODEs at Villum, through a statistical analysis and ML modeling
724 approach, indicates that ODEs are connected to clear (high amounts of radiation), calm conditions (cold
725 temperatures, high pressures, and low wind speeds) with air masses arriving from a northerly direction
726 having experienced surface contact with sea ice (northerly wind directions and air masses experiencing a
727 high amount of time over sea ice in the central Arctic Ocean). Our ML model revealed the most important
728 variables are similar throughout each month (time air masses spent over sea ice, radiation, temperature, and
729 pressure) but exhibit different orders (Fig. 9). This indicates that the ML model can discern the overall
730 conditions leading to ODEs but also reveal distinct circumstances in each month. For instance, the time air
731 masses spent over sea ice was consistently among the top variables for each month, which likely indicates
732 the release of halogen species from sea ice (or snow on top of sea ice) is a key condition for the observation
733 of ODEs at Villum. During March, the most important variable is radiation, whilst during May it is
734 temperature. Interestingly, these two variables (radiation and temperature) are often limited during these
735 months (March and May), with low values of radiation during March and temperatures closer to 0 °C during
736 May (Fig. 5d and c, respectively). In the following paragraphs, we discuss each variable's relation to ODEs
737 for each spring month through our statistical analysis, ML modeling, and back-trajectory source regions.

738 Solar radiation is required for the photolysis of molecular halogen species (Peterson et al., 2018;
739 Pratt et al., 2013; Raso et al., 2017; Wang et al., 2019). The results presented in Fig. 4e show that ODEs
740 can occur across all values of radiation during April and May whilst March shows a clearer dependency.
741 Only during March were solar radiation medians significantly different during ODEs and Non-ODEs (Fig.
742 5d) and solar radiation appears to be a limiting factor. During April and May, sunlight is omnipresent,
743 therefore a clear lack of dependency for ozone mixing ratios and normalized ODE hours with radiation is
744 not unexpected. This is supported by the high importance of radiation in the ML model during March
745 compared to April and May (Fig. 9b). The results from the statistical analysis suggest that while the
746 presence of solar radiation is required, the intensity is not a limiting factor for the occurrence of ODEs.
747 However, the relationships between ambient and SHAP values of radiation indicate there is a near-linear
748 relationship (Fig. 10d), which highlights the added value of ML modeling. Alternatively, this could be due
749 to ODEs resulting from the advection of previously depleted air masses, and in situ solar radiation
750 measurements are not indicative of conditions along the trajectory path (although solar radiation exhibits a
751 high degree of autocorrelation over all relevant lags) or in regions where depletion is occurring (Bottenheim
752 and Chan, 2006; Halfacre et al., 2014). It should be noted that solar radiation measurements started in the
753 autumn of 2014 thus only five years of data are included in the statistical analysis while the ML model was
754 supplemented with radiation from ERA5 (see Methods), this could also contribute to the discrepancy
755 between analysis methods.

756 Cold temperatures have been shown to be an important factor influencing ODEs (Simpson et al.,
757 2007b, 2015), indeed reactions on acidic, frozen heterogeneous surfaces can lead to the release of bromine,
758 which is known from studies using reanalysis products (Seo et al., 2020; Zilker et al., 2023), laboratory
759 experiments (Abbatt et al., 2012; Halfacre et al., 2019), and mesocosm/field studies (Gao et al., 2022; Pöhler
760 et al., 2010; Pratt et al., 2013; Swanson et al., 2020). Cold temperatures also facilitate calcium carbonate
761 precipitation from sea ice which acidifies and lowers the buffering capacity of the salty sea ice surface thus

