Abstract. Global ocean biogeochemistry models are frequently used to derive a comprehensive estimate of the global ocean carbon uptake. These models are designed to represent the most important processes of the ocean carbon cycle, but the idealized process representation and uncertainties in the initialization of model variables lead to errors in their predictions. Here, observations of ocean physics (temperature and salinity) are assimilated into the ocean biogeochemistry model FESOM-REcoM over the period 2010-2020 to study the effect on the air-sea CO_2 flux and other biogeochemical variables. ~~While the free running model already represents~~ The assimilation nearly halves the model-observation differences in sea surface temperature and salinity~~rather well, the assimilation further improves it and hence influences the~~ , with modest effects on the modeled ecosystem and CO_2 fluxes. The ~~assimilation has mainly regional~~ main effects on the air-sea CO_2 flux ~~, with the~~ occur on small scales in highly dynamic regions, which pose challenges to ocean models. The largest imprint of assimilation is in the Southern Ocean during winter. South of $50\,°S$, winter CO_2 outgassing is reduced and thus the ~~mean~~ regional CO_2 uptake increases by $0.18\,Pg\,C\,yr^{-1}$ through the assimilation. Other particularly strong regional effects on the air-sea CO_2 flux are located in the area of the North Atlantic Current. Yet, the effect on the global ocean carbon uptake is a comparatively small increase by $0.05\,Pg\,C\,yr^{-1}$ induced by the assimilation, yielding a global mean uptake of ~~$2.78\,Pg\,C\,yr^{-1}$~~ $2.78\,Pg\,C\,yr^{-1}$ for the period 2010-2020.

1 Introduction

The ocean plays a pivotal role in regulating the global carbon budget and thereby mitigating the impacts of anthropogenic carbon dioxide (CO_2) emissions on the Earth's climate. Since the 1960s, the ocean has absorbed consistently around 25% of anthropogenic CO_2 emissions annually (Friedlingstein et al., 2023) and has cumulatively taken up 26–34% of fossil and land-use change ~~CO2~~ CO_2 emissions since the onset of the ~~Industrial Revolution~~ industrial revolution (Crisp et al., 2022). However, quantification of air-sea CO_2 flux still remains challenging. Air-sea CO2 flux is usually inferred from the gradient of partial pressure (pCO_2) or fugacity (fCO_2) of CO_2 across the air-sea interface (Wanninkhof, 2014). Yet, during 2010-2020, which constitutes the best-sampled decade in terms of surface ocean pCO_2 observations so far, observations covered merely

3% of the monthly global ocean (as calculated from the 1°x1°-gridded SOCAT product; Bakker et al., 2016). While the North Atlantic and North Pacific are comparably well observed, data remain scarce in vast regions, such as the Indian Ocean, South Pacific and areas south of 30°S during austral winter, where less than 1% of SOCAT grid cells have been sampled. Although these observations are thought to be representative of a larger area (Jones et al., 2012; Hauck et al., 2020), challenges in deriving a comprehensive global estimate of the global ocean CO_2 uptake arise due to substantial spatial and temporal pCO_2 variations and potential biases induced by the irregular sampling pattern (Denvil-Sommer et al., 2021; Gloege et al., 2021; Hauck et al., 2023b). Particularly in the Southern Ocean, the uncertainty is considerable (Gerber et al., 2009; Gloege et al., 2021), where estimates of the mean flux ~~deviate by 14–26% (Hauck et al., 2023b)~~range from -0.37 to $-1.25\,\mathrm{PgC\,yr^{-1}}$ for the period 2010-2018 (data provided by Hauck et al., 2023b).

~~Initially~~In the Global Carbon Budget, estimates of the ocean carbon sink were initially derived from hindcast simulations of global ocean biogeochemistry models (GOBMs) (Le Quéré et al., 2009; Wanninkhof et al., 2013; Hauck et al., 2020). More recently, air-sea CO_2 flux estimates were added based on regression and machine learning techniques, interpolating pCO_2 observations to achieve global coverage through advanced statistical methods (referred to as pCO_2 products; Rödenbeck et al., 2015). Furthermore, atmospheric transport models that ingest atmospheric CO_2 measurements were employed to estimate the ocean carbon uptake ~~(referred to as atmospheric inversions; Peylin et al., 2013)~~(referred to as atmospheric inversions; Peylin et al., 2013) . Although the different estimation methods have provided valuable and robust insights into large-scale patterns of oceanic carbon uptake (Gruber et al., 2009), discrepancies have emerged. Assessments based on pCO_2-products tend to yield larger estimates of the ocean carbon sink, with stronger trends towards more uptake, compared to estimates based on models (Friedlingstein et al., 2023; Terhaar et al., 2022). The larger estimates are supported by ocean interior observations (Müller et al., 2023), atmospheric oxygen data and atmospheric inversions (Friedlingstein et al., 2023). For the years 2010-2020, pCO_2 products included in the Global Carbon Project suggest a mean oceanic sink of $3.0 \pm 0.4\,\mathrm{Pg\,C\,yr^{-1}}$, while the ~~model mean~~ mean of Global Carbon Project GOBMs is $2.5 \pm 0.4\,\mathrm{Pg\,C\,yr^{-1}}$ ~~, with trends of~~ (data provided by Friedlingstein et al., 2023). Trends over the same time period are $0.7\,\mathrm{Pg\,C\,yr^{-1}\,dec^{-1}}$ and $0.3\,\mathrm{Pg\,C\,yr^{-1}\,dec^{-1}}$, respectively~~(data provided by Friedlingstein et al., 2023)~~ .

Machine learning estimates ~~, on the one hand, perform better~~ perform well when trained with sufficient data ~~, such as in the northern hemisphere~~ (Gloege et al., 2021). However, ~~as with other methods,~~ their performance is less reliable in data-sparse areas. Particularly in the Southern Ocean, many pCO_2~~products~~ -products show diverging results from one another and are likely biased towards more ocean uptake (Hauck et al., 2023b). However even in parts of the North Pacific, which is undersampled in the 2010s, some pCO_2 products show spurious decadal trends (Mayot et al., 2024). Models provide process-driven estimates of the CO_2 flux across the entire global ocean, drawing from the theory of ocean dynamics, biological and chemical processes (Hauck et al., 2020; Fennel et al., 2022). Despite the growing confidence in our mechanistic understanding of the ocean carbon cycle (Crisp et al., 2022), models are also ~~subjected~~ subject to uncertainty. This uncertainty stems from uncertainties in model parametrizations, model spin-up and initial conditions, unresolved sub-gridscale processes and uncertainties in the atmospheric forcing (Hauck et al., 2020; Terhaar et al., 2024).

Data assimilation (DA) ~~has been~~ can be employed to address the emerging discrepancies between ~~data products and models . So far, DA studies of the air-sea CO_2 flux~~ pCO_2-products and models (Carroll et al., 2020). Several studies assimilating ocean surface pCO_2 have focused on specific regions ~~(e.g. the Southern Ocean; Verdy and Mazloff, 2017)~~(e.g., a baseline state of air-sea CO_2 flu , few years ~~(e.g. 2009-2011; Brix et al., 2015)~~ (e.g., optimized biogeochemical initial fields for the period 2009-2011 in Brix et al., 2015) or the climatological mean state ~~(e.g. Gerber et al., 2009); apart from a single multidecadal study covering the global ocean (Carroll et al., 2020). In each of these studies, an Adjoint or Green's Function DA approach is used to determine optimised boundary conditions, forcing terms and/or parameter values for the simulation.~~ (e.g., corrections of large-scale pCO_2 model biases in While . These studies capture well the assimilated pCO_2 observations, while obeying physical laws and biogeochemical (BGC) equations. Data assimilation also provides a better understanding of various components of the ocean carbon cycle, such as the transport of anthropogenic CO_2 in the ocean (e.g., a reconstruction of anthropogenic carbon storage since 1770 in Gerber et al., 2009) , regional and interannual variability of the air-sea CO_2 flux (e.g., global reanalysis in Ford and Barciela, 2017; Carroll et al., 2020; Valsala , the biological carbon pump (e.g., carbon export at a nutrient-rich and nutrient-poor site and estimation of BGC parameters related to air-s and specific ecosystems (e.g., the North West European Shelf ecosystem in Ciavatta et al., 2016, 2018). So far, however, there is no data assimilation product that provides a long-term, annually updated estimate of global ocean CO_2 uptake.

While previous studies indicate that the available BGC observations, when assimilated in isolation, are too sparse to constrain the modeled carbon cycle ~~(Verdy and Mazloff, 2017)~~(Verdy and Mazloff, 2017; Spring et al., 2021), the assimilation of physical variables is expected to have a significant indirect effect on the modeled ~~CO_2 uptake because upwelling and subduction of DIC, as well as the physical transport of other biogeochemical tracers, will be affected~~ air-sea CO_2 fluxes (Bernardello et al., 2024). This is because the uptake of atmospheric CO_2 depends ultimately on the modeled physical carbon transport between the surface, the mixed layer and the deep ocean in the form of dissolved inorganic carbon (DIC) through mixing, upwelling and subduction (Doney et al., 2004). According to current knowledge, ocean physics is the dominant driver of interannual variability ~~in the~~ of the global air-sea CO_2 flux ~~(Doney et al., 2009; Keppler and Landschützer, 2019; Mayot et al., 2023; Liao . Furthermore, in GOBMs, well-constrained physics are particularly important to capture the ocean storage of anthropogenic carbon (C_{ant}), as the rate of anthropogenic CO_2 uptake depends ultimately on~~ and also responsible for stagnation and acceleration of the ~~modeled physical carbon transport from the~~ CO_2 uptake on decadal scales (Doney et al., 2009; Keppler and Landschützer, 2019; May . Related to the strong control that physics exert on the interannual variability of air-sea ~~interface across the mixed layer into the deep ocean in the form of dissolved inorganic carbon (DIC) (Davila et al., 2022). It was shown~~ CO_2 fluxes, it was shown in one idealized study that assimilating ocean physics at the initial state of a model simulation has a stronger and more positive impact on the modeled carbon cycle on interannual time-scales than assimilating the BGC initial state (Fransner et al., 2020). ~~Therefore the question arises which processes are most important when altered physics change CO_2 fluxes in DA approaches. We~~ However, the relative importance of uncertainties in physical and biogeochemical fields generally remains an open research question (e.g. Séférian et al., 2014; Li et al., 2016; Lebehot et al., 2019). Therefore, we here use ensemble-based data assimilation of ocean physics into a global ocean biogeochemistry model aiming to improve the modeled air-sea CO_2 flux for the years 2010-2020. For ~~assimilation we use an ensemble Kalman filter variant (Nerger et al., 2012). With thisapproach, we describe the impact of continuously assimilating ocean-physics~~ this, we continuously assimilate temperature and salinity observations from

remote-sensing at the surface and from in-situ profile measurements for eleven years ~~on the model's air-sea CO_2 flux. Here, we identify the mechanisms of how physics DA affects the modeled air-sea CO_2 flux, differentiating between the thermally, DIC- and alkalinity induced components and changes in mixing, and lateral and vertical transport~~and update the modelled temperature, salinity, horizontal velocities and sea surface height, using an ensemble Kalman filter variant (Nerger et al., 2012) .

