10 **Abstract.** Modelling firn density is crucial for understanding the current mass balance of the Greenland ice sheet (GrIS) and  
predicting its future. As snowmelt increases in a warming climate on the GrIS, accurate information about firn density and  
its variability over time and space becomes increasingly important in the percolation zone. Previous research indicates that  
none of the existing models accurately simulate firn properties at sites with varying snowmelt rates due to the limited  
knowledge of liquid water percolation and the complexity of firn densification. Here, we enhance the representation of the  
15 firn densification model based on the Community Firn Model (CFM) by (i) using the stressed-based dry-firn densification  
scheme and recently published parametrizations for firn characteristics, (ii) modifying the expression of irreducible water in  
the Darcy-flow scheme, and (iii) allowing the time step to be adaptive. The improved model is employed at two  
climatologically distinct sites, Dye-2 and KAN\_U, two sites in the southwest percolation zone of the GrIS, to evaluate its  
performance. The modelled firn depth-density profiles at the two study sites generally agree well with the in situ  
20 measurements obtained from 16 firn cores drilled between 2012 and 2019. At Dye-2, with comparatively high accumulation  
and low snowmelt rates, the model simulates thin ice lenses and/or ice layers in the top 10 m of the firn column. The  
modelled firn density aligns with the average level of observations, with the relative bias in density ranging from 0.36% to  
6%. At the KAN\_U site, characterized by relatively low accumulation and high snowmelt rates, the model captures high-  
density layers ( $\sim 917 \text{ kg} \cdot \text{m}^{-3}$ ) caused by the refreezing of liquid water. The observed ice slabs are partly reproduced, and the  
25 relative bias in density between simulations and observations at all 8 cores is within  $\pm 5\%$ .

### 1 Introduction

Accurate information about firn density and its variability over time and space is necessary both to understand the current  
mass balance of the Greenland ice sheet (GrIS) and to predict its future for multiple reasons. Firstly, firn depth and density  
30 are required to convert elevation (volume) changes measured from satellite altimetry to mass changes, which remains a

primary source of uncertainty in mass balance assessments (Shepherd et al., 2012, 2020; Huss et al., 2013; Thompson et al., 2023). Secondly, firn depth and density are required to convert firn column thickness to ice thickness to calculate solid-ice discharge over the grounding line (Rignot et al., 2019; Veldhuijsen et al., 2023). Thirdly, firn density and spatial distribution are required to calculate the amount of air-filled pore space within the firn column (firn air content; FAC), which implies the meltwater retention potential and the capacity of firn to buffer surface meltwater into the ocean (Enderlin et al., 2014; Machguth et al., 2016; van den Broeke et al., 2016; Mottram et al., 2019). Moreover, the FAC of the total firn column is also valuable for remotely sensed surface height change correction, enabling the conversion of height changes into mass changes (Sørensen et al., 2011; Simonsen et al., 2013; Kuipers Munneke et al., 2015). Given the absence of suitable methodologies or techniques for directly measuring firn depth and density throughout the GrIS, firn densification models are typically used to obtain vertical variations in density at a particular time and space (Ligtenberg et al., 2011; Morris and Wingham, 2015; Smith et al., 2020).

The surface of the GrIS can be divided into the accumulation zone and the ablation zone based on the equilibrium line altitude (ELA), with the accumulation zone further divided into the dry snow zone and the percolation zone depending on the presence of liquid water (Steger et al., 2017). The dry snow zone is not affected by snowmelt and/or rainfall, and firn densification in this zone is forced by overburden stress, i.e. the weight of overlying snow/firn (Herron and Langway, 1980). In the GrIS, this zone is decreasing because areas experiencing snowmelt and/or rainfall have become more widespread and denser in response to the warming climate over the past decades. For example, an unprecedented melt event occurred in July 2012, with surface melt encompassing nearly the entire GrIS (Nghiem et al., 2012). As a result, the percolation zone of the GrIS is expanding. Most liquid water (from snowmelt and rainfall) tends to infiltrate into the subsurface firn column in this zone. Afterwards, it may either be stored in the firn's pore space (Pfeffer et al., 1991; Harper et al., 2012), or refreeze within the firn layer (van den Broeke et al., 2016), or remain unfrozen in firn aquifers (Forster et al., 2014), or depart from the firn column via runoff when encountering an impermeable layer (Machguth et al., 2016). Researchers found sharply increased firn density and significant density variability within the upper firn column of the percolation zone (Machguth et al., 2016; MacFerrin et al., 2019; Rennermalm et al., 2021), which are likely attributed to the refreezing of liquid water. This refreezing process produces ice lenses (thinner than 0.1 m) or ice layers (between 0.1 and 1 m thick), both of which can accumulate into ice slabs (thicker than 1 m) (MacFerrin et al., 2022), primarily influencing firn properties in two ways. Firstly, the release of latent heat during refreezing has the potential to induce a notable increase in firn temperature, further accelerating the rate of firn densification. Secondly, stress exerted by ice lenses or ice layers further compresses and densifies firn, thus leading to a higher density within the firn layer. Furthermore, refreezing potentially acts as a buffer against meltwater entering the ocean,

delaying mass loss through runoff (Harper et al., 2012). Understanding refreezing processes is therefore critical for simulating firn density in the percolation zone, estimating the GrIS's mass loss and its influence on global sea-level rise.

Numerous semi-empirical and physics-based firn models have been developed to simulate firn properties and compared well  
65 with observations on both Greenland and Antarctica (e.g. Arthern et al., 2010; Ligtenberg et al., 2011; Kuipers Munneke et al., 2015; van Kampenhout et al., 2017). However, the agreement between observed and simulated firn densities decreases with the increasing snowmelt rates (Kuipers Munneke et al., 2015; Ligtenberg et al., 2018), indicating that firn density modelling in the percolation zone remains a challenge. Many observational studies have demonstrated that meltwater infiltrates into the firn through two pathways, namely by homogeneous wetting front, also known as matrix flow, and by  
70 heterogeneous infiltration in the form of discrete vertical channels, also called preferential flow (Pfeffer et al., 1996; Humphrey et al., 2012). Verjans et al. (2019) indicated that substantial knowledge gaps and poor representation of firn percolation processes are significant limiting factors in firn model performance in the percolation zone. Vandecrux et al. (2020c) found that none of the nine firn densification models accurately simulated meltwater infiltration at sites with varying snowmelt rates. Thompson et al. (2023) used two firn models (the SNOWPACK model and the CFM-GSFC model) to  
75 quantify firn properties across the GrIS and found that the model bias is highest where liquid water is abundant.

In this study, we use the Community Firn Model (CFM; Stevens et al., 2020) as the modelling framework to simulate the firn depth-density profile in two climatologically distinct sites in the percolation zone of the GrIS: one characterized by relatively low accumulation and high snowmelt rates (KAN\_U) and the other by comparatively high accumulation and low snowmelt  
80 rates (Dye-2). The representation of firn densification is improved by (i) using the stressed-based dry-firn densification scheme and recently published parametrizations for surface density and thermal conductivity, (ii) modifying the expression of the irreducible water in the Darcy-flow scheme to assess the capillary retention, refreezing, and runoff of liquid water within the firn layer, and (iii) allowing the time step to be adaptive. The upper boundary of the model is driven by the polar version of the Regional Atmospheric Climate Model (RACMO2.3p2; Noël et al., 2019). In Sect. 4, We assess the overall  
85 capability of the model to reproduce density profiles by comparing the modelled firn density with observations obtained from the nearest core with a length exceeding 10 m. In addition, we compare the simulation results with previous firn density modelling studies at Dye-2 and KAN\_U by qualitatively and/or quantitatively comparing them with firn density observations, respectively. Finally, the sensitivity of the firn densification model to the choice of dry-firn compaction schemes, water flow schemes, and time step sizes are analyzed and discussed.

## 90 **2 Data**

### **2.1 Climatic forcing**

The climatic forcing data of the model used in this study are snow mass accumulation (snowfall minus sublimation), liquid water flux (snowmelt plus rainfall), skin temperature, and 2 m air temperature. Rainfall is the difference between total precipitation and snowfall. Restricted by the availability of observational data in terms of time and space, these climatic data  
95 are typically collected from regional climate models (RCMs). The RCMs commonly employed for the investigation of meteorological and climatic characteristics of the GrIS involve RACMO2.3p2 (the Regional Atmospheric Climate Model version 2.3p2), MAR (the Modèle Atmosphérique Régional), PROMICE (Programme for Monitoring of the Greenland Ice Sheet), and HIRHAM (the High-Resolution Limited-Area Model). By comparing these RCMs to in situ meteorological data and point SEB/SMB measurements, the accuracy of RACMO2.3p2 is higher than the other models over the GrIS (Noël et al.,  
100 2018; Fettweis et al., 2020; Van Dalum et al., 2021). The forcing from RACMO2.3p2 has been demonstrated to yield significant improvements in modelled firn densification (Ligtenberg et al., 2018). Therefore, in order to precisely simulate the firn depth-density profiles, the atmospheric forcing of the model is collected from RACMO2.3p2 in this study.