762 promoting halogen release (Sander et al., 2006). Observational evidence has shown halogen activation
763 ceases at above-freezing temperatures (Burd et al., 2017; Jeong et al., 2022). While several studies have
764 reported a temperature dependency of ODEs (Koo et al., 2012; Pöhler et al., 2010; Tarasick and Bottenheim,
765 2002; Zeng et al., 2006), other studies have not (Halfacre et al., 2014; Jacobi et al., 2010; Neuman et al.,
766 2010; Solberg et al., 1996). Any relationship between ODEs and temperature is likely a result of air masses
767 having surface contact with the cold Arctic Ocean before arriving at Villum, where cold temperatures aid
768 in the re-freezing of leads as well as formation of sea ice and frost flowers (Kaleschke et al., 2004; Yang et
769 al., 2020), all of which are known halogen sources. Cold temperatures could also indicate the presence of
770 a temperature inversion, which traps oxidants and ozone near the surface and inhibits vertical mixing, which
771 replenishes ozone and terminates ODEs (Moore et al., 2014). Temperature has the greatest influence on
772 ODEs during May (Fig. 9d), which is the only month which regularly experiences temperatures above the
773 threshold range of -10 to -13 °C found through our ML model analysis (Figs. 4, 5, and 10). Similar to
774 radiation, the temperature used in this analysis does not necessarily represent the temperature where ozone
775 depletion occurred, although temperature is usually highly correlated to previous days' measurements and
776 therefore gives a good indication of the temperature upwind of Villum. Therefore, this temperature
777 threshold range should not be interpreted as absolute but rather as the existence of a threshold where
778 temperature has little effect below and a negative contribution to ODEs above. This observation could help
779 explain the contradictory evidence about a temperature dependence for ODEs. Depending on the local
780 conditions of the measurement site, ODEs might be observed at temperatures below this threshold range
781 (which would indicate no relationship) or above this threshold range (where ODEs show a negative
782 relationship with temperature). This threshold range would be site specific and emphasizes the need for
783 Pan-Arctic assessments of the temperature dependency of ODEs.

784 Above-average values of RH are revealed to be conducive to ODEs through our statistical and ML
785 model analysis (Figs. 4, 5, and 10). A relationship between RH and ODEs in the Arctic has not been reported
786 in the literature before (to the authors' knowledge) and the physical mechanism behind this observation
787 remains unclear. However, the relationship between RH and ozone has been explored in Antarctica by Frieß
788 et al. (2023), who showed negative correlations at Neumayer and Arrival Heights, supporting observations
789 made in this study. We hypothesize that the higher normalized ODE hours (Fig. 4a) and positive SHAP
790 values (Fig. 10a) for above-average RH values during ODEs are likely connected to air masses spending
791 time over the central Arctic Ocean where RH would be higher due to the cold temperatures and escape of
792 water vapor through open leads and polynya (Bintanja and Selten, 2014; Boisvert et al., 2015). The lower
793 values of normalized ODE hours (Fig. 4a) and negative SHAP values (Fig. 10a) for below-average RH
794 could also be related to drier air masses having experienced higher altitudes during transport to Villum,
795 which are ozone-rich and less influenced by the surface (Moore et al., 2014).

796 Northerly wind directions are more common during ODEs compared to Non-ODEs (Fig. S6),
797 corresponding to low ozone values, high normalized ODE hours, and positive SHAP values (Figs. 4b and
798 10f). A similar observation was made at Utqiaġvik/Barrow, Alaska, for low ozone mixing ratios showing a
799 clear minimum when wind arrived from northerly directions (Helmig et al., 2012). Halfacre et al. (2014)
800 used buoy measurements from the Beaufort Sea of ozone and air mass direction to show that northerly
801 directions were dominating but easterly and westerly directions also made a contribution, showing that in
802 the central Arctic Ocean wind direction has less of an influence due to the omnidirectional presence of sea
803 ice. These observations are directly related to the presence of sea ice in a northerly direction relative to
804 these land-based stations (Fig. 1).