~~An accurate representation of ocean physics is a prerequisite, but not necessarily sufficient for a realistic simulation of the CO_2 flux. Coupled ecosystem models are adapted to the associated physics~~ Several difficulties are associated with physics DA into GOBMs. A common issue is erroneous equatorial upwelling leading to unrealistically high biological productivity in the tropics (Park et al., 2018; Gasparin et al., 2021; Raghukumar et al., 2015). Furthermore, any coupled ecosystem model is adapted to its associated physical model with its strengths and weaknesses through carefully selected parameter values ~~. Furthermore, the natural carbon cycle in models is tuned to an equilibrium for the physical model state at pre-industrial conditions without DA, and it was shown that the~~ and a spin-up to near-equilibrium. Accordingly, the modeled carbon cycle may react very sensitive to deviations from ~~this physical state , leading~~ the physical state that is typical for this model (Kriest et al., 2020; Spring et al., 2021). Potentially, this leads to biases in the carbon cycle through ~~data assimilation (Spring et al., 2021)~~ physics DA. The question therefore arises ~~as~~ to what extent an ecosystem model coupled to a data-assimilated physical model also represents a more realistic biogeochemistry~~. We will present cases where physics data-assimilation leads to worse and better agreement with BGC observations.~~ , and which mechanisms drive the response of the CO_2 flux in physics DA approaches. One possible driver is the physical transport of DIC and alkalinity because velocities and diffusivity are changed by the DA, affecting in particular the upwelling of carbon-rich waters and subduction, which is important to capture the ocean storage of anthropogenic carbon (Davila et al., 2022). Furthermore, physics DA may change pCO_2 directly through its temperature-dependence, an effect emphasized by Verdy and Mazloff (2017). Additionally, the modelled biological pump might be altered, for example through the temperature-dependency of phytoplankton growth or through effects of stratification on nutrient availability.

In this study, we describe the response of the model's air-sea CO_2 flux to physics DA and identify the underlying mechanistic drivers. To this end, we differentiate between the thermally, DIC- and alkalinity induced components and changes in lateral and vertical transport through mixing and advection. We focus, firstly, on the global air-sea ~~CO2~~ CO_2 flux. Secondly, we investigate the Southern Ocean given the relevant impact of DA in Southern Ocean winter in our study. Thirdly, we present regions in the North Atlantic given observational coverage and relevant local processes there.

2 Methods

2.1 Model FESOM-REcoM

The oceanic model component, FESOM2.1, computes the advection, diffusion, and mixing of passive biogeochemical tracers. The model is based on hydrostatic primitive equations under the Boussinesq approximation and utilizes a finite-volume discretization approach with surface triangles projected vertically to form prisms. Salinity (S), temperature (T), and biogeochem-

ical ~~(BGC)~~ tracers are located at the vertices of triangles (nodes), while the horizontal velocities are centered at the triangles (elements). The model allows for a variable mesh resolution (see Section 2.2) and incorporates parametrizations for diffusion and eddy-stirring along isoneutral surfaces, for which parametrized mixing is scaled by mesh resolution (Danilov et al., 2017). Vertical mixing is parametrized through the KPP scheme and the mixing depth is specified through a ~~boundary layer~~'boundary layer' (the layer of active mixing, which may have a vertical structure because the mixing of all properties across the layer is not instantan , with an additional vertical mixing scheme used in the Southern Ocean (Monin–Obukhov parametrization, Timmermann and Beckmann, 2 . The surface salinity (SSS) is restored towards ~~climatology and scaled by a fictional flux at the ocean surface of 0.1m/day~~the World Ocean Atlas climatology through a fictional surface flux with $v_{\mathrm{SSS}} = 50\,\mathrm{m}/300\,\mathrm{days}$ according to equation 1 and as in Gürses et al. (2023):

$$(\mathrm{SSS}_{\mathrm{clim}} - \mathrm{SSS}_{\mathrm{model}}) * v_{\mathrm{SSS}} * (h_{\mathrm{surf}})^{-1} \quad (1)$$

with surface-layer width h_{surf}. A detailed description of FESOM2.1 ~~is provided by Danilov et al. (2017)~~ and a model assessment ~~by~~ are provided by Danilov et al. (2017) and Scholz et al. (2019, 2022).

The ocean biogeochemistry component, the Regulated Ecosystem Model version 3 (REcoM3), describes processes in the ocean carbon cycle and represents oceanic carbon in the form of dissolved inorganic carbon~~(DIC)~~, dissolved organic carbon~~(DOC)~~, plankton and detritus (Gürses et al., 2023). REcoM3 contains 28 BGC tracers (listed in Appendix Table A1). There are two phytoplankton groups: diatoms and small phytoplankton with implicit representation of calcifiers; two zooplankton groups: mixed and polar macro zooplankton (Karakuş et al., 2021); and two classes of detritus~~: fast and slow-sinking~~. REcoM3 includes variable intracellular stoichiometry with ratios of C:N:Chl:$CaCO_3$ for the small phytoplankton and C:N:Chl:Si for diatoms, which is propagated to zooplankton and detritus (Schartau et al., 2007; Hohn, 2008). The publicly available Routines To Model The Ocean Carbonate System ~~(mocsy2.0) (Orr and Epitalon, 2015)~~ (mocsy2.0, Orr and Epitalon, 2015) are used to compute pCO_2 and air-sea CO_2 flux, employing the gas-exchange parameterization of Wanninkhof (2014). Alkalinity is restored by a fictional surface flux of ~~10m/yr~~$10\,\mathrm{m\,yr^{-1}}$ (as in Hauck et al., 2013; Schourup-Kristensen et al., 2014; Gürses et al., 2023) . The current model version FESOM2.1–REcoM3 was assessed by Gürses et al. (2023) and previous versions were evaluated and applied in global and regional studies of the ocean carbon cycle and planktonic ecosystems (Hauck et al., 2013; Schourup-Kristensen et al., 2014; Hauck et al., 2020; Karakuş et al., 2021).

2.2 Simulation set-up

The model setup for both simulations closely follows Gürses et al. (2023). The mesh resolution is nominally 1 degree, ranging between 120 km and 20 km with enhanced resolution in the equatorial belt and north of 50 °N (126858 surface nodes). It has 47 vertical layers with thickness ranging from 5 m at the surface to 250 m in the deep ocean, as described by Scholz et al. (2019, CORE mesh) . The model time step is 45 minutes. For atmospheric forcing, JRA55-do v.1.5.0 is used, a reanalysis product tailored for driving ocean-sea-ice models (Tsujino et al., 2018). The atmospheric CO_2 mixing ratio (xCO_2) values were taken from the Global Carbon Budget (Joos and Spahni, 2008; Ballantyne et al., 2012; Friedlingstein et al., 2023). We use model restart fields from Gürses et al. (2023) where the model was spun-up by repeating the year-1961 JRA forcing for 189 years with preindustrial

atmospheric CO_2 conditions, followed by a period from 1800 to 1957 with increasing atmospheric CO_2. Subsequently, simulations were continued with historical JRA forcing from 1958 to 2009. During the assimilation window (2010-2020), we conduct two ensemble simulations to study the impact of data assimilation (DA): one without DA (referred to as FREE) and another identical setup applying DA (referred to as ASML). For each simulation, the ensemble mean for the following variables is written as output: temperature, salinity, velocity, boundary-layer depth, surface pCO_2, DIC, alkalinity, nutrients, chlorophyll, net primary production and biological export through sinking of detritus at 190 m. For the year 2020, additional output is available for individual ensemble members, mixed-layer depth, physical sources or sinks of DIC and alkalinity through horizontal and vertical advection and diffusion, and biological net sources or sinks of DIC and alkalinity through combined processes: For DIC, the net biological term is the sum of photosynthesis, respiration, remineralization of dissolved organic carbon, and formation and dissolution of calcite (Gürses et al., 2023, equation A6). For alkalinity, the net biological term is the sum of nitrogen assimilation and remineralization, and formation and dissolution of calcite (Gürses et al., 2023, equation A7).

2.3 Data Assimilation

2.3.1 Assimilated observations

The assimilated observations are sea surface temperature (SST), sea surface salinity and profiles of temperature and salinity. The assimilated SST observations are from the Operational Sea Surface Temperature and Ice Analysis (OSTIA) data set (CMEMS Marine Data Store; Good et al., 2020; Donlon et al., 2012; Stark et al., 2007). OSTIA provides daily gap-free maps of SST at a horizontal resolution of $0.05° \times 0.05°$, compiled from in-situ and satellite data from infrared and microwave radiometers. The OSTIA observations were averaged to the FESOM2.1 model grid because their spatial resolution is higher than the nominal resolution of the model grid. An observation error standard deviation of $0.8\,°C$ is prescribed for the DA following Nerger et al. (2020). Observations are excluded in the DA process if the difference between the model and observation exceeds three times the observation error standard deviation, thus $2.4\,°C$, and at grid points with sea ice in the model, as in Tang et al. (2020) and Mu et al. (2022). This exclusion keeps the model stable despite large differences between model and observations at these sites, in particular as water temperature and salinity develop differently under sea ice than under the influence of the atmosphere (Tang et al., 2020). Instead, a 'gentler' correction is made by assimilating neighboring points. After the initial phase, about 7% of SST observations are excluded because of the $2.4\,°C$-threshold. Nevertheless, the data assimilation still has a strong effect in areas where these large model-observation discrepancies are typically found (North Atlantic, Japan and Southern Ocean).

The assimilated SSS data is taken from the European Space Agency (ESA) Sea Surface Salinity Climate Change Initiative (CCI) v03.21 data set (Boutin et al., 2021). ESA-CCI contains daily data at a spatial resolution of 50 km, albeit not capturing temporal variability below weekly. The ESA-CCI observations are averaged to the FESOM2.1 model grid. We prescribe a constant observation error standard deviation of 0.5 psu following Nerger et al. (2024). Like for the SST data, SSS observations are excluded at locations where sea ice is present in the model.

The assimilated temperature and salinity profiles are taken from the EN.4.2.2 data set (Good et al., 2013). The EN4 dataset contains quality-controlled profiles from various in-situ ocean profiling instruments. To assimilate the profiles, the observations are assigned to the respective model layers (depth range) in the vertical. In the horizontal, the model values are computed as the average of the grid points of the triangle enclosing the observation. The observation error standard deviation is set to 0.8 °C for temperature and to 0.5 psu for salinity, as in Tang et al. (2020).