RACMO2.3p2 is forced at the lateral boundaries by a combination of European Centre for Medium-Range Weather  
105 Forecasts (ECMWF) reanalysis datasets from ERA-40 over 1958-1978, ERA-Interim over 1979-1989, and ERA5 over 1990-2020 (Noël et al., 2019). The data of snowfall, snowmelt, total precipitation, sublimation, and 2 m air temperature are statistically downscaled on a daily basis from RACMO2.3p2 at 5.5 km resolution onto a 1 km grid for the period 1958-2020. In addition, skin temperature is available on a daily basis for the same time period but on the native RACMO2.3p2 grid at 5.5 km.

### 110 **2.2 Study sites**

In this study, case studies are conducted at Dye-2 (66.48° N, 46.28° W) and KAN\_U (67.00° N, 47.02° W), two typical study sites in the percolation zone of the southwest GrIS (Fig. 1). Table 1 summarizes the geographical and climatological information of the two study sites. Situated in the southwest and at a lower elevation, KAN\_U experiences a slightly higher annual mean surface temperature (-16.79°C) than Dye-2 (-18.34°C) between 1958 and 2020, resulting in higher snowmelt  
115 rates. Specifically, KAN\_U exhibits an annual mean snowmelt of 282.83 mm w.e. (water equivalent) during this period, and meanwhile, Dye-2 display corresponding values of 145.97 mm w.e. With the increase in surface temperature of the GrIS over the past two decades, both snowfall and snowmelt have changed. A slight reduction in accumulation and an increase in snowmelt have been observed in KAN\_U since 2008 (Fig. 2). In particular, the annual snowmelt exceeded the annual

120 accumulation in the warm years of 2010, 2012, 2016, and 2019. As a slightly warm site, the annual snowmelt at Dye-2  
 typically fluctuates between 32.42 and 310.56 mm w.e., except for the exceptionally high melt year of 2012, during which  
 the annual snowmelt exceeded the annual mass accumulation.

**Figure 1. The geographical information of Dye-2 and KAN\_U on the Greenland Ice Sheet.**

125

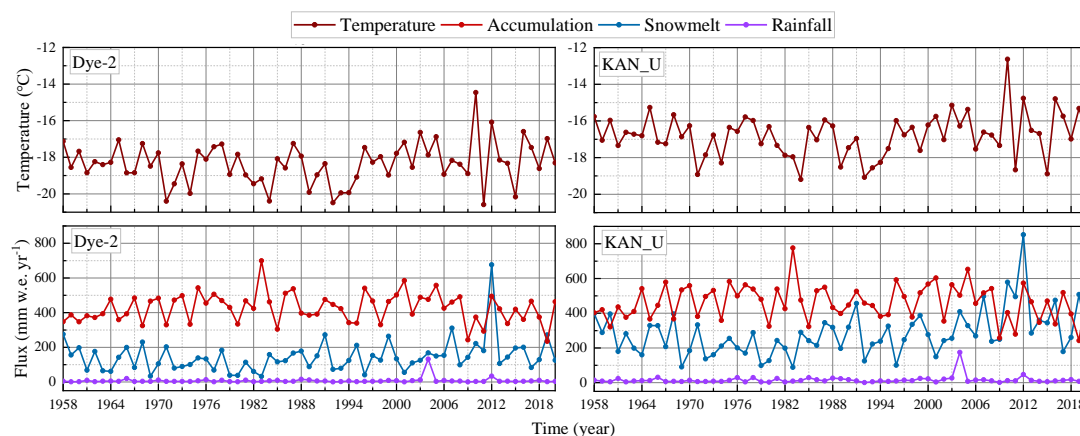

**Table 1. The climatological information about the two study sites. The annual mean surface temperature, accumulation and snowmelt are calculated on the basis of the RACMO2.3p2 model for the period from 1958 to 2020.**

| Site  | Latitude (°) | Longitude (°) | Elevation (m) | Annual mean surface temperature (°C) | Annual mean accumulation (mm w.e.) | Annual mean snowmelt (mm w.e.) |
|-------|--------------|---------------|---------------|--------------------------------------|------------------------------------|--------------------------------|
| Dye-2 | 66.48        | -46.28        | 2119          | -18.34                               | 426.32                             | 145.79                         |
| KAN_U | 67.00        | -47.02        | 1840          | -16.79                               | 463.38                             | 282.83                         |

130 Characterized by distinct climatic conditions, the control mechanism of firm densification differs in these two sites. High  
 accumulation and moderate snowmelt at Dye-2 make it a representative percolation zone. The firm densification at this site is  
 primarily driven by overburden stress. Meanwhile, liquid water generated at the surface percolates into the firm and releases  
 latent heat when refreezing as ice lenses or ice layers, resulting in considerable variability in firm density. Due to relatively  
 low accumulation and high snowmelt rates at KAN\_U, the firm density at this site is mainly influenced by liquid water and  
 135 remains generally high. Moreover, significant annual snowmelt events favour the formation of ice slabs at KAN\_U,  
 impeding further liquid water infiltration at depth and facilitating liquid water runoff (MacFerrin et al., 2019). These two

sites are thus typical for assessing the capability of a firn densification model to simulate firn density under different snowmelt rates and control mechanisms in the percolation zone.

140

### 2.3 Firn cores

145 In order to validate the modelled firn density profiles, we compared the modelled results to punctual in situ measurements obtained from firn cores. A set of 16 previously published cores with lengths exceeding 10 m in the study sites are collected for this study (Table 2). These cores were primarily drilled in late April or May between 2012 and 2019 (Machguth et al., 2016; MacFerrin et al., 2019; Vandecrux et al., 2019; Rennermalm et al., 2021), coinciding with substantial snowmelt, which provided an optimal condition for observing firn density in the presence of liquid water. The naming of the cores follows the

150 same naming convention by Rennermalm et al. (2021), i.e., cores are labelled with the site name, drilling year and a sequential number if more than one core was drilled in any year (e.g. KAN\_U-12-1). All firn core records included data on density and ice layer stratigraphy. The density of each core segment was same, and the stratigraphy of each core segment was visually inspected at a vertical resolution of 0.01 m (Machguth et al., 2016; MacFerrin et al., 2019; Vandecrux et al., 2019) or 0.005 m (Rennermalm et al., 2021). To estimate density profiles at the same frequency, we resample firn densities

155 to a resolution of 0.01 m. If density data for a specific core segment is absent, we assign it the mean density of the adjacent two core segments. For density values measured from the cores exceeding  $917 \text{ kg m}^{-3}$  (the density of pure ice), we define them as unreasonable (Rennermalm et al., 2021) and adjust them to  $917 \text{ kg m}^{-3}$ . Moreover, if the initial depth of firn core is not zero (Dye-2-15, KAN\_U-12-1, KAN\_U-12-2, KAN\_U-12-3, KAN\_U-13-2, KAN\_U-15, and KAN\_U-17), the firn

densities preceding the initial depth are set to the mean surface density during 1958-2020, which is 315 and 320 kg m<sup>-3</sup> for

160 Dye-2 and KAN\_U respectively.

**Table 2. Characteristics of firn cores used in this study, including core retrieval date, location information, elevation, initial and end depth below the surface, as well as source. Source refers to 1) Machguth et al., 2016, 2) MacFerrin et al., 2019, 3) Vandecrux et al., 2019, and 4) Rennermalm et al., 2021.**

| Core name  | Date       | Latitude (°) | Longitude (°) | Elevation (m a.s.l.) | Initial depth (m) | End depth (m) | Source |

### 165 3 Firn densification model

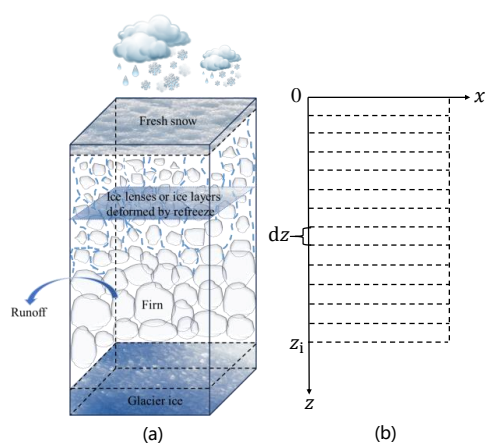

After settling to the surface, fresh snow undergoes compaction under the forcing of overburden stress. Meanwhile, the liquid water composed from snowmelt and rainfall percolates downward into the firn column due to the porosity and permeability of the firn grains. Liquid water will refreeze and form ice lenses or ice layers when reaching a firn layer with sufficient cold content and pore space. Here, cold content refers to the energy required to raise the temperature of the firn to melting temperature (Langen et al., 2017). Due to capillary forces, a portion of liquid water is retained within the firn layer, unable to percolate further or refreeze. In addition, once liquid water encounters an ice layer (between 0.1 and 1 m thick) or ice slab (thicker than 1 m), it is challenging to percolate further and thus departs from the firn column through runoff (Fig. 4a).