805 Wind speed can have dual effects on ozone variability, with low wind speeds corresponding to a
806 stable boundary layer where reactants are confined to a small volume and high wind speeds generating
807 blowing snow, which acts as a source of reactive halogen species as well as favoring advection of air masses
808 previously depleted in ozone (Jones et al., 2009; Swanson et al., 2020). The distribution of wind speeds
809 during March and April were consistently higher for ODEs compared to Non-ODEs, this relationship is
810 reversed for May (Fig. 5b) but in all months relatively low wind speeds prevailed ($< \sim 3 \text{ m s}^{-1}$). Our statistical
811 analysis revealed no relationship between wind speeds and ozone mixing ratios/normalized ODE hours
812 during March, a tendency for high normalized ODE hours with higher wind speeds during April (although
813 little effect on ozone mixing ratios), and two modes during May (one at low and one at high wind speeds)
814 (Fig. 4c). The ML model also showed a similar relationship during May (positive SHAP values at low and
815 high wind speeds), although these high wind speeds did not occur very often. Overall, wind speeds are
816 usually low at Villum (Figs. 4c, 5b, and 10b; Nguyen et al. (2016)). Low ozone mixing ratios concurrent
817 with low wind speeds have also been observed at Utqiagvik/Barrow, Alaska, at Zeppelin Observatory on
818 Svalbard, and from buoy measurements in the Arctic Ocean (Bottenheim et al., 2009; Halfacre et al., 2014;
819 Helmig et al., 2012; Solberg et al., 1996). Conversely, enhanced BrO events at Zeppelin, Eureka, and Alert
820 as well as for the Arctic region have been connected to high wind speeds, mostly likely related to stormy
821 conditions that generate blowing snow (Seo et al., 2020; Swanson et al., 2020; Zhao et al., 2016; Zilker et
822 al., 2023). In the Antarctic, positive correlations between wind speed and surface ozone were observed
823 during spring at Arrival Heights but not at Nuemayer, likely due to Arrival Heights being more influenced
824 by local topography effects (Frieß et al., 2023). The results of our statistical and ML model analysis suggest
825 that ODEs at Villum occur mainly under stable conditions with low wind speeds and are likely not
826 connected to the generation of halogen species through blowing snow and Arctic cyclones. High wind
827 speeds can also enhance vertical mixing of ozone enriched air masses from aloft, which could mask the
828 contribution of halogen activation from blowing snow. Only during May does high wind speeds regularly
829 make a positive contribution to the model output, and the magnitude of this contribution is small (Fig. 10b).
830 Overall, the rare occurrence of high wind speeds (Fig. S4b) hinders any definitive conclusions about their
831 effect on ODEs.

832 Distributions of pressure are consistently higher for ODEs compared to Non-ODEs during each
833 spring month (Fig. 5e) and above-average pressure is related to the occurrence of ODEs as shown through
834 our statistical analysis (Fig. 4f) and our ML model (Fig. 10e). High-pressure systems could indicate the
835 presence of a stably stratified lower troposphere and low-pressure systems could signal the passage of
836 frontal systems which are conducive for strong vertical mixing (which bring ozone rich down from aloft)
837 and a break up of inversion layers (Hopper et al., 1998; Jacobi et al., 2010; Simpson et al., 2015). Ozone
838 and atmospheric pressure have been shown to be anti-correlated during spring in the Arctic Ocean (Jacobi
839 et al., 2010). Conversely, low pressures have been associated with ODEs at Zeppelin (Zilker et al., 2023)
840 and BrO enhancement events over the Arctic region (Blechschmidt et al., 2016; Seo et al., 2020) and at
841 Eureka, Canada (Zhao et al., 2016), where they were related to polar storms and blowing snow generation
842 of reactive halogens. The pressure dependence of ODEs found at Villum is congruent with the relationship
843 for wind speed (Fig. 10b) and further suggests that Arctic cyclones and blowing snow do not have an
844 important effect on ODEs at Villum. Furthermore, very high values of pressure are likely associated with
845 descending air masses from aloft which are often enriched in ozone and contain few sources of halogen
846 species (Simpson et al., 2007b; Peterson et al., 2015; Swanson et al., 2020), which could explain the

847 negative SHAP values at high values of pressure although it should be noted that these values do not occur
848 often (Fig. 10e).