2.3.2 Assimilation method and implementation

For the assimilation, we use the Localized Error Subspace Transform Kalman Filter (LESTKF, Nerger et al., 2012). The LESTKF ~~incorporates new observations as they emerge by updating the previous estimate of the state~~sequentially updates the model forecast, incorporating observations when and where available. The model state and error covariance are represented by an ensemble simulation. Thereby, the assimilation of temperature and salinity affects the state of the physical model in its whole, including the horizontal velocities and sea-surface height. A review of the LESTKF and other filters frequently used in geophysics can be found in Vetra-Carvalho et al. (2018). The assimilation is implemented using the Parallel Data Assimilation Framework (PDAF2.1), a software environment for data assimilation. PDAF is an open source project and provides fully implemented DA algorithms (Nerger et al., 2020, pdaf.awi.de). The current implementation builds on the works of Mu et al. (2022) who used DA of ocean temperature and salinity for sea-ice forecasts with FESOM2.0 coupled to an atmospheric model, and Tang et al. (2020) who studied the dynamic impact of oceanic DA into FESOM1.4 onto a coupled atmospheric component.

With localization of the LESTKF, ~~observations are weighted by distance , thereby avoiding the model being~~ the observation error is increased for an increasing horizontal distance between an observation and a model grid point, which weighs down the influence of a more distant observation. This avoids that the model is influenced by observations at distant locations through spurious ensemble estimated correlations. We use a localization radius of 200 km and choose a 5th-order polynomial weighting function that mimics a Gaussian function (Gaspari and Cohn, 1999). We apply daily analysis steps at 0 UTC model time, assimilating all available observations for the day. The DA process only directly updates the physical model variables temperature, salinity, horizontal velocities and sea surface height. After each assimilation step, corrections are applied to the analysis state to ensure the consistency of model physics: Salinity is set to a minimum value of zero and temperature to a minimum value of $-2\,^{\circ}\mathrm{C}$, if ~~necessary. The~~ the value is otherwise below. The increment of sea surface height (SSH) ~~update~~ is limited to two standard deviations of the ensemble. While in the simulation the correction was necessary for about 10% of SSH updates and 0.01 ‰ of temperature values at each step, the correction of salinity was never required. The analysis step is followed by an ensemble forecast of 1 day.

The ensemble size is 40, a compromise to balance computational resources while ensuring a sufficiently large ensemble with enough variability even in the deep ocean. The ensemble is generated through an initial perturbation of sea surface height, horizontal and vertical velocities, temperature, salinity and sea-ice concentration ~~generated from a 1-year model run as described by Tang et al. (2020).~~ based on the implementation of Tang et al. (2020). This initial ensemble perturbation is generated by second-order exact sampling (Pham, 2001) from a model trajectory of FESOM2.1. With this method, the leading Empirical Orthogonal Functions (EOFs) of a model trajectory are used to generate an ensemble perturbation that contains the

leading patterns of model variability. A time-scale must be chosen for the variability that is represented by the ensemble. Here, we chose variability on a weekly time-scale (Tang et al., 2020).

To maintain ensemble spread, we apply a perturbed atmospheric forcing with an autoregressive perturbation ~~($\mathrm{perturb_n}$)~~ ($\mathrm{perturb_{e,n}}$) at every model time step (n) to each ensemble member (e), with:

$$\mathrm{perturb_{n+1}} = (1 - \mathrm{arc}) * \mathrm{perturb_n} + \mathrm{arc} * s * (N_{\mathrm{ens}} - 1) * \mathrm{rand}$$

$$\mathrm{perturb_{e,n+1}} = (1 - \mathrm{arc}) * \mathrm{perturb_{e,n}} + \mathrm{arc} * s * \mathrm{rand_e} \quad (2)$$

where rand is a stochastic element~~that is based on a covariance matrix derived~~, again generated by second-order exact sampling from a 72-days-long ~~period~~ trajectory of atmospheric forcing ~~; the~~ fields that captures patterns of day-to-day atmospheric variability. The autoregression coefficient (arc) ~~is~~ can be used to tune how quickly the perturbation changes and is set to the inverse number of model steps per day~~; and~~. s is a scaling factor for each perturbed atmospheric forcing field. For specific humidity, downwelling longwave radiation and air temperature $s = 10$ is used. The perturbation of winds is set to the smaller value $s = 2$ because the air-sea CO_2 flux in the model is particularly sensitive to perturbations of the wind fields. ~~Because the ensemble spread still~~ Due to the functioning of the Kalman filter (which updates the model error covariance in each analysis step to reflect the new reduced uncertainty), the ensemble spread decays at each analysis step. As the method relies on a sufficiently large ensemble spread, an inflation of the ensemble ~~is applied in each analysis step by applying a forgetting factor ρ (see e.g. Nerger et al., 2005). This inflation uses a time-varying forgetting factor between $\rho = 0.95$ and $\rho = 1$, where~~ covariance is applied (Pham et al., 1998). Thereby, the ensemble covariance matrix is amplified by a factor of $1/\rho$ before entering the updating step. This so-called forgetting factor downweighs that past observations have reduced the model uncertainty (see e.g. Nerger et al., 2005). The forgetting factor is tuned to maintain model uncertainty, where $\rho = 1$ means no inflation and smaller values mean larger inflation. Here, we use a time-varying forgetting factor between $\rho = 0.95$ and $\rho = 1$. The strongest inflation ($\rho = 0.95$) is applied during the first two weeks of the DA process. During the following 75 days ρ is increased to 0.99~~and from thereon stays between~~. From month 17 onwards, the forgetting factor is set to either 0.99 ~~and~~ or 1.0 depending on ~~a temperature threshold for the~~ the ensemble standard deviation of ~~the ensemble spread.~~

2.3.3 ~~Assimilated observations~~

~~We assimilate sea surface temperature(SST), sea surface salinity (SSS) and profiles of temperature (T) and salinity (S). The assimilated SST observations stem from the Operational Sea Surface Temperature and Ice Analysis (OSTIA) data set (CMEMS, 2023; Good et al., 2020; Donlon et al., 2012; Stark et al., 2007). OSTIA provides daily gap-free maps of SST at a horizontal resolution of $0.05° \times 0.05°$, compiled from in-situ and satellite data from infrared and microwave radiometers. The OSTIA observations were averaged to the FESOM2.1 model grid because their spatial resolution is higher than the nominal resolution of the model grid. We prescribe an observation error~~ temperature. The ensemble standard deviation of the local instantaneous air-sea CO_2 fluxes that results from the perturbation of physical fields is larger than that of the global

CO_2 flux, with a mean standard deviation of ~~$0.8\,°C$ for the DA (Nerger et al., 2020). Observations are excluded in the DA process, if the difference between the model and observation exceeds $2.4\,°C$ and at grid points with sea ice in the model, as in Tang et al. (2020) and Mu et al. (2022). This keeps the model stable despite large differences between model and observations at these sites, as water temperature and salinity develop differently under sea ice than under the influence of the atmosphere (Tang et al., 2020).~~

~~The assimilated SSS data is taken from the European Space Agency (ESA) Sea Surface Salinity Climate Change Initiative (CCI) (Boutin et al., 2021) v03.21 data set. ESA-CCI contains daily sampled SSS data at a spatial resolution of 50 km and a time resolution of 1 week. The ESA-CCI observations are averaged to the FESOM2.1 model grid. We prescribe a constant observation error~~ $0.32\,\mathrm{mmol\,m^{-2}\,day^{-1}}$ for monthly means of local fluxes compared to a standard deviation of ~~0.5 psu (Nerger et al., 2024). Like for the SST data, SSS observations are excluded at locations where sea ice is present in the model.~~

~~The assimilated temperature and salinity profiles are taken from the EN.4.2.2 data set (Good et al., 2013). The EN4 dataset contains quality-controlled profiles from various in-situ ocean profiling instruments. To assimilate the profile observations, the model values are computed as the average of the grid points of the triangle enclosing the observation because the number of observations is fewer than model grid points. The observation error~~ $0.0068\,\mathrm{mmol\,m^{-2}\,day^{-1}}$ ($0.01\,\mathrm{PgC\,yr^{-1}}$) for the annual global flux in FREE in the year 2020. The largest ensemble standard deviation is ~~set to $0.8\,°C$ for temperature and to 0.5 psu for salinity, as in Tang et al. (2020).~~

2.4 ~~Simulation set-up~~

~~The model setup for both simulations closely follows (Gürses et al., 2023). The model mesh is irregular and has a nominal resolution of 1 degree, with enhanced resolution in the equatorial belt and north of $50\,°N$. It has 47 vertical layers with thickness ranging from 5 m at the surface to 250 m in the deep ocean, as described by Scholz et al. (2019). The model time step is 45 minutes. For atmospheric forcing, we use JRA55-do v.1.5.0, areanalysis product tailored for driving ocean-sea-ice models (Tsujino et al., 2018). The atmospheric CO_2 mixing ratio (xCO_2)values were taken from the Global Carbon Budget (Joos and Spahni, 2008; Ballantyne et al., 2012; Friedlingstein et al., 2023). We use model restart fields from Gürses et al. (2023) where the model was spun-up by repeating the year-1961 JRA forcing for 189 years with preindustrial atmospheric CO_2 conditions, followed by a period from 1800 to 1957 with increasing atmospheric CO_2~~ generated in the Southern Ocean, the North Atlantic and the North Pacific (map in Fig. A1a), which corresponds to regions of high uncertainty in existing CO_2 flux estimates (Pérez et al., 2024; Hauck et al., 2023a; Mayot et al., 2024). However, the modelled standard deviation should not be understood as the true uncertainty of the model, but as a value dependent on tuning (Evensen, 2003). ~~Subsequently, simulations were continued with historical JRA forcing from 1958 to 2009. During the assimilation window (2010-2020), we conduct two ensemble simulations to study the impact of data assimilation (DA) covering the period of the years 2010 to 2020: one without DA (referred to as FREE) and another identical setup applying DA (referred to as ASML).~~

2.4 Data analysis

~~To assess the model results we focus on the ensemble mean.~~ We present CO_2 flux estimates for the period 2010-2020, that are compared to the 'Regional Carbon Cycle Assessment and Processes 2' (RECCAP2) global air-sea CO_2 flux estimates (DeVries et al., 2023). ~~For the comparison of the global air-sea CO_2 flux in our simulations with the~~ The RECCAP2 ~~CO_2 flux estimates, the~~ pCO_2 products account for oceanic outgassing of river carbon into the atmosphere. To make them comparable with our estimate stemming from a model without river carbon input, we apply a river flux adjustment (Friedlingstein et al., 2023; Regnier et al., 2022) ~~is applied to the~~ to the RECCAP2 pCO_2 products. Thus, we quantify the anthropogenic perturbation of the ocean carbon sink ~~without rivers~~ (as S_{OCEAN} in the Global Carbon Budget Friedlingstein et al., 2023; Hauck et al., 2020), and not the contemporary net air-sea CO_2 flux with outgassing of river carbon (as in the original RECCAP2 pCO_2 products).