In order to simulate the firn density under the forcing of overburden stress and liquid water, we establish a 1D vertical Lagrangian model with the vertically downward direction as the positive direction (Fig. 4b). The vertical coordinate,  $z$ , increases downwards. The base area of the firn column is defined as 1 m<sup>2</sup>. The firn column is divided into a finite number of firn layers, each with a thickness denoted as  $dz$ , which is related to snow accumulation at each time step. This study sets time

step sizes as the time required for the snow accumulation to reach a specific value. Through continuous experimentation, the optimal accumulation amount here is determined to be 0.014 m w.e. at Dye-2 and 0.017 m w.e. at KAN\_U. New added surface accumulation is instantly treated as the upper layer of the vertical firn column while removing one firn layer from the bottom of the firn column. Every individual firn layer is partitioned into distinct contributions from firn, air, ice, and liquid water, with each component expressed in terms of m w.e. units. Firn properties change from layer to layer due to the varying proportions of these four components. Nevertheless, within each layer, firn properties are assumed to remain constant. We keep track of the density of each firn layer during its downward motion to simulate the depth-density profile.

185

**Figure 3. Schematic representation of firn densification processes (a) and simple layering scheme used in this study (b).**

### 3.1 Fresh-snow density

190 An essential boundary condition for the model is the density of the first firn layer within the firn column,  $\rho_s$  ( $\text{kg m}^{-3}$ ). Fresh-snow density is typically stated as a constant value, like  $350 \text{ kg m}^{-3}$  (Stevens et al., 2020), or as a function of meteorological variables such as temperature and wind speed (Keenan et al., 2021). Considering the dynamic nature of atmospheric conditions, which leads to a certain variability in surface density, a parameterized equation may provide a more realistic approximation of actual fresh-snow density than a constant value. Differing from earlier investigations, which typically use

195 the first 1.0 m of snow (Kuipers Munneke et al., 2015) and thus systematically overestimate the actual snow density at the surface, Fausto et al. (2018) focused only on the upper 0.1 m of snow at 200 locations of the GrIS to develop a parameterization for fresh-snow density and found:

$$\rho_s = 362.1 + 2.78 \cdot T_a, \quad (1)$$

Here,  $T_a$  is the annual mean near-surface (usually 2 m) air temperature ( $^{\circ}\text{C}$ ),  $\rho_s$  represents the fresh-snow density ( $\text{kg m}^{-3}$ ).

200 This equation inherently involves densification from wind and drifting snow. Although the actual density of fresh snow could vary with each accumulation event, the parameterization is derived by fitting the measured snow densities to mean annual temperatures. Therefore, in this model,  $T_a$  is calculated as the average near-surface air temperature of the year preceding the accumulation event to avoid introducing an additional uncertainty.

### 3.2 Grain growth and microstructure evolution

205 The continuous accumulation of fresh snow subjects the underlying firm layer to augmented stress. Stress disparities develop at grain boundaries due to variations in grain boundary curvature and stored strain energy among crystal grains. High-stress regions on concave surfaces interacting with low-stress regions on other surfaces give rise to an unstable state, prompting grain boundary sliding and causing a rearrangement of grain structures. As a result, the system composed of grains undergoes motion aimed at minimizing surface area, leading to a gradual engulfing of smaller crystals by bigger ones, a  
210 phenomenon usually known as grain growth (Ren et al., 2020).

The shape of firm grains is typically depicted as sphericity or dendricity. Considering the challenges associated with simulating dendritic grain growth and the lack of relevant laboratory observations and model simulations, we simulate firm grains as spherical grains. Grain growth is then simulated as a process of radius expansion around the grain's center. Hence,  
215 the radius of a particle  $r$  (m) is determined from the initial radius  $r_0$  (m) and the growth rate  $R_g$  ( $\text{m}^2 \text{s}^{-1}$ ) as a function of time:

$$r^2(t) = R_g t + r_0^2, \quad (2)$$

The Arrhenius equation is used to calculate the growth rate  $R_g$ , which is a function of grain growth coefficient  $R_0$  ( $\text{m}^2 \text{s}^{-1}$ ), grain-growth activation energy  $E_g$  ( $\text{kJ mol}^{-1}$ ), gas constant  $R$  ( $8.314 \text{ J (kg K)}^{-1}$ ), and firm temperature  $T$  (K):

$$R_g = R_0 \exp\left(-\frac{E_g}{RT}\right), \quad (3)$$

220 The above parameterization assumes linear grain growth under isothermal conditions. Research indicates that values of  $E_g$  vary between  $47 \text{ kJ mol}^{-1}$  (Gow, 1969) and  $42.4 \text{ kJ mol}^{-1}$  (Cuffey and Paterson, 2010). Following Arthern et al. (2010), we set  $R_0$  to be  $1.3 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$  and  $E_g$  to be  $42.4 \text{ kJ mol}^{-1}$ . The initial grain radius,  $r_0$ , usually is prescribed as a constant value, such as  $0.1 \text{ mm}$  (Katsushima et al., 2009). In this study, we use the empirical formula obtained from Linow et al. (2012) to calculate the initial grain radius:

$$225 \quad r_0(\bar{T}, \bar{b}) = b_0 + b_1 \bar{T} + b_2 \bar{b}, \quad (4)$$

with  $b_0 = 0.781 \text{ m}$ ,  $b_1 = 0.0085 \text{ m K}^{-1}$ ,  $b_2 = -0.279 \text{ yr (m w.e.)}^{-1}$ ,  $\bar{T}$  is the mean annual temperature (K), and  $\bar{b}$  is the mean annual accumulation rate ( $\text{m w.e. yr}^{-1}$ ).

### 3.3 Firn temperature evolution

Following the CFM model, the vertical temperature distribution and its evolution are simulated by solving a one-dimensional  
230 and time-dependent heat-transfer equation (Patankar, 1980):

$$\rho c_f \frac{\partial T}{\partial t} = \frac{dK}{dz} \cdot \nabla T + K \cdot \nabla^2 T, \quad (5)$$

In this equation,  $K$  is the thermal conductivity of the firn ( $\text{W m}^{-1} \text{K}^{-1}$ ), which is related to firn density  $\rho$  and firn temperature  
 $T$ , thus  $\frac{dK}{dz} = \frac{\partial K}{\partial \rho} \frac{\partial \rho}{\partial z} + \frac{\partial K}{\partial T} \frac{\partial T}{\partial z}$ ;  $c_f$  is the specific heat capacity of firn ( $\text{J kg}^{-1} \text{K}^{-1}$ ), which is considered to be equal to the specific  
heat capacity of ice here. Under one-dimensional conditions,  $\nabla = \frac{\partial}{\partial z}$ . Considering the effect of latent heat released during  
235 refreezing, the firn temperature will be updated after liquid water refreezing (Sect. 3.5.3).

Firn thermal conductivity, a crucial factor in simulating heat diffusion, is extensively investigated based on field and  
laboratory experiments (Van Dusen and Washburn, 1929; Schwerdtfeger, 1963; Yen, 1981; Sturm et al., 1997; Calonne et al.,  
2011). Nevertheless, no universally accepted parameterization exists for firn thermal conductivity, and most of the existing  
240 predictive formulas are developed for a given temperature or density range, making them inapplicable at temperatures or  
densities outside of the provided range. Calonne et al. (2019) developed a parameterization of firn thermal conductivity from  
3-D images of snow, firn, or porous ice microstructures, covering a density range from 100 to 888  $\text{kg m}^{-3}$ , at different  
temperatures. This parameterization has been confirmed to be valid for a wide range of temperatures and densities typically  
observed in the firn layers of ice sheets, making it appropriate for simulations of the GrIS. Therefore, the firn thermal  
245 conductivity follows Calonne et al. (2019) in this study.

### 3.4 Dry-firn compaction scheme

With the accumulation of new snow at the surface (the top of the firn column), the firn is buried deeper and tracked during  
their downward motion. At every time step, each firn layer is compacted under the stress exerted by the gravity of snow/firn  
250 above it. Therefore, firn properties are directly related to overburden stress, which causes sintering and mechanical creep and  
is the dominant force in firn densification (van Kampenhout et al., 2017). The CROCUS model developed for mountain  
snowpack (Brun et al., 1992; Vionnet et al., 2012) has been used to simulate firn densification on the GrIS (Langen et al.,  
2017; Verjans et al., 2019). Verjans et al. (2019) indicated that incorporating a percolation scheme into a stress-based  
densification model ensures that mass redistribution caused by percolation appropriately influences the densification process.

255 As in Verjans et al. (2019), we choose the CROCUS model as the dry-firm compaction scheme, which relates the overburden stress  $\sigma$  ( $\text{kg m}^{-1} \text{s}^{-1}$ ) to the densification rate with a viscosity  $\eta$  ( $\text{kg s}^{-1} \text{m}^{-1}$ ):

$$\frac{d\rho}{dt} = \frac{\rho\sigma}{\eta}, \quad (6)$$

$$\eta = f_1 f_2 \eta_0 \frac{\rho}{c_\eta} \exp(a_\eta(T_m - T) + b_\eta \rho), \quad (7)$$

where  $T_m$  is the melting temperature (273.15 K),  $\eta_0 = 7.62237 \times 10^6 \text{ kg s}^{-1} \text{m}^{-1}$ ,  $a_\eta = 0.1 \text{ K}^{-1}$ ,  $b_\eta = 0.023 \text{ m}^3 \text{kg}^{-1}$ ,  $c_\eta = 358$  260  $\text{kg m}^{-3}$  following van Kampenhout et al. (2017).  $f_1$  and  $f_2$  are two correction factors to snow viscosity that accounts for viscosity differences due to the presence of liquid water and grain sizes respectively. Following Langen et al. (2017) and van Kampenhout et al. (2017),  $f_2$  is set to 4, neglecting the change in  $\eta$  for grain sizes smaller than 0.34 mm.  $f_1$  is represented as a function of the liquid water content  $\theta_w$  ( $\text{m}^3 \text{m}^{-3}$ ):  $f_1 = 1/(1 + 60\theta_w)$ .