849 Heterogeneous, photochemical reactions on the snowpack have been demonstrated to be a source
850 of reactive halogen species (Pratt et al., 2013; Raso et al., 2017; Peterson et al., 2018; McNamara et al.,
851 2020; Custard et al., 2017), as well as the generation of blowing snow at high wind speeds and subsequent
852 release of reactive halogens (Jones et al., 2009; Marelle et al., 2021; Chen et al., 2022; Swanson et al., 2022;
853 Zilker et al., 2023; Frieß et al., 2023). Air masses spend little time over snow on land during each spring
854 month (Fig. S4g) and on average ODEs actually experience less time over snow on land compared to Non-
855 ODEs (Fig. 5h). Non-ODEs experiencing more time over snow on land is likely tied to the different regions
856 of snow on land contact for Non-ODEs (southern half of Greenland) (Fig. S6d-f), while source regions of
857 air mass contact with snow on land during ODEs are consistently in the Canadian Archipelago and
858 Greenlandic coasts during the spring months (Fig. S6a-e). The Canadian Archipelago has been
859 demonstrated to be a hotspot for BrO enhancements (Bognar et al., 2020; Bougoudis et al., 2020; Seo et al.,
860 2020), which has been connected to low pressure and high wind speeds suggesting blowing snow to be a
861 source of halogen species in this region. Contributions from other continental regions (Alaska and Siberia)
862 to snowpack exposure only appear in April (Fig. 7b), which could reflect the greater extent of the polar
863 dome during this month (Stohl, 2006). Snowpack located on the west coast of Greenland only appears to
864 contribute to ODEs during May (Fig. 7c), this could be related to air masses spending more time below the
865 mixed layer during May compared to other months (Fig. 5h). Our statistical analysis suggests there is no
866 clear dependency of ozone mixing ratios and normalized ODE hours on varying amounts of times spent
867 over snow on land (Fig. 4h). Our ML model revealed that low values of time spent over snow on land
868 contributes negatively whereas after a threshold range of 26-39 % (depending on the month), time spent
869 over snow on land makes a small positive contribution to the model output that varies little with increasing
870 values (Fig. 10). This is supported by the back-trajectory analysis, which showed that ODE air masses are
871 not preferentially experiencing more time over snow on land during any particular point along the trajectory
872 length compared to Non-ODEs (Fig. 8g-i). High amounts of time spent over snow on land are uncommon
873 during each spring month, therefore, it is difficult to assess the importance of snowpack mechanisms on
874 ozone depletion at Villum. Generation of halogen species in the Canadian Archipelago, either through
875 snowpack emissions or blowing snow at higher wind speeds, appears to consistently make a minor influence
876 on ODEs during each spring month.

877 Sea ice sourced halogens have been indicated to be responsible for halogen generation necessary
878 for ozone depletion in the Arctic (Simpson et al., 2007b; Halfacre et al., 2014; Simpson et al., 2015; Burd
879 et al., 2017; Yang et al., 2020; Marelle et al., 2021; Brockway et al., 2024) and Anantarctic (Frieß et al.,
880 2023). It should be noted that the snowpack on top of sea ice is the likely source of these halogens, given
881 that the surface of sea ice is not conducive for halogen activation (Abbatt et al., 2012), although the satellite
882 product used in this study cannot differentiate between snow covered sea ice and bare sea ice (see Methods).
883 The amount of time spent over sea ice increases from early to late spring (Fig. S4f) and ODE air masses
884 experience higher values of time over sea ice during each spring month compared to Non-ODEs (Fig. 5f).
885 Our statistical analysis displays increased (decreased) normalized ODE hours (ozone mixing ratios) with
886 higher values of time spent over sea ice (Fig. 4g), which is congruent with the ML model showing higher
887 SHAP values for more time spent over sea ice. This relationship is linearly, positive and on average
888 becomes positive after the 13 to 19 % threshold range (Fig. 10g). Indicating that air masses need to spend
889 only a fraction of time over sea ice for it to increase the probability of observing an ODE at Villum. The