To study the effect of DA on the CO_2 flux, we define regions where the effect is pronounced and where different mechanisms are active~~. In the Southern Ocean, we use~~ , based on the biomes defined by Fay and McKinley (2014). These are, ~~from North to South~~going polewards from the subtropics in each hemisphere, the Subtropical Seasonally Stratified Biome (STSS), the Subpolar Seasonally Stratified Biome (SPSS) and the Sea-Ice Biome (ICE)~~(see Fig. 5). Within the STSS~~. In the Southern Ocean ($_{SO}$), within the $STSS_{SO}$, we differentiate between the area where the assimilation leads to a more positive air-sea CO_2 flux (positive: out of the ocean), referred to as $STSS_{SO}+$ and the area where the assimilation leads to a more negative air-sea flux, the ~~STSS-~~ $STSS_{SO}-$ (Fig. 5a and b). In the North Atlantic ($_{NA}$), we consider four coherent regions within the $STSS_{NA}$ and $SPSS_{NA}$, defined by the time-mean difference of the air-sea CO_2 fluxes in ASML and FREE (ΔF_{CO_2}~~, Fig. 7a and b~~). The Central $STSS_{NA}-$ and Western $STSS_{NA}+$ are located in the central North Atlantic $STSS_{NA}$ biome and are confined by $\Delta F_{CO_2} < -1\,\mathrm{mmol\,C\,day^{-1}m^{-2}}$ and $\Delta F_{CO_2} > 1\,\mathrm{mmol\,C\,day^{1}m^{-2}}$, respectively (see Fig. 7b). The Newfoundland Basin~~and East Coast SPSS+~~ and Coastal $SPSS_{NA}-$ are part of the $SPSS_{NA}$. The former is located east of Newfoundland and south of Greenland, and is confined by $\Delta F_{CO_2} > 3\,\mathrm{mmol\,C\,day^{-1}m^{-2}}$; and the latter is located off the North American coast and confined by $\Delta F_{CO_2} < -1\,\mathrm{mmol\,C\,day^{-1}m^{-2}}$. The Central $STSS_{NA}-$ and Western $STSS_{NA}+$ lie on the warm side of the ~~NAC~~North Atlantic Current (NAC), and the Newfoundland Basin~~and West Coast SPSS+~~ and Coastal $SPSS_{NA}-$ lie on the cold side of the NAC, which is evident from the modeled surface velocity field (Fig. A2a).

Within these regions, we identify the time of the year when the DA affects air-sea CO_2 flux and calculate the difference of ASML and FREE for ~~SST, SSS, surface velocities and transports, density, boundary layer depth, surface pCO_2, DIC, alkalinity and surface chlorophyll~~physical and biogeochemical fields. In order to assess the ~~drivers of~~ dynamic DA effects on surface pCO_2, it is useful to distinguish between different variables that constitute the change in pCO_2. Oceanic pCO_2 varies mainly with temperature, DIC and alkalinity. Thus, we decompose changes in pCO_2 ~~are decomposed after the simulation~~ into their contributions from changes in SST~~(SST)~~, surface DIC ~~(DIC) and~~ and surface alkalinity (Alk)~~following the linear~~ . For that, we apply the following approximations of Sarmiento and Gruber (2006) and Takahashi et al. (1993):

$$\Delta \mathrm{pCO_{2,DIC}} = \frac{\mathrm{pCO_2}}{\mathrm{DIC}} * \gamma_{\mathrm{DIC}} * \Delta \mathrm{DIC} \tag{3}$$

$$\Delta \mathrm{pCO_{2,Alk}} = \frac{\mathrm{pCO_2}}{\mathrm{Alk}} * \gamma_{\mathrm{Alk}} * \Delta \mathrm{Alk} \tag{4}$$

$$\Delta \mathrm{pCO}_{2,\mathrm{SST}} = \mathrm{pCO}_2 * \exp(0.0423 * \Delta \mathrm{SST}) \quad (5)$$

~~with~~ Here, differences between ASML and FREE are denoted by Δ; else, the average of ASML and FREE is used for the computation. The sensitivities γ_{DIC} and γ_{Alk} describe how pCO_2 varies with changes in one variable while keeping all other variables constant. For the sensitivities, we use an approximation derived from seawater carbonate chemistry following Sarmiento and Gruber (2006):

$$\gamma_{\mathrm{DIC}} = \frac{3 * \mathrm{Alk} * \mathrm{DIC} - 2 * \mathrm{DIC}^2}{(2 * \mathrm{DIC} - \mathrm{Alk})(\mathrm{Alk} - \mathrm{DIC})} \quad (6)$$

$$\gamma_{\mathrm{Alk}} = \frac{-\mathrm{Alk}^2}{(2 * \mathrm{DIC} - \mathrm{Alk})(\mathrm{Alk} - \mathrm{DIC})} \quad (7)$$

~~Values~~ Based on the range of valid values for γ_{DIC} and γ_{Alk} according to the explicit formulation by Egleston et al. (2010), values are excluded above 18 and below -19, respectively. This affects parts of the Southern Ocean SPSS~~and ICE~~$_{\mathrm{SO}}$ and ICE$_{\mathrm{SO}}$ biome (see white areas in Fig. 6b and c). Finally, the effect on the air-sea CO_2 flux relates directly to the pCO_2-difference at each grid point, as detailed in Orr et al. (2017, equations 6-15):

$$\Delta F_{\mathrm{CO}_2} = \alpha \cdot k_w \cdot \Delta \mathrm{pCO}_2 \quad (8)$$

where α is the solubility of CO_2 in seawater and k_w is the gas-transfer velocity.

To evaluate the impact of ~~the DA on the modeled~~ DA on ocean physics, we compare the simulated SST and SSS to the assimilated observations (Section 2.3.1). For temperature and salinity at depth, we use the EN4-OA product (Good et al., 2013, updated to v . EN4-OA is an objective analysis ingesting the assimilated EN4 profile data, interpolated to global coverage on 42 depth levels. Furthermore, we compare the sea-ice concentration with remote sensing observations from OSI-SAF 2010-2020 (EUMETSAT, 2022) , the mixed-layer depth in the year 2020 with the profile-observation based climatology of de Boyer Montégut et al. (2004, updated version and the horizontal near-surface velocities 2010-2020 with the drifter-based climatology of Laurindo et al. (2017).

To evaluate the impact of the DA on biogeochemistry, we compare model outputs with ~~independent~~ observational datasets of surface pCO_2, DIC, alkalinity and surface chlorophyll. ~~For each observation type (OBS), we define the improvement as:~~

$$\mathrm{improvement}_{\mathrm{OBS}} = |\mathrm{FREE} - \mathrm{OBS}| - |\mathrm{ASML} - \mathrm{OBS}|$$

To evaluate surface pCO_2, we use observations from the Surface Ocean CO_2 Atlas (SOCAT Version 2023, Bakker et al., 2023, 2016), which are provided as a monthly gridded and quality-controlled compilation.

To assess DIC and alkalinity, we compare the modeled surface fields to the GLODAPv2.2023 bottle data (Lauvset et al., 2024b). At depth, we compare the model output to the GLODAPv2 DIC and alkalinity climatology (Lauvset et al., 2016), which is based on observations from the period 1972-2013 and normalized to 2002.

To evaluate global surface chlorophyll, we use observations from ESA-CCI, which is a multi-sensor satellite ocean-color chlorophyll-a dataset with monthly global coverage (Sathyendranath et al., 2021). In addition, for the Southern Ocean, we use the mean of three satellite products (Johnson et al., 2013) that were processed with more suitable algorithms for southern high latitudes. For each observation type (OBS), we define the improvement as:

$$\text{improvement}_{\text{OBS}} = |\text{FREE} - \text{OBS}| - |\text{ASML} - \text{OBS}| \tag{9}$$

3 ~~Effect of DA on ocean physics~~Results

3.1 Effect of DA on ocean physics

Before we investigate the CO_2 flux, we first evaluate the effect of DA on the modeled physics. In particular, we compare the model output of both simulations with the assimilated observations to verify that the assimilation brings them into better agreement with the observations. ~~Additionally, we compare the temperature and salinity with the partly-independent EN4-OA product (Good et al., 2013, updated to version 4.2.2). EN4-OA is an objective analysis ingesting the assimilated EN4 profile data, interpolated to global coverage on 42 depth levels. Furthermore, we compare the sea-ice concentration with remote sensing observations from OSI-SAF (EUMETSAT, 2022).~~

The assimilation improves the agreement with the assimilated SST observations. On a global average, the SST in FREE is $0.14\,^{\circ}\mathrm{C}$ colder than the observations, which is estimated to lead to a solubility-driven global air-sea flux difference of $-0.06\,\mathrm{Pg\,C\,yr^{-1}}$ (Eqs. (5) and (8)). FREE exhibits an extensive cold bias of SST in the tropics and subtropics in all ocean basins and a warm bias in the Southern Ocean south of $40\,^{\circ}\mathrm{S}$, visible in Fig. 1a; mean state of SST in Fig. A3a). Additionally, FREE shows regional SST biases in ~~particularly~~ particular near strong currents or in eddy-rich regions, such as the ~~North Atlantic Current (NAC)~~NAC, Kuroshio, and the Southern Subtropical Front. The assimilation reduces the SST south of $40\,^{\circ}\mathrm{S}$ and in the North Pacific, and increases the SST in the tropics and subtropics (see Fig. 1b). The effect of DA is an absolute change by $0.30\,^{\circ}\mathrm{C}$ on global average and is particularly strong in the Southern Ocean and in the North Atlantic. Through the assimilation, the model state becomes more similar to the observations globally, which is evident from the positive improvement in Fig. 1c. In total, the global mean absolute difference ~~in SST~~ of SST to the observations is reduced from $0.59\,^{\circ}\mathrm{C}$ to $0.32\,^{\circ}\mathrm{C}$. The assimilation-induced change in SST is estimated to drive a direct solubility-driven effect on the global-air sea CO_2 flux of $-0.14\,\mathrm{Pg\,C\,yr^{-1}}$ (Eqs. (5) and (8)). Yet, this global attribution is subject to high uncertainty due to the non-linear dependency of pCO_2 on temperature, and because regionally large effects with opposite signs lead to uncertainty in the global mean.