### 3.5 Liquid water scheme

265 As long as liquid water is available at the surface and the porosity of the firm allows percolation, water will percolate to a deeper layer by gravitation. Percolation proceeds until all the water is depleted or an impermeable layer is encountered, where any excess water at that time step is instantly considered as runoff. For some firm layers, the pore space can accommodate both air and water. The variable  $P$  ( $/$ ) is used to denote the porosity of a firm layer with a thickness of  $dz$ , which is defined as the ratio of the volume of pore space inside the firm layer to the total volume of the firm layer and 270 calculated from the firm density  $\rho$  and ice density  $\rho_i$  ( $917 \text{ kg m}^{-3}$ ):  $P = 1 - \rho/\rho_i$ . The pore space within the firm layer, denoted as  $\varphi$  ( $\text{m}^3$ ), is determined by multiplying the porosity  $P$  by the thickness of the layer  $dz$ . Moreover, the vertical firm water flux depends on the firm's irreducible water content (Coléou and Lesaffre, 1998), the firm's saturated (Calonne et al., 2012) and unsaturated (Hirashima et al., 2010) hydraulic conductivities, and a coefficient that accounts for the effect of ice content on the firm hydraulic conductivity (Colbeck, 1975). In this study, we use the Darcy-flow scheme in the CFM model 275 to simulate water percolation, capillary retention, and refreezing. A slight difference is that we calculate the water-holding capacity according to Coléou and Lesaffre (1998) and calculate the irreducible water amount within each layer as the product of that layer's liquid water volume and water-holding capacity.

#### 3.5.1 Water saturation

The maximal pore space that can be occupied by liquid water is known as the saturated water volume. Considering the 280 volume expansion resulting from the refreezing of all liquid water within the pore space into ice, the saturated water content is expressed as:  $\theta_s = V_{wm}/dz$  ( $\text{m}^3 \text{m}^{-3}$ ), where the saturated water volume  $V_{wm} = \varphi * (\rho_i/\rho_w)$  ( $\text{m}^3$ ). Due to the forcing of capillary and adhesive forces, a small fraction of the water will be retained within some of the available pore space of the

firm layer and not subject to vertical transfer, often referred to as irreducible water. The maximum water saturation that can be sustained by the capillary tension of firm grains is termed the water-holding capacity,  $S_{wi}$  (/), with values employed in  
285 models varying widely (Langen et al., 2017). For example, a common practice is to use constant values (Colbeck, 1974; Yamaguchi et al., 2010; Reijmer et al., 2012; Steger et al., 2017). In this study, we follow the formulation from Coléou and Lesaffre (1998), where the water-holding capacity  $S_{wi}$  is taken as a function of firm density  $\rho$ :

$$S_{wi} = \frac{W_{mi}}{1 - W_{mi}} \frac{\rho_i \rho}{\rho_w (\rho_i - \rho)}, \quad (8)$$

$$W_{mi} = 0.057 \frac{\rho_i - \rho}{\rho} + 0.017, \quad (9)$$

290 Assuming the liquid water volume within one firm layer is  $V_w$  ( $m^3$ ), the irreducible water content  $\theta_i$  ( $m^3 m^{-3}$ ) can be represented as  $\theta_i = V_{wi}/dz$ , with  $V_{wi} = V_w * S_{wi}$  ( $m^3$ ). The effective water saturation  $\Theta$  (/) can be expressed as

$$\Theta = \frac{\theta_w - \theta_i}{\theta_s - \theta_i}, \quad (10)$$

where  $\theta_i < \theta_w < \theta_s$ , the liquid water content  $\theta_w$  is given as the ratio of  $V_w$  to  $dz$ . Here, at each time step, the liquid water volume in the  $j$ -th firm layer,  $(V_w)_j$ , is calculated as

$$295 (V_w)_j = (V'_w)_j + \min(V_{tot} - \sum_{n=1}^{j-1} (V_w)_n, (V_{wm})_j - (V'_w)_j), \quad (11)$$

where  $V'_w$  represents the liquid water volume from the preceding time step that can be refrozen but has not yet refrozen due to the limited cold content,  $V_{tot}$  is the total liquid water input during this time step,  $(V_{wm} - V'_w)$  represents the maximum amount of liquid water that can be accommodated in a firm layer (including irreducible water). When encountering an impermeable firm layer, all excess liquid water runoff and the liquid water volume below this layer is equal to its value at the  
300 preceding time step.

### 3.5.2 liquid water amount within each layer

Water in excess of the irreducible water volume is allowed to move downward, we define the liquid water volume available for flow within a firm layer to be  $V_{av}$  (m w.e.), i.e.:  $V_{av} = V_w - V_{wi}$ . Because firm is a porous material, water flow in the firm column can be estimated using Darcy's law. Water flux  $q$  ( $m s^{-1}$ ) is a function of hydraulic conductivity  $K_w$  ( $m s^{-1}$ ) and  
305 capillary suction  $h$  (m):

$$q = K_w \left( \frac{dh}{dz} + 1 \right), \quad (12)$$

Here,  $dh/dz$  is the vertical hydraulic gradient in capillary suction, and the second term (+1) represents gravity. Porosity and pore structures influence capillary suction and hydraulic conductivity. However, characterizations such as pore shape, pore connectivity, and tortuosity are difficult to measure or simulate directly. In this study, following Hirashima et al. (2010) and  
310 Langen et al. (2017), the hydraulic conductivity and the capillary suction are parameterized in terms of firm grain radius  $r$ ,

effective liquid saturation  $\theta$ , and firm density  $\rho$ . Shimizu (1970) formulated a saturated hydraulic conductivity based on laboratory experiments using kerosene, showing that hydraulic conductivity can be estimated as a function of grain size and snow density:

$$K_s = 0.308 \frac{g}{\nu_w} r^2 \exp(-0.0078\rho), \quad (13)$$

315 Here,  $g$  is the acceleration due to gravity ( $\text{m} \cdot \text{s}^{-2}$ ), and  $\nu_w = 1.787 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$  is the kinematic viscosity of water. Van Genuchten (1980) developed an accurate expression for the capillary suction in soil, and Hirashima et al. (2010) further optimized the expression:

$$h = \frac{1}{\alpha} \left( \theta^{-\frac{1}{m}} - 1 \right)^{\frac{1}{n}}, \quad (14)$$

In this equation,  $\alpha = 14.6r + 1.9$ ,  $n = 15.68 \exp(-0.92r) + 1$ ,  $m = 1 - \frac{1}{n}$ . Van Genuchten (1980) combined the theory of

320 Mualem (1976) to estimate the unsaturated hydraulic conductivity,  $K_r$ , as follows:

$$K_r = \theta^{\frac{1}{2}} \left[ 1 - \left( 1 - \theta^{\frac{1}{m}} \right)^m \right]^2, \quad (15)$$

The hydraulic conductivity of firm can be expressed as the multiplication of the saturated hydraulic conductivity  $K_s$ , and the unsaturated hydraulic conductivity  $K_r$ . Furthermore, the ice lenses or ice layers formed by refreezing have the potential to impede the infiltration of liquid water. This effect is parameterized by introducing an additional permeability factor  $K_f$ ,  
325 resulting in the equation  $K_w = K_s * K_r * K_f$ . In order to make the model more sensitive to the formation of thin ice lenses and to reduce excessive refreezing, we set a thick of 0.1 m as the impermeable threshold, which is the maximum thickness of ice lenses. Therefore,  $K_f$  is set to zero when the ice thickness is less than 0.1 m, otherwise  $K_f = 1$ .

Based on the above information, we can calculate the water transport amount within a Darcy time step, usually denoted as

330  $q d\tau$ . Hirashima et al. (2010) suggested that the simulations will become unstable if the water transport amount in a Darcy time step approaches the water content. Thus, the Darcy time steps must be appropriately selected. They pointed out that the limit of the water transport amount in a Darcy time step,  $q_{\text{lim}}$  (m w.e.), is approximated by the amount needed to reach equilibrium conditions between two adjacent vertical layers. Following the CFM model, we initially assume a value of 60 seconds for  $d\tau$  and subsequently iteratively adjust this value to approximate the time required for achieving equilibrium  
335 conditions (Equation 20 in Hirashima et al. (2010)). Finally, the water transport amount in a Darcy time step is calculated as

$q_{\text{lim}} \left[ 1 - \exp\left(-\frac{q}{q_{\text{lim}}} d\tau\right) \right]$  (m w.e. units). Considering the liquid water volume available for flow, the actual water transport amount in a firm layer is the minimal value between  $q_{\text{lim}} \left[ 1 - \exp\left(-\frac{q}{q_{\text{lim}}} d\tau\right) \right]$  and  $V_{\text{av}}$ , and we denote it using  $u$ . The inflow into the  $j$ -th firm layer is the outflow from the  $(j-1)$ -th firm layer. Therefore, the liquid water volume within  $j$ -th layer is

updated as  $(V_w)_j + u_{j-1} - u_j - R_j$ , where  $V_w$  is the liquid water volume before water flow, calculated by Eq. (11);  $R_j$

340 represents the liquid water loss through lateral runoff in  $j$ -th firm layer calculated by the Darcy parameterization.