890 back-trajectory analysis shows that ODE air masses experience more time over sea ice closer to the
891 measurement site compared to Non-ODEs (Fig. 8g-i). It has been found that ODEs can be the result of the
892 transport of previously depleted air masses, where ozone depletion was occurring relatively far (several
893 hundred kilometers) from the observation point (Halfacre et al., 2014; Tarasick and Bottenheim, 2002;
894 Yang et al., 2020). As the spring progresses from March to May, it appears that the main ODE geographic
895 source regions for sea ice contact are moving closer to Villum each month (Fig. 7d-f). During March, ODEs
896 are initiated over the Chukchi Sea, which is usually covered by first-year sea ice (FYI) (Fig. 1). During
897 April, ODE air mass source regions are located over the Beaufort and Chukchi Seas but also over the central
898 Arctic Ocean, which represents a mix of FYI and multi-year sea ice (MYI). During May, ODE air mass
899 source regions are in closer proximity to Villum, mainly arriving from the central Arctic Ocean, which
900 contains the highest concentration of MYI. This source region analysis is supported by the wind
901 sector/speed analysis, which displays a northerly wind direction dependency for ODEs during each spring
902 month (Figs. 4b, S5, and 10f). During March and April, wind speeds during ODEs are consistently higher
903 compared to Non-ODEs whilst, during May, wind speeds are lower (Fig. 5b). This could indicate that in
904 March ODEs likely result from the transport of ozone-depleted air masses from FYI regions, April
905 experiences a mixture of transport-related ODEs and ODEs occurring closer to Villum from FYI and MYI
906 regions, whilst May ODEs occur in proximity to the measurement site, arriving mainly from regions with
907 MYI but also with influences from FYI in the central Arctic Ocean. This is supported by Herrmann et al.
908 (2022), who suggested that MYI makes important contributions to ozone depletion at Villum, and by
909 Marelle et al. (2021) who showed that both snowpack emissions and blowing snow can contribute to ozone
910 depletion, although sea ice surfaces were responsible for regional ozone depletion and halogen activation.
911 It should be noted that this analysis is based on trajectory frequency maps and average sea ice age over the
912 observation period and a more detailed investigation of sea ice age would help elucidate the exact
913 contribution of FYI and MYI on ODEs.

914 While this and previous work point towards ODEs being a surface-related process through the
915 generation of reactive halogen species from sea-ice and snowpack mechanisms, the activation of halogen
916 species on aerosol particles aloft has also been demonstrated in the Arctic (Bognar et al., 2020; Peterson et
917 al., 2017; Seabrook and Whiteway, 2016; Solberg et al., 1996). In the Antarctic, strong, positive correlations
918 between aerosol extinction and BrO mixing ratios have been observed during spring (Frieß et al., 2023).
919 A general feature of the distributions for ODEs and Non-ODEs when progressing from March to May is
920 that trajectories spend increasingly less time above the mixed layer (Fig. 5h). Our statistical analysis
921 indicates that, in general, ODEs are more likely to occur and ozone mixing ratios are more likely to be
922 lower when air masses spend more time near the surface (Fig. 4i). Although ODE trajectories spend less
923 time above the mixed layer compared to Non-ODEs trajectories (Figs. 5h and 8g-i), they are still spending
924 a considerable amount of time aloft as the median time spent above the mixed layer only drops below 50
925 % during May (Fig. 5h). The recycling of halogen species on lofted aerosol particles could explain the
926 ODEs experiencing a significant amount of time above the mixed layer. This would be especially relevant
927 for the earlier spring months (March and April) given the burden of acidic, tropospheric aerosols (i.e., Arctic
928 Haze) is greatest during these months (Flyger et al., 1980; Heidam et al., 1999, 2004; Nguyen et al., 2013,
929 2016) and the increased amount of time air masses spend above mixed layer during these months. Our ML
930 model revealed on average a positive contribution at > 46 to 53 % threshold range of time spent above the
931 mixed layer (Fig. 10i). A physical explanation for our ML results for the time above the mixed layer SHAP
932 values could be that ozone is initially depleted within the boundary layer followed by lifting above the

933 boundary layer and remain depleted either through inhibited mixing with ozone rich air (Moore et al., 2014),
934 decreased mixed layer height with frequently occurring surface temperature inversions (Pilz et al., 2024),
935 or halogen recycling on acidic aerosol particles aloft (Peterson et al., 2017). This could also be due to the
936 time spent over mixed layer being calculated over the entire trajectory length and therefore is not time
937 resolved. It is also important to note that SHAP values represent how well these variables explain the
938 behavior of our target variable in our ML model and not how well the input variables explain the behavior
939 of our target variable in the natural environment.