The assimilation also improves the agreement with the assimilated SSS observations. Additional experiments with and without salinity restoring towards climatology show that the best agreement with the SSS-CCI observations is achieved by simultaneously using assimilation and restoring. A benefit of the additional use of restoring is the global coverage of the SSS climatology. FREE shows a global SSS bias (0.49 psu, Fig. 1d). The assimilation leads to a global surface freshening (Fig. 1e). There are only a few regions where SSS in FREE is fresher than the observations and where the DA consequently increases

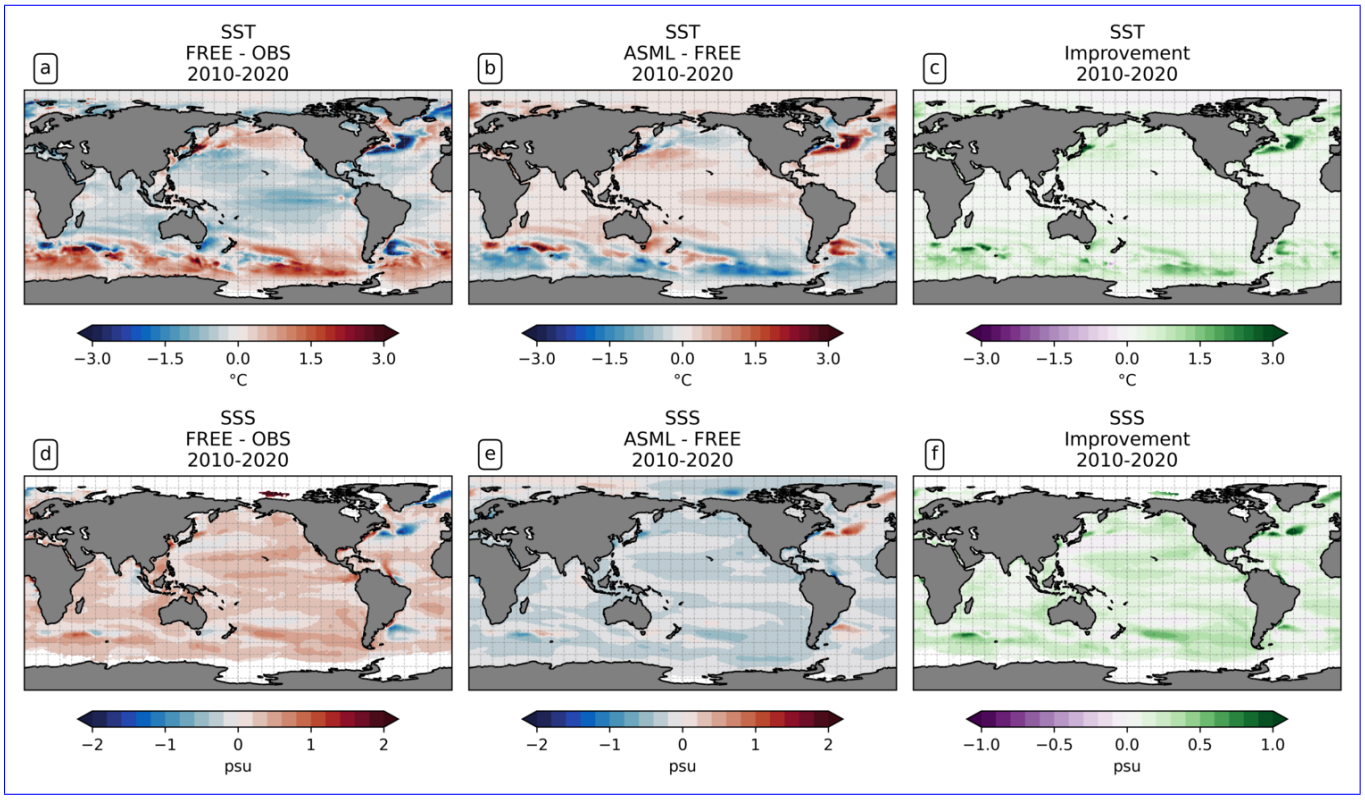

Figure 1. Effect of data assimilation on sea surface temperature (SST) and sea surface salinity (SSS). All panels show the mean over the period 2010-2020. (a) The model-observation difference in SST (FREE - OSTIA). (b) The difference ASML - FREE. (c) The improvement of monthly averaged model SST relative to OSTIA, where positive denotes that the assimilation brings the model closer to observations (Eq. (9)). (~~c~~ d - f) The same for SSS, computed with SSS from ESA-CCI.

the salinity~~. One of these regions lies in~~ , as for example in parts of the North Atlantic. The assimilation improves the model-observation agreement in 91% of the observed ocean area, particularly ~~much~~ in the North Atlantic Central $STSS_{NA}$ – and in the Southern Ocean $STSS_{SO}$ (Fig. 1f). ~~Albeit negative side effects~~ Tests with the assimilation of temperature alone show negative side-effects of temperature assimilation on SSS in some locations (not shown). In the final set-up with combined assimilation, negative effects on SSS are found in 9% of the observed area~~, the global~~ . Globally, the mean absolute difference is reduced from 0.32 to 0.17 psu relative to the SSS observations. The direct solubility-driven effect of salinity differences on the global air-sea CO_2 flux is estimated to be negligible.

The assimilation leads to a better agreement with subsurface temperature and salinity data from the ~~non-assimilated~~ EN4-OA product in the upper 1000 m. In the upper 100-200 m of the ocean, the model-observation difference in temperature follows the surface signal (compare Fig. 1a and Fig. 2a), and the difference is reduced by the assimilation (Fig. 2b and c). At intermediate depth (roughly 200-500 m), a subsurface warm bias exists in FREE in the southern hemisphere at mid-latitudes (Fig. 2; mean state in Fig. A4a). This bias affects the South Pacific, South Atlantic and southern Indian Ocean (not shown). ~~It~~ The bias

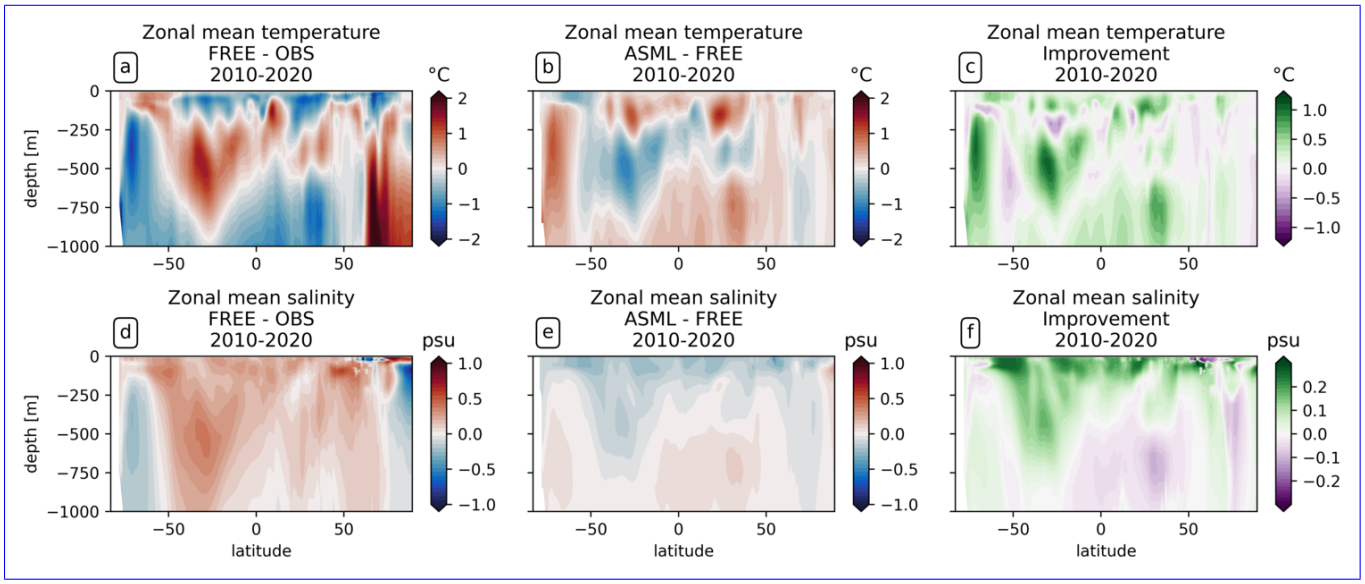

Figure 2. Effect of data assimilation on zonally averaged temperature and salinity in the upper 1000 m. All panels show the mean over the period 2010-2020. (a) The model-observation difference in temperature (FREE - EN4-OA). (b) The difference ASML - FREE. (c) The improvement of monthly averaged temperature relative to EN4-OA. (d - f) The same for salinity.

might be connected to the model's surface warm bias in the formation region of Antarctic intermediate water (Fig. 1a). Further model-observation differences exist at greater depth than 500 m, where the model's ~~subsurface~~ temperature is colder than the observations at almost all latitudes, but warmer than the observations north of 60 °N. At most latitudes and depths, the effect of the assimilation is to reduce the model observation-differences ~~. This can be seen from the difference of ASML and FREE, which has a reversed sign (compare Fig. 2a and Fig. 2b). Thereby, the improvement through DA is mostly positive (Fig. 2~~ (Fig. 2c).

~~For the salinity, the~~ The model is more saline than the observations from the surface down to a depth of about 1000 m for most latitudes (Fig. 2d). This shows that the model-observation difference in this depth range follows the surface signal. The exceptions to this are at high latitudes below 200 m, where FREE is fresher than the observations. At all other latitudes, the assimilation acts towards a freshening, with the strongest effect near the surface (Fig. 2e). This improves the agreement with observations particularly near the surface (Fig. 2d). However, the improvement is smaller at depth and becomes even negative for some latitudes in greater depth. This might be due to the limited amount of assimilated ~~in situ~~ in-situ salinity profiles.

The effect of the assimilation on temperature and salinity is most pronounced in the upper 1000 m and, below that, mostly decreases with depth (not shown). After the second year of assimilation, the mean absolute difference between ASML and FREE stabilizes in the range $0.35 - 0.36\,°C$ for SST and $0.20 - 0.25\,\mathrm{psu}$ for SSS, while the ~~difference of~~ effect of DA on the 3D fields keeps increasing throughout the years 2010-2020.