### 3.5.3 Refreezing

The increased mass of a given firm layer caused by refreezing is calculated according to its maximum refreezing potential,  $C_r$  (kg), and the liquid water amount available for refreezing,  $V_w$  (m w.e.), within the firm layer:

$$m_r = \min(C_r, V_w * \rho_w), \quad (16)$$

345 Given the specific heat capacity of ice,  $c_i = 152.5 + 7.122T$  (Cuffey and Paterson, 2010), and the latent heat of fusion,  $\mathcal{L}$  ( $3.335 \times 10^5 \text{ J kg}^{-1}$ ), the maximum refreezing potential can be defined as

$$C_r = \frac{Q_{\text{cold}}}{\mathcal{L}} = \frac{c_i * m * (T_m - T)}{\mathcal{L}}, \quad (17)$$

where  $Q_{\text{cold}}$  is the cold content of the firm layer,  $m$  is the mass of the firm layer before refreezing. Considering the latent heat released by refreezing, which can be calculated as:  $Q_L = m_r * \mathcal{L}$ , the firm temperature is updated to

350 
$$T = T_m - \frac{Q_{\text{cold}} - Q_L}{c_i(m + m_r)}, \quad (18)$$

Finally, the firm density in each firm layer with the presence of liquid water may be calculated as  $\rho = (m + m_r)/dz$ .

### 3.6 Model Initialization

The initial model density, temperature, grain size, and liquid water content in the firm column are obtained by repeatedly applying the spin-up period 1958-1979, which is considered representative of the climate of the preceding few hundred years and during which the forcing (i.e. surface accumulation, liquid water flux, and skin temperature) is assumed to have remained reasonably constant (van den Broeke et al., 2009; Brils et al., 2022). Observations and model studies support the assumption that the Greenland climate and surface mass balance (SMB) started to change significantly in the 1990s (Enderlin et al., 2014; McMillan et al., 2016), confirming that the period 1958-1979 can be selected for initialization purposes. Initialization is considered complete until the firm layer is in equilibrium with the surface climate. The equilibrium

360 is roughly reached when the entire firm column (defined here as the depth where the density reaches the pore close-off density of  $830 \text{ kg m}^{-3}$ ) has been fully refreshed by accumulation (Veldhuijsen et al., 2023). Due to variable snow accumulation rates, the required spin-up time can vary significantly, resulting in a self-adaptive time frame where the 22-year climate interval is repeated to provide a time series long enough for a full firm column refreshment. If the spin-up time required is not divisible by 22, we round up to the next integer to exceed the required time.

### 365 3.7 Metrics of model evaluation

Several metrics are used to compare the modelled firm density to both the observations and the previous firm density modelling studies. The root mean square error (RMSE) is a statistical measure used to assess the accuracy of a model's simulations compared to observations. A lower RMSE value indicates better agreement between simulations and observations, implying higher accuracy of the model. The formula for RMSE is

$$370 \text{ RMSE} = \sqrt{\frac{\sum_{i=1}^n (M_i - O_i)^2}{n}}, \quad (19)$$

where  $M_i$  is the modelled value,  $O_i$  is the observed value, and  $i$  iterates over  $n$  number of values. To quantify the goodness of fit of model simulations, we use the Nash-Sutcliffe efficiency coefficient (NSE), which is typically employed in hydrological modelling (Nash and Sutcliffe, 1970). The value of NSE ranges from negative infinity to 1, with values closer to 1 indicating superior simulation accuracy. A value of 1 indicates perfect model performance and a value of 0 suggests that the simulated

375 results align with the mean level of the observed values. It is calculated as:

$$\text{NSE} = 1 - \frac{\sum_{i=1}^n (O_i - M_i)^2}{\sum_{i=1}^n (O_i - \bar{O})^2}, \quad (20)$$

where  $\bar{O}$  is the mean of observations. Moreover, we use the correlation coefficient ( $r$ ) to quantify the relationship between observations and simulations. In order to estimate the overall capability of the model to reproduce density profiles and the extent to which the model underestimates or overestimates, we calculate the relative bias between observed and modelled

380 firm density and FAC. The relative bias in firm density is calculated as

$$\text{Relative bias} = \frac{\sum_{i=1}^n (M_i - O_i)}{\sum_{i=1}^n (O_i)} \times 100\%, \quad (21)$$

The FAC is the integrated volume of air contained within the firm from the surface to a certain depth per unit area (van Angelen et al., 2013; Ligtenberg et al., 2018), which is represented as

$$\text{FAC} = \int_0^{z_m} \frac{\rho_i - \rho(z)}{\rho_i} dz, \quad (22)$$

385 where  $z_m$  is the maximal observation depth,  $\rho(z)$  is the firm density at a given depth. For comparison, we resample the observed and simulated density to a resolution of 0.01 m, so  $dz = 0.01$  here.

## 4 Results

### 4.1 Dye-2

Based on the initial firm depth-density profile obtained from the spin-up procedure, we run the established firm densification model to calculate the firm density for each firm layer at each time step between 1958 and 2020. To qualitatively assess the accuracy of the firm densification model in forming a depth-density profile, we compare the modelled firm density with the observed density profile and ice layer stratigraphy from the core of the closest date (Fig. 4). Compared to the dry-firm density

profile, the modelled firn density increases sharply for all 8 cores, especially in the top 10 m of the firn column. This result can be attributed to the increased snowmelt in recent years and the subsequent refreezing within the firn layer, which forms ice lenses and/or ice layers. Due to the high snowmelt rate in 2012, a meter-thick ice layer formed and was later buried in the following months and years, emerging at approximately 5 m depth in the Dye-2-19 core. Below this ice layer, several thin ice lenses and density variability are exhibited as a result of seasonal and interannual variations in snowmelt. Compared to observations, the model partly simulates the high-density firn layers observed in the first 10 m of the firn column while underestimating the density variability observed.

400

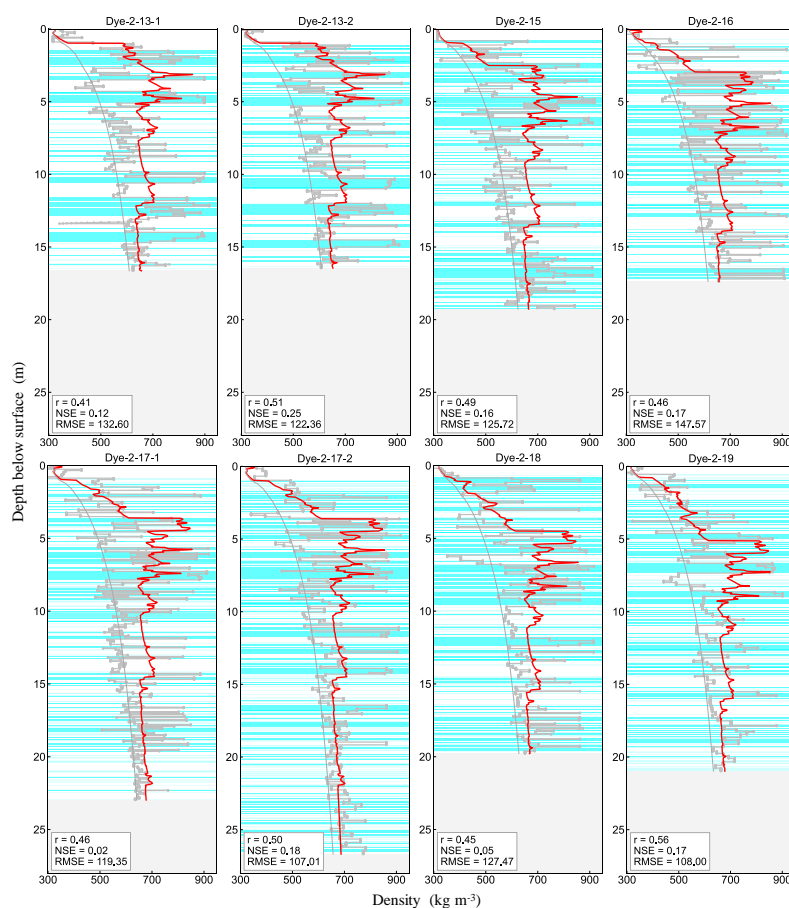

Figure 4. Observed (gray dotted line) and modelled (red solid line) firn depth-density profiles at Dye-2. Ice layer stratigraphy is shown as cyan horizontal lines. The gray-shaded regions indicate no data. The thin inclined line denotes the dry firn density simulated using the CROCUS model. The correlation coefficient ( $r$ ), Nash-Sutcliffe efficiency coefficient (NSE), and root mean square error (RMSE) are displayed in the bottom left of each panel.