940 To understand the conditions leading to a correct model prediction for the input variables and
941 investigate the cause of the relationship between ambient and SHAP values for time spent above the mixed
942 layer, we calculated the distribution of ambient and SHAP values for correctly and incorrectly labeled
943 observations of ODEs and Non-ODEs for all spring months combined and each month individually. The
944 results for the ambient and SHAP value distributions are displayed in Fig. S11 and S12, respectively. The
945 variables with the largest differences in the distribution of correct vs incorrect ODEs are time spent above
946 the mixed layer, time spent over sea ice, and radiation, whilst RH, time spent over snow on land, wind
947 direction, and wind speed showed little differences (Fig. S11). The variables with the largest differences
948 are also indicated as the most important variables and variables with little differences were shown to be the
949 least important (Fig. 10), except for time above the mixed layer. Temperature displays a large difference
950 between correct and incorrectly labeled ODEs when evaluating all spring months combined but when
951 analyzing individual spring months, this difference is diminished, which likely is a result of the seasonal
952 progress of warmer temperatures later in the spring (Fig. 5c). The distributions for SHAP values between
953 correctly and incorrectly labeled ODEs shows that time spent over sea ice SHAP values experienced the
954 largest difference for all spring months combined and each individual month (Fig. S12). Other variables
955 showing large differences in the distribution of SHAP values include pressure, temperature, radiation, and
956 wind direction. Time spent above the mixed layer did not show large differences between correctly and
957 incorrectly labeled ODEs, likely a result of the small magnitude of the SHAP values for time spent above
958 the mixed layer, indicating this variable does not largely contribute to the model output (Fig. 9), therefore,
959 while this relationship is counterintuitive it is not affecting the accurate prediction of ODEs in our ML
960 model. The large differences between the distribution of time spent above the mixed layer for correctly vs
961 incorrectly labeled ODEs could be the underlying cause of the counterintuitive relationship between
962 ambient and SHAP values for this variable displayed in Fig. 10, this could also be a result of ODE
963 trajectories experiencing a majority of time above the mixed layer further back along the trajectory length
964 (Fig. 8a-c). Other factors that could contribute to this relationship include the length of the back-trajectory
965 (trajectories experience comparatively more time above the mixed layer further backward),
966 misrepresentation of the mixed layer height from the HYSPLIT model (too low of a mixed layer height
967 would result in a larger fraction of air masses above this altitude), the uncertainty of HYSPLIT increases
968 proportionately with the trajectory length, and the starting altitude of the back-trajectories being too high
969 (higher starting altitude would result in a larger fraction of air masses residing above the mixed layer).
970 Proper representation of air mass history therefore is an important aspect of evaluating ODEs and other
971 atmospheric phenomena and future studies should evaluate this in more detail including the effects of
972 varying trajectory lengths, the accuracy of the mixed layer height from HYSPLIT, and starting altitude at
973 the receptor location. Overall, this shows the ability of ML to identify the appropriateness of input variables
974 for modeling atmospheric phenomena and suggests that the importance of time spent above the mixed layer

975 and time spent over sea ice might be over- and under-estimated, respectively, as the ML model mis-
976 characterizes their effect on ODEs.

977

978

979 5. Summary and Outlook

980 ODEs occur every spring with an increasing frequency from early to late spring. This seasonal pattern is
981 the result of higher amounts of radiation, air masses spending more time within the mixed layer and over
982 sea ice, and source regions for air mass contact with sea ice (and thus ozone depletion) moving closer to
983 Villum from March to May. ODE duration and frequency displayed positive trends during April and May,
984 respectively, however, we have low confidence in the frequency trend. Positive trends in ODE frequency
985 at other Arctic sites suggest this is a Pan-Arctic phenomenon. Possible causes for the positive trends in
986 duration and frequency of ODEs include more FYI, BrO, saltier snowpack, changing transport patterns,
987 and increased occurrence of refreezing leads.