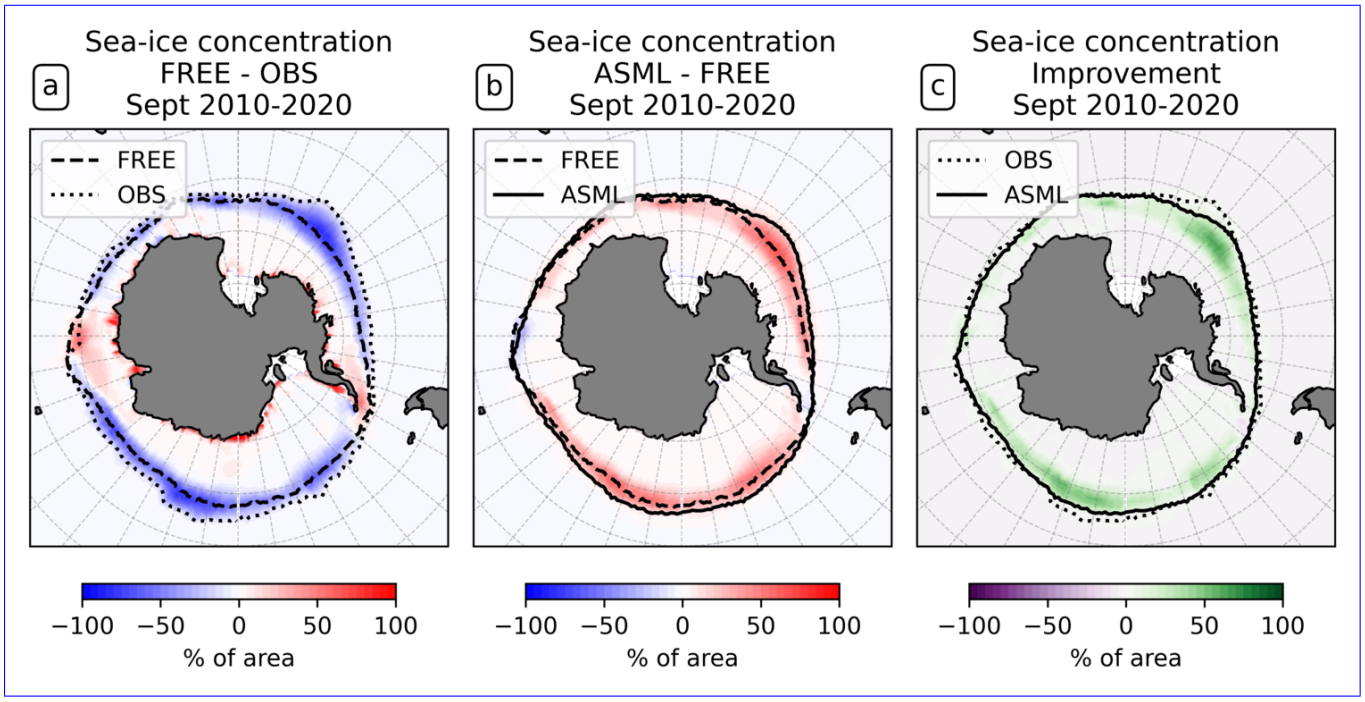

Figure 3. Effect of data assimilation on Antarctic sea-ice concentration in September. All panels show differences in the sea-ice concentration averaged for the month September over the period 2010-2020. The 15%-line for FREE, ASML and OSI-SAF observations is shown as a dashed, continuous or dotted line in panels a or b, respectively. (a) The difference between FREE and OSI-SAF observations. (b) The difference between ASML and FREE. (c) The improvement of September mean sea-ice concentration.

Sea ice reacts dynamically to the changed ocean physical state. In the Southern Ocean, FREE is characterized by a lower sea-ice concentration compared to OSI-SAF observations. The ~~maximum extentof~~ sea-ice extent, here defined as the area where the sea-ice ~~in September~~ concentration is more than 15%, reaches a maximum in September. The maximum extent is smaller in FREE than OSI-SAF, which is demonstrated by the 15%~~-lines~~ -line surrounding that area for FREE and OSI-SAF (Fig. 3a; mean state of sea-ice concentration in Fig. A5), and by the sea-ice concentration difference for the month September (Fig. 3b). Through DA, a higher Antarctic sea-ice concentration is obtained (see Fig. 3b). This improves the agreement with OSI-SAF (Fig. 3c). During all other seasons, the assimilation leads to a higher sea-ice concentration in the Antarctic, a larger sea-ice extent and a better agreement with OSI-SAF as well (only September is shown). In the Arctic, the differences between FREE, ASML and OSI-SAF are regionally different (not shown).

~~A common issue in data assimilation in GOBMs is erroneous equatorial upwelling, leading to unrealistically high biological productivity in the tropics (Park et al., 2018). In FESOM-REcoM, the~~ The boundary-layer depth and mixed-layer depth are mostly reduced through DA. In particular, deep water formation events characterised by a mixed-layer depth of more than 1000 m or 500 m occur less frequently in ASML (not shown). This improves the agreement with the profile-observation based mixed-layer climatology of de Boyer Montégut et al. (2004), reducing the mean absolute difference to the climatology

from 27 m to 19 m (comparison of mixer-layer depth in Fig. A6). In addition, the absolute difference of near-surface horizontal velocities to the drifter-observation based climatology of Laurindo et al. (2017) is reduced by about 10% through DA (comparison of surface velocities in Fig. A7). The biological productivity near the equator is stable in ASML and FREE, indicating that FESOM-REcoM does not suffer from the erroneous upwelling known from previous DA studies (Park et al., 2018). The meridional overturning, however, shows spurious structures, which may point to hidden assimilation artifacts on vertical velocities~~(see Appendix Text A1 for further discussion). The~~ . Throughout the assimilation period, spurious, spatially limited and often deep overturning structures emerge, evolve through several months or years, and disappear in the tropical Indian, Pacific and Atlantic basin (not shown). Thereby, the surface overturning cell sometimes breaks apart where it should extend over the equator, exposing the bottom cell to the surface (Fig. A8b). Transport in the North Atlantic at 26.5 °N, an indicator for the strength of the Atlantic Meridional Overturning Circulation, is between 8-9 Sv in FREE. In ASML, during the first two years of assimilation, transport at 26.5 °N decreases to below 3 Sv and, during the following years, recovers to 7-8 Sv (2016-2020). One possible cause is the effect of data assimilation on the eddy parameterisation (Gent and Mcwilliams, 1990). The parameterised eddy activity is relevant for the dynamics in the deep ocean, and corrupting it may have a negative impact on the large-scale oceanic circulation, as described in Sidorenko (2004, Chapter 5.5 onwards) for a previous version of the ocean model FESOM.

In summary, the ASML temperature and salinity fields ~~at and near the surface in ASML~~ from the surface to several hundred meters below, and mixed-layer depth are in good agreement with ~~the observations. Thus, it can be assumed that the velocities~~ observations, and the agreement of horizontal near-surface velocities with observations is improved. This can be interpreted as an indication that the velocity field in the upper part of the ocean ~~are~~ is also well represented. ~~Therefore~~Although the spurious effects on deep ocean circulation should be further addressed in future work, we are confident that the DA provides an improved physical state in the upper ocean, which serves as an improved basis to estimate the air-sea CO_2 flux~~, although the spurious effects on deep ocean circulation should be further addressed in future work~~.

4 ~~Results~~

3.1 ~~Global~~ Effect of DA on global CO_2 flux

The ocean absorbs ~~$2.78\,\mathrm{Pg\,C\,dec^{-1}}$~~ $2.78\,\mathrm{Pg\,C\,yr^{-1}}$ in ASML and ~~$2.83\,\mathrm{Pg\,C\,dec^{-1}}$~~ $2.83\,\mathrm{Pg\,C\,yr^{-1}}$ in FREE during 2010-2020 (Fig. 4b), thus the assimilation decreases the global mean oceanic CO_2 uptake by ~~$0.05\,\mathrm{Pg\,C\,dec^{-1}}$~~ $0.05\,\mathrm{Pg\,C\,yr^{-1}}$. The temporal evolution of the annual global CO_2 flux is similar in ASML and FREE (Fig. 4a). The first assimilation year, 2010, stands out because it is one of the very few years during which the assimilation increases the oceanic CO_2 uptake. This slightly reduces the trend in CO_2 uptake 2010-2020 ~~($-0.40 \pm 0.09\,\mathrm{Pg\,C\,dec^{-1}}$ versus $-0.38 \pm 0.11\,\mathrm{Pg\,C\,dec^{-1}}$~~from $-0.40 \pm 0.09\,\mathrm{Pg\,C\,yr^{-1}\,dec^{-1}}$ in FREE to $-0.38 \pm 0.11\,\mathrm{Pg\,C\,yr^{-1}\,dec^{-1}}$ in ASML (negative: into the ocean). The trend, thereby, remains within its confidence interval. Furthermore, the assimilation reduces the interannual variability of the global mean oceanic uptake slightly, demonstrated by a standard deviation of detrended annual means of ~~$0.11\,\mathrm{Pg\,C\,dec^{-1}}$~~ $0.11\,\mathrm{Pg\,C\,yr^{-1}}$ in FREE and ~~$0.08\,\mathrm{Pg\,C\,dec^{-1}}$~~ $0.08\,\mathrm{Pg\,C\,yr^{-1}}$ in ASML (not significantly different according to F-test). Through DA, the

ensemble standard deviation of the global CO_2 flux is reduced from $1.0 \times 10^{-2}\,\mathrm{Pg\,C\,yr^{-1}}$ in FREE to $0.7 \times 10^{-2}\,\mathrm{Pg\,C\,yr^{-1}}$ in ASML in the year 2020.

The strongest time-mean air-sea CO_2 flux ~~(negative: into the ocean)~~ is found at mid and high latitudes (Fig. 4c). The large-scale pattern of the CO_2 flux is generally very similar in FREE and in ASML (FREE not shown). ~~However, the effect of the assimilation on the CO_2 flux varies from region to region (Fig. 4d).~~ The largest local changes through DA, both towards stronger or weaker CO_2 fluxes, occur in the North Atlantic in the area of the NAC and in the coastal North Pacific (Fig. 4d). The most prominent large-scale effect though, is in the Southern Ocean (Fig. 4e and f). South of $50\,^{\circ}\mathrm{S}$, the area-integrated CO_2 uptake increases by ~~$0.18\,\mathrm{Pg\,C\,dec^{-1}}$~~ $0.18\,\mathrm{Pg\,C\,yr^{-1}}$ through the assimilation~~(Fig. 4e and f)~~. In contrast, the uptake decreases by ~~$0.07\,\mathrm{Pg\,C\,dec^{-1}}$~~ $0.07\,\mathrm{Pg\,C\,yr^{-1}}$ between 40-$50\,^{\circ}\mathrm{S}$. With the exception of the Southern Ocean, CO_2 uptake decreases in all world oceans by a small amount (Fig. 4d~~and e~~).

3.2 ~~Regional~~ Effect of DA on regional CO_2 fluxes and their drivers

~~The impact of the DA on the CO_2 flux is particularly large~~

3.2.1 Southern Ocean

In the Southern Ocean, the ocean takes up CO_2 in the annual average (Fig. 5a), with regionally heterogeneous effects of DA (Fig. 5b). While the effect of DA on surface pCO_2 and the air-sea CO_2 flux can almost entirely be explained by the combined variation of DIC and alkalinity at most latitudes north of $40\,^{\circ}\mathrm{S}$, the thermal effect also needs to be considered in the Southern Ocean ~~, where we now inspect individual regions .~~ (global zonal mean pCO_2-effects in Fig. A9a). In the following, we examine how the assimilation influences the air-sea CO_2 flux across individual regions in the Southern Ocean.

STSS$_{SO}$ In the northernmost biome of the Southern Ocean, the subtropical seasonally stratified biome (STSS~~, outlined in Fig. 5a$_{SO}$~~), the mean oceanic CO_2 uptake is comparably high (Fig. 5a). ~~Here, the~~ The uptake is largest in austral winter and spring (June to November, Fig. 5c and d). ~~In the more northern~~ The part of the STSS~~, which we call the STSS+, the CO_2 uptake is reduced through the assimilation, demonstrated~~ $_{SO}$ characterized by a positive CO_2 flux difference between ASML and FREE ~~in this area (Fig. 5b). The reduction is greatest in winter and spring, which is shown through a positive flux differencebetween ASML and FREE from July to October (Fig. 5g). In contrast, in the more southern part of the STSS,~~ (positive difference: reduced uptake through assimilation), which we call the ~~STSS-, the assimilation increases the oceanic CO_2 uptake (Fig. 5~~STSS$_{SO}$+, roughly forms an outer northerly ring around the STSS$_{SO}$ biome (hatched area in Fig. 5a and b). The ~~increase~~ reduction of CO_2 uptake ~~through DA is largest in summer and autumn (November to April, Fig. 5h~~in the STSS$_{SO}$+ is greatest in winter and spring from July to October (Fig. 5g).