405

To quantify the model’s performance in reproducing the heterogeneity of firn density, we employed three evaluation metrics:  $r$ , NSE, and RMSE. Additionally, the relative bias in firn density and FAC are calculated to understand the overall capability of the model in reproducing density profiles and the extent to which the model underestimates or overestimates (Table 3). In general, the simulations align with the average level of observations, with the relative bias in density ranging from 0.36% (Dye-2-13-2) to 6% (Dye-2-17-1), and the smallest NSE being 0.02 (Dye-2-17-1). Moreover, the correlation coefficient ( $r$ ) is around 0.5 for all cores, also indicating that the model is able to capture the general trend of observations at Dye-2 to some extent, but it does not accurately reproduce the specific characteristics of the observed density. The Dye-2-16 core exhibits the largest process error (RMSE=147.57 kg m<sup>-3</sup>) among all 8 cores, likely due to the greatest density variability in this core. However, the relative bias in density and FAC of this core is not the highest, possibly due to the model’s overestimations and underestimations of the observed density counterbalancing each other. The Dye-2-17-2 core exhibits the highest relative bias in density (6%) among 8 cores. This may be attributed to the dry-firn density, which is theoretically expected to closely match the low-density peaks in the observed density profiles, being overestimated in this core.

**Table 3. Statistics and model outputs of 8 firn cores drilled at Dye-2 between 2013 and 2019, including the mean observed and modelled firn density for the entire core depth range ( $\bar{\rho}_O$  and  $\bar{\rho}_M$ ), relative bias in density, observed and modelled FAC and their relative bias.**

#### 4.2 KAN\_U

Characterized by warm climatic conditions and abundant snowmelt, the modelled firn density generally remains high at KAN\_U (Fig. 5). For the KAN\_U-13-1 and KAN\_U-13-2 cores, many high-density firn layers are observed within the 1-4 m depth range of the firn column, which is primarily attributed to high snowmelt rates in 2010, 2011, and 2012, as well as the subsequent refreezing. These high-density layers form an approximately three-meter-thick ice slab, which becomes buried downward in the following months and years. In the observations, an almost continuous ice slab is observed in the upper of all cores, with varying thicknesses among the cores. Taking the KAN\_U-13-1 core as an example, the model

reproduces the high-density layers at 1-4 m depth. In the approximately 4-6 m depth range, the firn density is slightly underestimated, possibly related to the percolation scheme of matrix flow. The matrix flow typically remains constrained to the upper several meters of the firn column and cannot transfer water below ice layers (Verjans et al., 2019). As a result, during the high-snowmelt summers from 2010 to 2012, liquid water leaves the firn column through runoff after encountering  
 435 ice layers. However, in reality, in sites like KAN\_U where liquid water is abundant, preferential flow is likely to bypass ice layers and thus refreeze the cold underlying firn layers, resulting in thicker ice slabs than simulations.

**Figure 5.** Observed (gray dotted line) and modelled (red solid line) firn depth-density profiles at KAN\_U. Ice layer stratigraphy is  
 440 shown as cyan horizontal lines. The gray-shaded regions indicate no data. The thin inclined line denotes dry firn density simulated using the CROCUS model. The correlation coefficient (r), Nash-Sutcliffe efficiency coefficient (NSE), and root mean square error (RMSE) are displayed in the bottom left of each panel.

The modelled depth-density profiles compare well within uncertainties to observations for all cores, primarily due to the  
 445 model capturing the high-density layers and partly reproducing the presence of ice slabs. The relative deviation in density is

within  $\pm 5\%$ , and NSE ranges from 0.27 (KAN\_U-13-2) to 0.56 (KAN\_U-15). However, the model is unable to accurately simulate low-density firn layers that are either unaffected or minimally affected by liquid water, despite the fact that these low-density layers are few at KAN\_U. As a result, the model demonstrates the best performance in the KAN\_U-15 core ( $r=0.77$ ,  $NSE = 0.56$ , and  $RMSE = 102.90 \text{ kg m}^{-3}$ ), which has the fewest low-density firn layers among all 8 cores. The KAN\_U-17 core exhibits the largest density bias ( $-4.71\%$ ) and FAC bias ( $30.96\%$ ) among all cores, possibly associated with underestimated density within the 1-8 m depth range. In this range, numerous observed density values are deemed unreasonable (exceeding  $917 \text{ kg m}^{-3}$ ), and we set these values to  $917 \text{ kg m}^{-3}$ .

**Table 4. Statistics and model outputs of 8 firn cores drilled at KAN\_U between 2012 and 2017, including the mean observed and modelled firn density for the entire core depth range ( $\bar{\rho}_O$  and  $\bar{\rho}_M$ ), relative bias in density, observed and modelled FAC and their relative bias.**

| Core name  | $\bar{\rho}_O$ ( $\text{kg m}^{-3}$ ) | $\bar{\rho}_M$ ( $\text{kg m}^{-3}$ ) | Relative bias in density (%) | Observed FAC (m) | Modelled FAC (m) | Relative bias in FAC (%) |

## 5 Discussion

### 5.1 Comparison with previous studies

In this section, we compare the simulation results obtained at Dye-2 and KAN\_U with previous firn density modelling studies at these two sites by qualitatively and/or quantitatively comparing them with firn density observations, respectively. Specifically, the modelled firn density at Dye-2 provided by Vandecrux et al. (2020c) and the modelled FAC at KAN\_U provided by Verjans et al. (2019) are compared to our simulations. Here, the Dye-2-13-2 core is selected for mutual comparison of the models by considering the principle of selecting a longer core to compare more information and choosing a core with fewer outliers within the available time ranges. Nine firn densification models used in Vandecrux et al. (2020c) are listed in Table 5. To compare the modelled firn density of each model with the observations from the Dye-2-13-2 core, we select the simulated depth-density profiles corresponding to midnight on the core drilling date from the outputs of the nine models and then resample them to a vertical resolution of 0.01m. The modelled firn density in the KAN\_U-13-1 core is

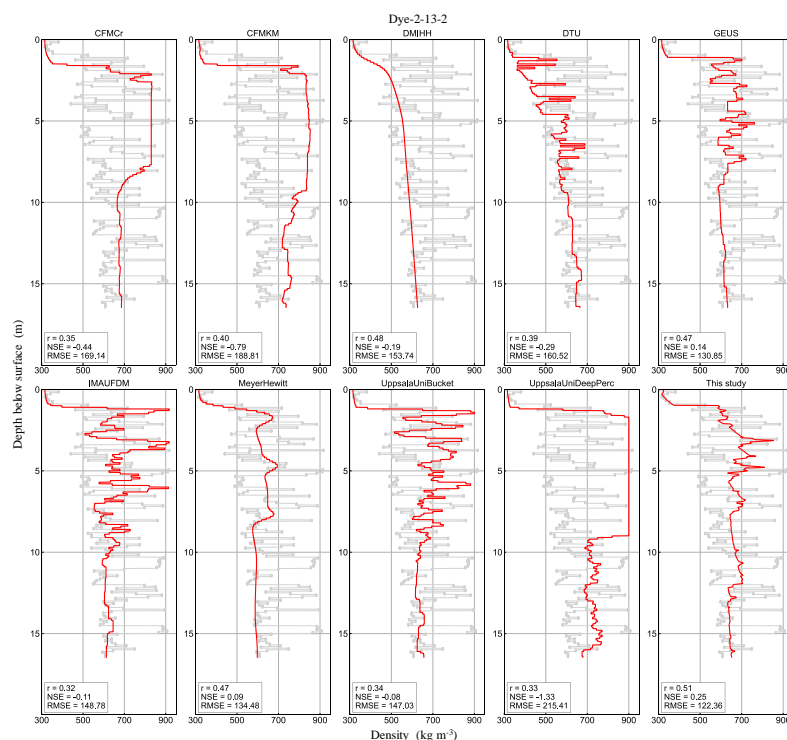

selected to calculate the top 15 m FAC, which is then compared with the FAC results simulated using different densification  
 470 schemes in this core by Verjans et al. (2019). We refer the reader to Verjans et al. (2019) for the modelled density profiles of  
 different densification schemes and more details on the parameterization of different densification schemes.