988 ODEs are likely to occur during clear (high amounts of radiation), calm (cold temperatures, high
989 pressure, low wind speeds) conditions with air masses arriving from northerly wind directions with sea ice
990 contact (high time over sea ice, high RH). Time spent over sea ice, radiation, temperature, and pressure are
991 shown to be the most important factors affecting ODEs. The most important variable affecting ODEs
992 changes as spring progresses are radiation during March, sea ice during April, and temperature during May.
993 During March and May, radiation and temperature are often the limiting factors, with smaller amounts of
994 radiation observed during March and warmer temperatures observed during May. The source regions for
995 ozone depletion also change as spring progresses. During March, sea ice (likely FYI) in the Chukchi Sea is
996 the main source region for ODE air masses. During April, a mix of FYI and MYI in the Chukchi and
997 Beaufort Seas and the central Arctic Ocean are the main source regions for ODEs. During May, sea ice
998 (likely a mix of FYI and MYI) in the central Arctic Ocean is the main ODE source region. Air masses
999 experiencing snowpack contact within the mixed layer from the Canadian Archipelago make a consistent
1000 yet minor contribution during each spring month. The back-trajectory and wind speed analysis indicate that
1001 ozone depletion occurs upwind of Villum during early spring and moves progressively closer towards
1002 Villum during late spring.

1003 We show that ODEs can be accurately predicted using ML modeling, with physically interpretable
1004 results. We also show that ML can be a useful tool for investigating atmospheric phenomena, by quantifying
1005 the importance of each variable, identifying threshold ranges for positive contributions, and investigating
1006 the appropriateness of input variables. Of the sources leading to halogen emission (sea ice or snow on top
1007 of sea ice, snowpack on land, and recycling on aerosol particles aloft), our results suggest that emissions
1008 from sea ice regions are the most important.

1009 While this work has made progress in understanding the dynamics of ozone depletion in the Arctic,
1010 further investigation is warranted. Recent research has shown that ozone mixing ratios are increasing around
1011 the Arctic (Christiansen et al., 2022, 2017; Cooper et al., 2020; Law et al., 2023), coupled with the positive
1012 trend in Pan-Arctic ODE frequencies and the positive trend in ODE duration observed in this study, suggest
1013 that the factors controlling ozone variability are being altered and warrant a detailed investigation into the
1014 underlying causes. Recently, iodine has been shown to be as important as bromine to ozone destruction in
1015 the central Arctic Ocean (Benavent et al., 2022), further studies investigating this discovery at Pan-Arctic
1016 stations are needed to evaluate iodine's role in ozone depletion over the entire Arctic region, ML could aid
1017 in this task. Future studies investigating ozone and ODE dynamics would benefit from the incorporation of
1018 direct measurements of halogen species to investigate different chemical regimes of ozone destruction,
1019 which will help predict the response of springtime ozone dynamics in a future climate. Direct halogen

1020 measurements will also help elucidate the cause of ODE initiation, duration, and termination as well as
1021 determine if ODEs are the result of the transport of already depleted air masses or if ODEs are occurring
1022 locally at Villum. Incorporating time-resolved air mass history variables and air-mass exposure to first- and
1023 multi-year ice sea ice concentration would help clarify the role of different cryosphere environments in
1024 ozone destruction. Analyzing meteorological conditions along the trajectory path (e.g., temperature and
1025 radiation) would help extrapolate the observations from individual stations to the larger Arctic region.
1026 Future studies should also consider the vertical structure of the lower atmosphere (i.e., the mixed layer
1027 height and its variability) when initializing trajectory calculation as this can have an effect on the air mass
1028 history, although this can be computationally challenging for a multi-decadal dataset. While this and many
1029 other studies investigate ozone at the surface, the radiative forcing of ozone is largely determined by its
1030 vertical distribution (Lacis et al., 1990; Stevenson et al., 2013), therefore, studies investigating the vertical
1031 as well as the horizontal distribution are needed. This could be accomplished through the use of tethered
1032 balloons deployed at ground-based stations or directly on the sea ice (Pilz et al., 2022; Pohorsky et al.,
1033 2024).

1034 The added value of ML modeling over classical statistical analysis is highlighted by identifying
1035 variable importance, quantitative relationships, threshold ranges, and input variable deficiencies. While a
1036 statistical analysis can qualitatively identify relationships, ML can identify synergistic efforts regarding
1037 interactions between variables, indicating the right mix of conditions is necessary for ODEs to occur – high
1038 sea ice contact, high amounts of radiation, cold temperatures, and high pressure. The ML methodology
1039 could be applied to other Arctic stations, either individually or utilizing multi-station (e.g., ground-based,
1040 ship-based, buoys) merging techniques for Pan-Arctic modeling of ODEs, where the environmental drivers
1041 of ODEs could be investigated from a geographic perspective. This would be especially pertinent for
1042 measurements performed over sea ice, where the actual ozone destruction is likely occurring. ML modeling
1043 could also be used to investigate other atmospheric phenomena such as AMDEs and BrO enhancement
1044 events and for bias-correcting chemical transport models.