~~Further south, in the subpolar seasonally stratified biome (SPSS), the ocean absorbs CO_2 all~~ The increase in pCO_2 in the STSS$_{SO}$+ is partly driven by lowered alkalinity and partly by increased surface DIC (Fig. 6b and c). These, as well as the colder SST and fresher SSS in the STSS$_{SO}$+ (Fig. 1b and e) are indications for a year-round ~~(Fig. 5a). The oceanic uptake is increased through the assimilation, shown by a negative difference of ASML and FREE in Fig. 5b . The largest difference between ASML and FREE is seen in spring from September to October (Fig. 5i). Due to the seasonal effect of DA,~~ stronger

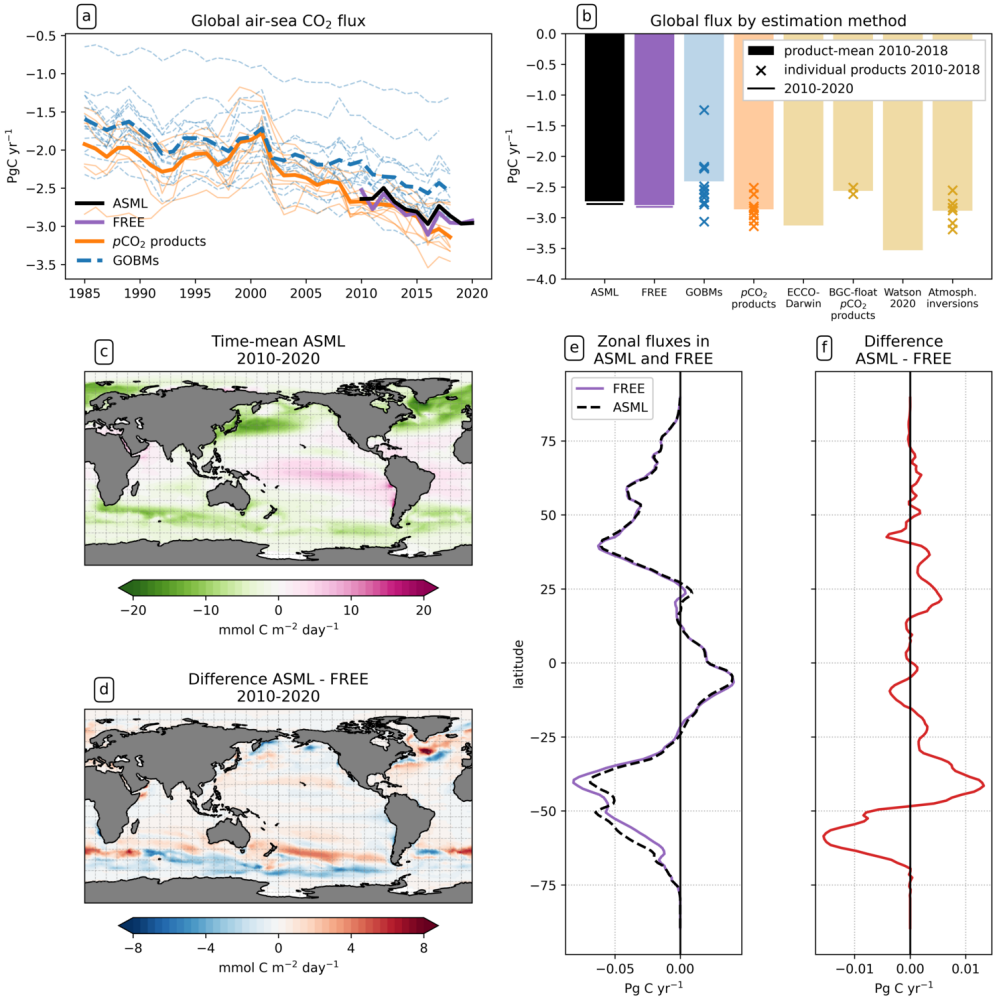

Figure 4. Effect of data assimilation on the air-sea CO_2 flux (negative: into the ocean). (a) Annual time-series of global flux in ~~$PgC\,dec^{-1}$~~ $PgC\,yr^{-1}$ in FESOM-REcoM-PDAF with ASML (black) and FREE (violet); and ~~RECCAP~~ RECCAP2 estimates (DeVries et al., 2023) with pCO_2-products (orange) and GOBMs (blue) and their respective ~~ensemble~~ means (bold lines). Here, the river flux adjustment (~~$-0.65\,PgC\,dec^{-1}$~~ $-0.65\,PgC\,yr^{-1}$) was applied to the pCO_2 products. (b) Time-mean global flux 2010-2018 in ASML (black), FREE (violet); and RECCAP estimates grouped by method (DeVries et al., 2023). Crosses represent individual estimates (e.g. individual GOBMs) and bars represent the ~~ensemble~~ method mean (e.g. mean of twelve GOBMs). Here, the river flux term was applied to all estimates except the models following the Global Carbon Budget methodology (Friedlingstein et al., 2023). For FESOM-RECoM-PDAF, additionally the time-mean 2010-2020 is shown (horizontal lines). (c) Spatial distribution of CO_2 flux averaged over the period 2010-2020 in ASML. (d) Spatial distribution of CO_2 flux difference between ASML and FREE averaged over the period 2010-2020 (e) Zonal averages of CO_2 flux 2010-2020 in ASML and FREE, and their difference in (f).

Additionally, lines in a and b denote the regions, and the green hatching denotes the $STSS_{SO}+$. (a) Map of mean CO_2 flux in ASML. (b) Map of difference between CO_2 flux in ASML and FREE. (c - f) Seasonal cycle of air-sea CO_2 flux by region. Shading indicates the range of ensemble members in the year 2020. (g - j) Seasonal difference in air-sea CO_2 flux between ASML and FREE by region. Note the different scales.

influence of subantarctic waters. This is evident from typical water properties in the subantarctic and subtropical Southern Ocean. In the seasonal cycle of the CO_2 flux in the SPSS is altered. In ASML, the CO_2 uptake is weakest in February, gets stronger in autumn (MAM), stalls growing in winter (JJA) and resumes to get stronger in spring (SON), reaching peak uptake in November (Fig. 5e) . In FREE, the CO_2 uptake is weakening in winter, is weakest in September and gets stronger afterwards, reaching peak uptake in December.

In the seasonally ice-covered biome (ICE) surrounding the Antarctic continent, the time-mean CO_2 flux is smaller than in the other biomes (Fig. 5a). In this region, the ocean absorbs CO_2 during summer and there is a smaller outgassing during winter (Fig. 5f), as the region is mostly ice-covered in winter (see sea-ice concentration in September in Fig. 3subantarctic, surface DIC is higher, surface alkalinity is lower, temperature is colder and salinity is lower (maps of mean SST, SSS, DIC and alkalinity in Fig. A10). In the northern part of the ICE biome, close to the SPSS, the effect of the assimilation is similar to the effect within the SPSS itself (Fig. 5b). Here, the assimilation acts to increase ocean CO_2 uptake or to weaken CO_2 outgassing during winter and spring (Fig. 5i and j). Thereby, interestingly, the assimilation hinders outgassing of CO_2 from May to November in ASML in the ICE biome (Fig. 5f; comparison of winter outgassing with other estimates in Fig. A14). In the southern part of the ICE biome, near the Antarctic continent, the effect of the fragmented area of the $STSS_{SO}$+, different factors contribute to regional changes of the surface DIC and alkalinity budget in ASML (sources minus sinks of DIC and alkalinity in Fig. A11). Depending on location, an increased upward transport of DIC through mixing, an increase of DIC through a reduced biological sink of DIC in spring, or a decrease of alkalinity through changes in horizontal and vertical advection dominates. The seasonality of the effect of DA on the CO_2 flux is small.

Effect of data assimilation on Southern Ocean CO_2 flux and its seasonality averaged over the period 2010-2020. Negative numbers indicate a flux into the ocean. (a) Map of mean CO_2 flux in ASML. (b) Map of difference between CO_2 flux in ASML and FREE. (c – f) Seasonal cycle of air-sea CO_2 flux by region. (g – j) Seasonal difference in air-sea CO_2 flux between ASML and FREE by region. Note the different scales.

In the North Atlantic, the assimilation has noticeable effects on the CO_2 flux in the area of the NAC. In this region, the ocean absorbs CO_2 in the annual average (Fig. 7a). However, the ocean releases some CO_2 during summer, while the sea surface warms (Fig. 7c-f). In the Central STSS, the effect of the DA is to prevent outgassing during summer (Fig. 7air-sea CO_2 flux in the $STSS_{SO}$+ (Fig. 5c and g) . In the Western STSS and in the Newfoundland Basin, the ocean CO_2 uptake is decreased during winter (Fig. 7d ,e,h and j). In the East Coast SPSS, the ocean CO_2 uptake is increased (Fig. 7fand j). The regionally different dynamics of is determined by seasonal temperature differences between ASML and FREE (Fig. 6d and f). During summer, SST is slightly reduced (Fig. 6f), which lowers pCO_2 (Fig. 6a). This counteracts the effects of the assimilation that drive these differences in the air-sea CO_2 flux in the North Atlantic and Southern Ocean, will be investigated next.

Effect of data assimilation on North Atlantic CO_2 flux and its seasonality averaged over the period 2010-2020. Negative numbers indicate a flux into the ocean. (a) Map of mean CO_2flux in ASML. (b) Map of difference betweenCO_2flux in ASML and FREE. (c – f) Seasonal cycle of air-seaCO_2flux by region. (g – j) Seasonal difference in air-seaCO_2flux between ASML and FREE by region. Note different scales.

~~In the Southern Ocean, the reduced CO_2 uptake and increased pCO_2 in the STSS+ region is driven by increased surface DIC and lowered alkalinity~~ DIC and alkalinity on pCO_2 (Fig. 6b and c~~, hatched area) . These, as well as the colder SST and fresher SSS in the~~) and thus dampens the overall DA-effect on the air-sea CO_2 flux during summer.