**Table 5. List of firn densification models used for comparison at Dye-2, including the dry-firn densification scheme and water flow scheme used in each model. The model abbreviation is consistent with the model code name in Vandecrux et al., 2020c.**

**Figure 6. Observed (gray dotted line) and modelled (red solid line) firn depth-density profiles at the Dye-2-13-2 core.**

At the Dye-2-13-2 core, compared to the other nine models, the model in this study exhibits the smallest relative bias in  
 480 density (0.36%) and FAC (-0.85%), as well as the highest accuracy, with the lowest RMSE of 122.36 kg m<sup>-3</sup> and the highest  
 NSE of 0.25 (Fig. 6 and Table 6). The CFMCR, CFMKM, and UppsalaUniDeepPerc models build up an ice slab of several  
 meters thick near the surface, where no such ice slabs are observed, possibly attributed to the fact that these three models  
 consider both matrix flow and preferential flow. Preferential flow pathways enable water to bypass ice layers and refreeze  
 within the cold underlying firn, resulting in an overestimation of firn density at the minimal snowmelt production site of  
 485 Dye-2 (with the relative density bias of 8.57%, 16.40%, and 20.55%, respectively). The sharp contrasts between low-density  
 layers and high-density layers are smoothed in the DMIHH and MeyerHewitt models, which follow an Eulerian framework.  
 Using the matrix flow scheme (bucket-type percolation scheme or Darcy-flow scheme), as well as a Lagrangian framework,  
 the DTU, GEUS, IMAUFDM, UppsalaUniBucket, and our models all simulate thin, high-density layers formed by  
 refreezing. The DTU model only allows water retention and refreezing in the top firn layer, thus underestimating the overall  
 490 firn density (-12.72%). The GEUS model underestimates the firn density below 9 m (-5.67%). The IMAUFDM and  
 UppsalaUniBucket models exhibit density variability within the top 10 m, with overestimation of firn density at certain  
 depths, resulting in large RMSE values (148.78 kg m<sup>-3</sup> and 147.03 kg m<sup>-3</sup>, respectively).

**Table 6. Statistics and model outputs of firn density profiles simulated by 10 firn densification models at Dye-2-13-2, including the  
 495 mean firn density and FAC for the entire core depth range, relative bias in density and FAC. A slash indicates no data.**

| IMAUFDM            | 626.91                                | -2.50                           | 5.20    | 5.87                        |
| MeyerHewitt        | 592.93                                | -7.79                           | 5.81    | 18.27                       |
| UppsalaUniBucket   | 645.69                                | 0.42                            | 4.87    | -0.99                       |
| UppsalaUniDeepPerc | 775.09                                | 20.55                           | 2.55    | -48.21                      |

At the KAN\_U-13-1 core, the simulated top 15 m FAC in this study aligns well with the observed FAC in the top 15 m, with  
 a relative bias of 1.22% (Table 7), indicating that the model successfully captures the overall characteristics of the upper firn  
 density. In the density profile of the KAN\_U-13-1 core, an almost continuous ice slab is observed over the 1-7 m depth range

500 (Fig. 5 in this study and Fig. 8 in Verjans et al. (2019)). Below this ice slab, the firm density becomes more variable but remains generally high. In this study, the modelled density in the top 4 m closely aligns with the observed density, reproducing the presence of the ice slab observed (Fig. 5). Additionally, the model captures the high-density layers around 11-14 m depth. All three percolation schemes in Verjans et al. (2019) do not capture the high-density firm layers caused by the formation of ice slabs, with the modelled maximum density reaching approximately  $830 \text{ kg m}^{-3}$  (Fig. 8 in Verjans et al. 505 (2019)). The BK and RIM schemes significantly overestimate the top 15 m FAC (59.35% and 50%), which implies a significant underestimation of firm density, likely due to the matrix flow being unable to percolate liquid water to deeper depths and thus underestimating refreezing. The top 15 m FAC of the DPM scheme closely matches the observation (-2.44%). However, the DPM density profile exhibits a nearly constant density value within the depth range of 3 to 17 m, approximately  $810 \text{ kg m}^{-3}$ , not reproducing the density fluctuations between high-density layers and low-density layers 510 observed.

**Table 7. The top 15 m FAC and its relative bias with observation at the KAN\_U-13-1 core, which is both studied in Verjans et al. (2019) and this study. Verjans et al. (2019) implemented three types of water percolation schemes: the so-called bucket approach (BK), the Richards equation (Richards, 1931) in a single domain (RIM), and the Richards equation in a dual domain (DPM). 515 Among three percolation schemes, the BK and RIM schemes only consider matrix flow, while the DPM scheme accounts for both matrix flow and preferential flow. We refer to Verjans et al. (2019) more details on different densification schemes. A slash indicates no data.**

## 5.2 Comparison of different dry-firm densification schemes

520 To investigate differences in the depth-density profiles caused by different dry-firm densification schemes, we conducted simulations using five dry-firm densification schemes listed in Table 5, which are CROCUS, HL, KM, LIG, and SIM. Except for the dry-firm densification schemes, the model configurations and climatic forcing for all five models are identical. We select the longest two firm cores at two sites (Dye-2-17-2 and KAN\_U-13-1, respectively) to compare the simulated firm density with observations. Note that KAN\_U-17 is the longest core at KAN\_U, but it is not selected due to the high number 525 of outliers (density greater than  $917 \text{ kg m}^{-3}$ ) at this core.

The stress-based CROCUS model exhibits the closest mean density (1.65% at Dye-2, and -0.03% at KAN\_U) and FAC (-3.93% at Dye-2, and 0.14% at KAN\_U) to observations than the other four accumulation-rate-based models (HL, KM, LIG, SIM). This is possibly attributed to the stress-based nature of the CROCUS model ensuring appropriate mass redistribution  
 530 related to percolation, which affects densification (Verjans et al., 2019). The density profile simulated by the HL model is generally similar to that of the CROCUS model and exhibits more density variability. In contrast, the CROCUS model shows closer agreement with observations below 12 m depth at KAN\_U. The constitutive equations of the KM, LIG, and SIM models are all based on Arthern et al. (2010), resulting in relatively similar simulation results for these three models at both Dye-2 and KAN\_U. Compared to the CROCUS and HL models, these three models exhibit more sensitivity to temperature,  
 535 resulting in an overestimation of firm density, particularly below 15 m depth. Among them, the SIM model demonstrates the most pronounced overestimation, causing the highest mean density (11.13% at Dye-2, and 8.54% at KAN\_U) and the smallest FAC (-26.55% at Dye-2, and -43.44% at KAN\_U).

540 **Figure 8.** Observed (gray dotted line) and modelled (red solid line) firm depth-density profiles at the Dye-2-17-2 and KAN\_U-13-1 cores. The modelled density profiles are driven by different dry-firm densification schemes. Ice layer stratigraphy is shown as cyan horizontal lines. The gray-shaded regions indicate no data. The thin inclined line denotes dry firm density simulated using the corresponding dry-firm densification models. The correlation coefficient ( $r$ ), Nash-Sutcliffe efficiency coefficient (NSE), and root mean square error (RMSE) are displayed in the bottom left of each panel.

### 5.3 Comparison of different water flow schemes

550 Besides the dry-firn densification scheme, the choice of water flow scheme is also a crucial step in modelling firn density in the percolation zone. Verjans et al. (2019) demonstrated that apart from considering preferential flow, differences in the depth-density profiles simulated by schemes only employing matrix flow are minimal. In this section, we compare the depth-density profiles simulated using three different matrix flow schemes: the water flow scheme in Sect. 3.5, the Darcy-flow scheme, and the bucket percolation scheme. The latter two flow schemes are directly obtained from the CFM model and

555 share the same model configurations as the scheme in this study. Consistent with Sect. 5.2, the Dye-2-17-2 and KAN\_U-13-1 cores are selected to compare the firn depth-density profiles simulated by the three flow schemes with observations.

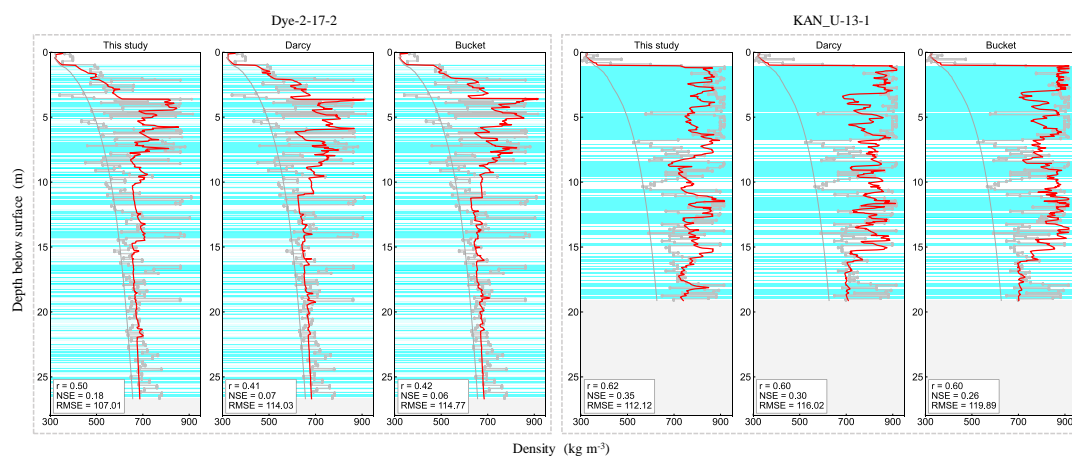

All three schemes are demonstrated to have the ability to reproduce the bulk density condition of the firn column at both Dye-2 and KAN\_U, with a maximum relative bias of 2.64% (Table 9). Among three percolation schemes, the scheme used in

560 this study exhibits the highest simulation accuracy, with the highest correlation coefficient (0.50 at Dye-2, and 0.62 at KAN\_U), the highest NSE (0.18 at Dye-2, and 0.35 at KAN\_U), and the smallest RMSE (107.01 kg m<sup>-3</sup> at Dye-2, and 112.12 kg m<sup>-3</sup> at KAN\_U). At the Dye-2-17-2 core, each flow scheme exhibits density variability in the first 10 m and simulates an ice layer at around 3 m depth. In contrast, the schemes using Darcy's law and bucket percolation slightly underestimate the thickness of the ice layer (Fig. 9). At the KAN\_U-13-1 core, none of the schemes reproduces the density

565 variability within the 7-11 m depth range. The scheme used in this study might compensate for high and low densities within this range, resulting in the model's overall performance closest to observations (-0.03% for mean density and 0.14% for

FAC). Both the Darcy-flow and bucket schemes exhibit density overestimation within this range, particularly the bucket scheme, leading to the highest mean density (2.38%) and lowest FAC (-12.09%) among the three models.