1045 The results from our ML model largely agree with our statistical analysis and are physically
1046 meaningful/interpretable but also reveal threshold ranges for certain variables that are not evident otherwise
1047 and can help predict the response of ODEs in a future climate. Rising temperatures in the Arctic (Rantanen
1048 et al., 2022) could affect ODEs through earlier onset of melt days by ceasing halogen emissions. The
1049 temperature relationship displayed in this study (Fig. 10c) indicates that rising temperatures would have the
1050 biggest effect in May and would not start to negatively affect ODEs until they rise above the threshold
1051 range of -10 to -13 °C. Arctic sea ice is rapidly diminishing (Kwok, 2018; Stroeve and Notz, 2018) and the
1052 Arctic Ocean is projected to be completely ice-free during summer in the coming decades (Kim et al., 2023;
1053 Notz and Community, 2020), which will have profound effects on ODEs (Simpson et al., 2007b, 2015).
1054 Retreating sea ice would have a major effect on ODEs when sea ice loss is propagated into the springtime
1055 and these effects would be most profound in May. Conversely, retreating sea ice would also increase sea
1056 salt aerosol emission through increased areas of open water, which is a source of bromine emission and
1057 recycling, therefore the competing effects of sea ice retreat require further investigation through coupled
1058 cryosphere-atmosphere modeling approaches. Changes in cloud cover, especially low-level liquid
1059 containing clouds, would affect the amount of solar radiation reaching the surface. Previous studies have
1060 presented evidence for positive and negative trends in low cloud cover for the Arctic region (Boccolari and
1061 Parmiggiani, 2018; Jenkins and Dai, 2022; Lelli et al., 2023; Sviashchennikov and Drugorub, 2022; Wang
1062 et al., 2021). Increases in cloud cover would affect the amount of radiation received at the surface, which

1063 would affect ODEs mainly in March when radiation is lower compared to the later spring months. How the
1064 Arctic and the nature of ODEs evolve with climate change remains an open question and should be the
1065 focus of future research endeavors.

1066

1067 **Financial Support**

1068 This research has been financially supported by the Danish Environmental Protection Agency and the
1069 Danish Energy Agency, with continuous funding over the years from the “Danish Program for Arctic
1070 Research” and ERA-PLANET (The European Network for observing our changing Planet) projects, as well
1071 as by iGOSP, iCUPE, and finally by the Graduate School of Science and Technology, Aarhus University.
1072 J.B.P received funding from the Swiss Data Science Center project C20-01 Arctic climate change:
1073 exploring the Natural Aerosol baseline for improved model Predictions (ArcticNAP). This project received
1074 additional funding from the Ingvar Kamprad Chair funded by Ferring Pharmaceuticals and held by Prof.
1075 Julia Schmale from École Polytechnique Fédérale de Lausanne (EPFL).

1076 **Acknowledgments**

1077 Villum Foundation is gratefully acknowledged for financing the establishment of Villum Research Station.
1078 Thanks to the Royal Danish Air Force and the Arctic Command for providing logistic support to the project.
1079 Christel Christoffersen, Bjarne Jensen, Martin Ole Bjært Sørensen, Claus Nordstrøm and Keld Mortensen
1080 are gratefully acknowledged for their technical support. The Danish Meteorological Institute (DMI) is
1081 acknowledged for measurements from Station Nord (Jensen, 2022). Michele Volpi from the Swiss Data
1082 Science Center (SDSC) is acknowledged for helpful discussions about machine learning modeling. Andrea
1083 Baccarini from EPFL is acknowledged for helping produce the map in Figure 1. David Beddows from
1084 University of Birmingham is acknowledged for help with the trajectory analysis.

1085 **Author Contributions**