570

**Figure 9.** Observed (gray dotted line) and modelled (red solid line) firn depth-density profiles at the Dye-2-17-2 and KAN\_U-13-1 cores. The modelled density profiles are driven by different percolation schemes. Ice layer stratigraphy is shown as cyan horizontal lines. The gray-shaded regions indicate no data. The thin inclined line denotes dry firn density simulated using the CROCUS model. The correlation coefficient ( $r$ ), Nash-Sutcliffe efficiency coefficient (NSE), and root mean square error (RMSE) are displayed in the bottom left of each panel.

#### 580 5.4 Comparison of time step sizes

The time step is an essential factor in firn densification models, representing the progression of time and the advection of firn layers. At each time step, new snow accumulation is added as a new firn layer at the top of the firn column and firn density is calculated based on the refreshed firn parameters such as layer mass, temperature, and liquid water content. In many

previous studies, the time step is set to a constant value, leading to a varied snow accumulation within each time step with  
 585 different climatic conditions. For example, Verjans et al. (2019) and Vandecrux et al. (2020c) ran models with three-hourly  
 time steps; Stevens et al. (2020) ran the CFM model with monthly time steps. We refer to this time-fixed model driving  
 method as time-driven, which has a limitation that it may overlook the impact of short-term weather fluctuations on  
 densification. A smaller amount of snowfall within a time step is more susceptible to being influenced by wind and is blown  
 from the surface of the firn column. As a result, negative snowfall amounts occur within certain time steps in the  
 590 RACMO2.3p2 model, which are ignored in the time-driven method. Moreover, running the model with fewer snowfall  
 amounts within a time step also increases the computational burden. Here, we run the model driven by accumulation,  
 defining the time step sizes as the time required for the snow accumulation to reach a certain value, referred to as  
 accumulation-driven. By waiting for the snow accumulation to reach a certain threshold before computation, it is possible to  
 simulate the effects of accumulation on firn more accurately and reduce making biased predictions when snowfall amounts  
 595 are minimal or negative. Due to the significant computational resources required by Darcy's law and the extensive data  
 needed to run daily time steps from 1958 to 2020, we compare results simulated using the bucket percolation scheme under  
 both accumulation-driven and time-driven conditions.

600 **Figure 10. Observed (gray dotted line) and modelled (red solid line) firn depth-density profiles at the Dye-2-17-2 and KAN\_U-13-1 cores. The modelled density profiles are driven by accumulation and time, respectively. The gray-shaded regions indicate no data. The thin inclined line denotes dry firn density simulated using the CROCUS model. The correlation coefficient (r), Nash-Sutcliffe efficiency coefficient (NSE), and root mean square error (RMSE) are displayed in the bottom left of each panel.**

605 The accumulation-driven method successfully captures the high-density layers at KAN\_U (Fig. 10), resulting in a smaller relative bias in density (2.38%) compared to that of the time-driven method (-6.77%) (Table 10). Moreover, this method also

simulates firn density relatively close to observations at Dye-2, with a relative density bias of 2.64%. At both sites, the time-driven method underestimates firn density, resulting in the modelled firn density being closer to the low-density peaks observed and the dry-firn density profiles, with a relative density bias of -1.79% at Dye-2 and -6.77% at KAN\_U. This underestimation is likely related to the lower amount of snowmelt during most time steps in the time-driven method and the limitations of matrix flow schemes. Specially, compared to schemes that account for preferential flow, a percolation scheme that only considers matrix flow is challenging to penetrate liquid water to greater depths (Vandecrux et al., 2020c; Verjans et al., 2019), inherently underestimating the liquid water refreezing. As a result, this scheme tends to perform better at sites with minimal snowmelt production, such as Dye-2. However, it encounters challenges in accurately capturing ice slab formation at KAN\_U, where liquid water is more abundant, leading to an underestimation of firn density at this site. Additionally, the scheme incorporating preferential flow produces overall results closer to observations at KAN\_U, but it significantly overestimates firn density at Dye-2 (Sect. 5.1). In this study, the accumulation-driven method accumulated a certain amount of snowfall and snowmelt at each time step, potentially compensating for the inability of matrix flow to penetrate liquid water to deeper depths.

620

## 6 Conclusion

This study uses the CFM model as the foundational framework to simulate firn density at Dye-2 and KAN\_U, two sites in the percolation zone of the southwest GrIS, with the model's upper boundary forced by the daily output of the region climate model RACMO2.3p2. The CROCUS compaction scheme and the Darcy-flow scheme are coupled to simulate firn properties. Various processes are considered in the firn densification model, including fresh-snow density variability, initial grain size variability, grain size growth, density-dependent and temperature-dependent thermal conductivity, dry-firn compaction, state-dependent hydraulic conductivity, retention, refreezing, and runoff. The expression of the irreducible water in the Darcy-flow

630

scheme is modified by the parameterization of Coléou and Lesaffre (1998). Moreover, the time step is set to the time required for the accumulation to reach a specific value in this study rather than being set to a fixed interval (such as hours, days, weeks, months, or years).

635 Comparison with the in situ measurements obtained from 16 firn cores shows that the model in this study performs well at both Dye-2 and KAN\_U, two climatologically distinct sites in the southwest percolation zone of the GrIS. At the minimal snowmelt production site of Dye-2, the model reproduces thin ice lenses or ice layers in the top 10 m of the firn column, which are caused by the increased snowmelt in recent years. The modelled firn density aligns with the average level of observations, with the relative bias in density ranging from 0.36% (Dye-2-13-2) to 6% (Dye-2-17-1). At the ice slab site of  
640 KAN\_U, the model captures the high-density firn layers and partly reproduces the observed ice slabs. For all 8 cores, the modelled density profiles compare well within uncertainties to observations, with a relative density bias being within  $\pm 5\%$ . As indicated by comparisons of dry-firn densification schemes, water flow schemes, and time step sizes, the model used in this study exhibits good agreement within uncertainties with observations at both Dye-2 and KAN\_U, possibly associated with the choice of time step. This study relates the time step with snow accumulation, which potentially compensates for the  
645 limitation of the matrix flow scheme, enabling the model to capture the formation of high-density firn layers at KAN\_U. Meanwhile, the nature of matrix flow enables the model in this study to exhibit good performance at Dye-2 as well.

Our study indicates that the high-density firn layers and overall characteristics of the upper firn density in the percolation zone could be captured by the choice of appropriate model configurations and climatic forcing data. However, the variability  
650 in firn density has yet to be fully reproduced due to the limited understanding and knowledge gaps of densification processes in the presence of liquid water. For example, the overestimation of low-density peaks may be caused by the limited knowledge of how the ice lenses and/or ice layers persist in the deep firn layers after formation. The power-law creep mechanisms or shear forces may induce the newly formed thin ice lenses and/or ice layers to break, potentially leading to a lower firn density compared to the direct downward shift of ice lenses and/or ice layers. In future firn densification  
655 modelling, machine learning methods should be considered to integrate data-driven and physical mechanisms, reducing uncertainties arising from poorly understood firn densification processes.

*Code and Data availability.* The RACMO2.3p2 data is available from Brice Noël without conditions (Noël et al., 2019). The Community Firn Model code is publicly available under the MIT license at <https://doi.org/10.5281/zenodo.8083362> (Stevens  
660 et al., 2023). The depth-density profiles and ice layer stratigraphy of 16 cores used in this study can be found at

<https://doi.org/10.18739/A2NP1WK6M> (Thompson et al., 2022) and <http://doi.org/10.18739/A2CZ3263B> (Xiao et al., 2022), respectively. The model outputs of Vandecrux et al. (2020c) are available online at <https://doi.org/10.22008/FK2/CVPUJL> (Vandecrux et al., 2020b). The codes and outputs of this study are available from the authors.

665 *Author contribution.* Xueyu Zhang completed the modelling work and wrote the original manuscript. Lin Liu designed the research together with Zhicai Luo and supervised the work. Brice Noël processed and provided the RACMO2.3p2 forcing data. All the authors contributed to the analysis, interpretation of the results and provided feedback on the final manuscript.

*Competing interests.* The authors declare that they have no conflict of interest.