The part of the STSS~~+ region (Fig. 1b and e) are indications for a year-round stronger influence of subantarctic waters. This is evident as in the subantarctic, surface DIC is higher and surface alkalinity is lower than in the subtropical Southern Ocean (Fig. A10c and d), and, furthermore, the subantarctic is characterized by cold temperatures and low salinity (Fig. A10~~ $_{SO}$ characterized by a negative CO_2 flux difference between ASML and FREE, which we call the $STSS_{SO}$–, is a fragmented region and roughly consists of segments of an inner southerly ring (non-hatched area in Fig. 5a and b). ~~In addition, reduced net primary production (NPP) in spring contributes to higher DIC in the STSS+ region in ASML (not shown). In contrast, the increased CO_2 uptake and reduced pCO_2 in the STSS-~~ Here, the increase of CO_2 uptake through DA is largest in summer and autumn (November to April, Fig. 5h). The reduction of pCO_2 is driven by increased alkalinity, and partly also by lower surface DIC ~~and by increased alkalinity~~ (Fig. 6b and c, non-hatched area). These, together with higher SST in ASML than FREE in the ~~STSS-~~ $STSS_{SO}$– regions (Fig. 1b), indicate a higher presence of subtropical waters (see characteristics of subtropical waters in Fig. A10). ~~Moreover, higher NPP contributes to~~ Where there is lower DIC in the ~~STSS- region~~ $STSS_{SO}$– in ASML ~~(not shown). The seasonality of the effect of DA on the air-sea CO_2 flux (Fig. 5c-d,g-h) is determined by seasonal temperature differences between ASML and FREE (Fig. 6d-g). In the STSS+ region, SST is slightly reduced during summer (Fig. 6f). This lowers pCO_2 in the STSS+ region (Fig. 6a), counteracts the effects of DIC and alkalinity on pCO_2 and thus dampens the overall effect on the air-sea CO_2 flux during summer. In contrast, in the STSS- region, the~~ Fig. 6b), this can mostly be explained by an increased biological sink of DIC, with the addition of sharply defined local changes in horizontal advection of DIC and alkalinity (Fig. A11). Additionally, seasonal temperature effects occur. During winter, SST is higher in ASML than ~~FREE during winter~~ in FREE (Fig. 6e and g). This increases pCO_2 in the ~~STSS- region~~ $STSS_{SO}$– (Fig. 6a), counteracting the effects of lower DIC and higher alkalinity on pCO_2 and dampening the overall ~~effect~~ DA-effect during winter. ~~In summary, the~~

The contrasting effects in the STSS~~are probably generated by a horizontal redistribution~~ $_{SO}$ indicate a horizontal shift of water masses within the $STSS_{SO}$ biome. In the center of the $STSS_{SO}$, the Subantarctic Front is located, which is associated with the Antarctic Circumpolar Current (ACC) and characterized by a strong gradient in SST, SSS and various other tracers (Chapman et al., 2020). Because SST and SSS are directly influenced and improved by the assimilation, the position of this front is also expected to change as a result of the assimilation, leading to a horizontal relocation of waters separated by the front. ~~In addition, differences in the horizontal transport~~ With the relocation of the front, dynamic shifts in regional characteristics occur, such as the amount of DIC and alkalinity ~~by the ACC (transport not shown), and differences in the velocities~~ transported vertically through mixing, and biological sources and sinks of DIC and alkalinity.

SPSS$_{SO}$ Further south, in the subpolar seasonally stratified biome ($SPSS_{SO}$), the ocean absorbs CO_2 all year-round (Fig. 5 a). The oceanic uptake is increased through the assimilation, shown by a negative difference of ASML and FREE in Fig. 5 b. The largest difference between ASML and FREE ~~(Fig. A18), indicate a horizontal redistribution with zonal and meridional components.~~ is seen in spring from September to October (Fig. 5i). Due to the seasonally varying effect of DA, the seasonal

cycle of the CO_2 flux in the $SPSS_{SO}$ is altered. In ASML, the CO_2 uptake is weakest in February, gets stronger in autumn (MAM), stagnates in winter (JJA) and resumes to grow in spring (SON), reaching peak uptake in November (Fig. 5e). In FREE, the CO_2 uptake weakens in winter, is weakest in September and gets stronger afterwards, reaching peak uptake in December.

In the $SPSS_{SO}$, the increased CO_2 uptake and lower surface pCO_2 during winter and spring is driven by a combination of ~~lower DIC and colder temperatures~~ colder temperatures and lower DIC (Fig. 6a and b), which ~~outweigh~~ outweighs the opposite effect of a decrease in alkalinity on pCO_2 (Fig. 6c, relative importance of thermal effect in Fig. A12a). Surface DIC is generally high due to ~~upwelling~~ upward transport of carbon-rich deep water ~~(Hauck et al., 2023a)~~(e.g. Hauck et al., 2023a) . The reason for lower surface DIC in ASML is ~~likely~~ that the upward transport ~~of DIC is reduced~~ through mixing is reduced (Fig. A11) through a more stable stratification, which is ~~shown by~~ also evident from a reduced density in the upper 300 m and an increased density below that (Fig. 6h). Thereby, the densities in the $SPSS_{SO}$ agree better with densities calculated from EN4-OA. ~~The more stable stratification reduces the depth of the boundary layer~~ Boundary layer and mixed layer in winter and spring ~~(not shown~~are shallower and thereby in better agreement with the observation-based climatology (Fig. A6). Vertical mixing within the boundary layer affects the vertical ~~profile of DIC~~ profiles of DIC and alkalinity, towards lower DIC in ASML above 100 m and higher DIC below (Fig. 6i). The vertical profile of DIC in ASML is closer to GLODAP DIC observations, albeit some differences to GLODAP still exist. Besides the fact that the differences in stratification and ~~boundary layer~~ boundary-layer depth affect the vertical DIC profile, they also imply less available surface nutrients in ASML. Probably due to ~~that, in the SPSS,~~ a combination of lower nutrient availability and colder surface temperature, ASML features lower NPP, lower chlorophyll concentrations and a lower phytoplankton biomass in the $SPSS_{SO}$ (not shown). Thereby, the modeled biogeochemical cycle adjusts to the lower transport of nutrients to the surface by transferring less organic material to depth, ultimately acting to compensate about 60% of the difference in physical transport of DIC (Fig. A13a) and adding to the reduction in surface alkalinity (Fig. A13b). Within the $SPSS_{SO}$ (roughly south of 50 °S), differences between FREE and ASML in terms of the temperature effect on pCO_2, vertical transport of DIC and alkalinity and biological sources and sinks are larger than at any other latitude (Fig. A13).

~~In the Northern~~ **ICE**$_{SO}$ In the seasonally ice-covered biome (ICE_{SO}) surrounding the Antarctic continent, the time-mean CO_2 flux is smaller than in other biomes (Fig. 5a). In this region, the ocean absorbs CO_2 during summer and there is a smaller outgassing during winter (Fig. 5f), as the region is mostly ice-covered in winter (see sea-ice concentration in September in Fig. 3). In the northern part of the ICE~~biome near the SPSS, the~~ $_{SO}$ biome, close to the $SPSS_{SO}$, the effect of the assimilation is similar to the effect within the $SPSS_{SO}$ itself (Fig. 5b). Here, the assimilation acts to increase ocean CO_2 uptake or to weaken CO_2 outgassing during winter and spring (Fig. 5i and j). Thereby, interestingly, the assimilation hinders outgassing of CO_2 from May to November in ASML in the ICE_{SO} biome (Fig. 5f; comparison of winter outgassing with other estimates in Fig. A14). The reduced outgassing and decreased pCO_2 during winter and spring is driven by similar processes as within the $SPSS_{SO}$. Again, lower surface DIC and colder temperatures (Fig. 6a and b) outweigh the opposite effect of a decrease in alkalinity on pCO_2 (Fig. 6c). As in the $SPSS_{SO}$, the reason for the decrease in pCO_2, is ~~, firstly, a more stable stratification through surface freshening, which reduces DIC above~~ reduced surface DIC and increased DIC below 100 m ~~depth and increases DIC below~~

(not shown) . Secondlyas a result of less upward transport of DIC through mixing (Fig. A11) in a more stable stratification due to surface freshening (Fig. 1e). In addition, as the surface temperature is lower in ASML (Fig. 1b), the winter sea-ice concentration is higher (Fig. 3b), which prevents winter outgassing of CO_2. In the southern part of the ICE_{SO} biome, near the Antarctic continent, the effect of the DA on the CO_2 flux is small.

In summary, in the Southern Ocean, the main effects of the DA on the CO_2 flux are, firstly ,an increase of the uptake in the SPSScaused by $_{SO}$ caused by surface cooling and by a more stable stratification and thus less upward transport of naturally carbon-rich water through mixingand secondly, an overall decrease of , and secondly an overall lower CO_2 uptake in the $STSS_{SO}$ as a consequence from a horizontal redistribution of water masses within the STSSspatial redistribution of fluxes near the Subantarctic Front.

3.2.2 North Atlantic

In the North Atlantic, the effects of the DA on the CO_2 flux are locally large, but there are differences to the Southern Ocean. assimilation has noticeable effects on the CO_2 flux in the area of the North Atlantic Current, where the ocean absorbs CO_2 in the annual average (Fig. 7a). During summer however, the ocean releases CO_2 while the sea surface warms (Fig. 7c-f). In the Central $STSS_{NA}-$, the effect of the DA is to prevent outgassing during summer (Fig. 7c and g). In the Western $STSS_{NA}+$ and in the Newfoundland Basin+, the ocean CO_2 uptake is decreased during winter (Fig. 7d, e, h and j). The regionally different dynamics of the effects of the assimilation that drive these differences in the air-sea CO_2 flux in the North Atlantic are investigated next.

Central $STSS_{NA}-$ In the Central $STSS_{NA}-$, the effect of the DA is towards increased uptake of CO_2 during boreal summer and autumn in ASML overall towards a more negative flux of CO_2 from May to November (Fig. 7g). This prevents summer outgassing , which occurs from June to October in FREE Thus, spring and autumn CO_2 uptake are increased and summer outgassing is prevented in ASML (Fig. 7c). The reason for the higher uptake and decreased surface pCO_2 is higher alkalinity in ASML (Fig. 8bc). In this region, the alkalinity effect, which reduces pCO_2, outweighs the opposing effects of DIC and SST on pCO_2 (Fig. 8a and eb). A higher alkalinity could point to the presence of waters of subtropical origin (Fig. A15d), transported northward with the NAC (Völker et al., 2002). Other fingerprints of waters advected transported by the NAC are a warm SST particularly in winter, a higher salinity and higher DIC than that of North Atlantic subpolar waters (Fig. A15a-c, Völker et al., 2002)(maps of mean SST, SSS, DIC, alkalinity in Fig. A15; Völker et al., 2002). The assimilation causes a change in these properties, towards a higher SST, higher salinity and higher DIC in the Central $STSS$(Fig. A15)$_{NA}-$. Simultaneously, ASML represents higher NPP, biological carbon export at 200a deeper boundary layer in this region (Fig. 8 d). While changes in the North Atlantic mixed-layer depth overall result in a spatial pattern in ASML that more closely aligns with the pattern in the observation-based mixed-layer climatology, the modelled mixed layer in the simulations is still overall deeper than in the climatology, leading to less agreement in the Central $STSS_{NA}-$ (Fig. A6). Likely facilitated by higher SST and more available nutrients through deeper mixing in winter and spring, ASML features a higher biological sink of DIC above 190 m (Fig. A16d), more biological carbon export through sinking of detritus at 190 m, surface chlorophyll and more column integrated phytoplankton biomass and surface chlorophyll in spring, which is shown illustrated by the example of

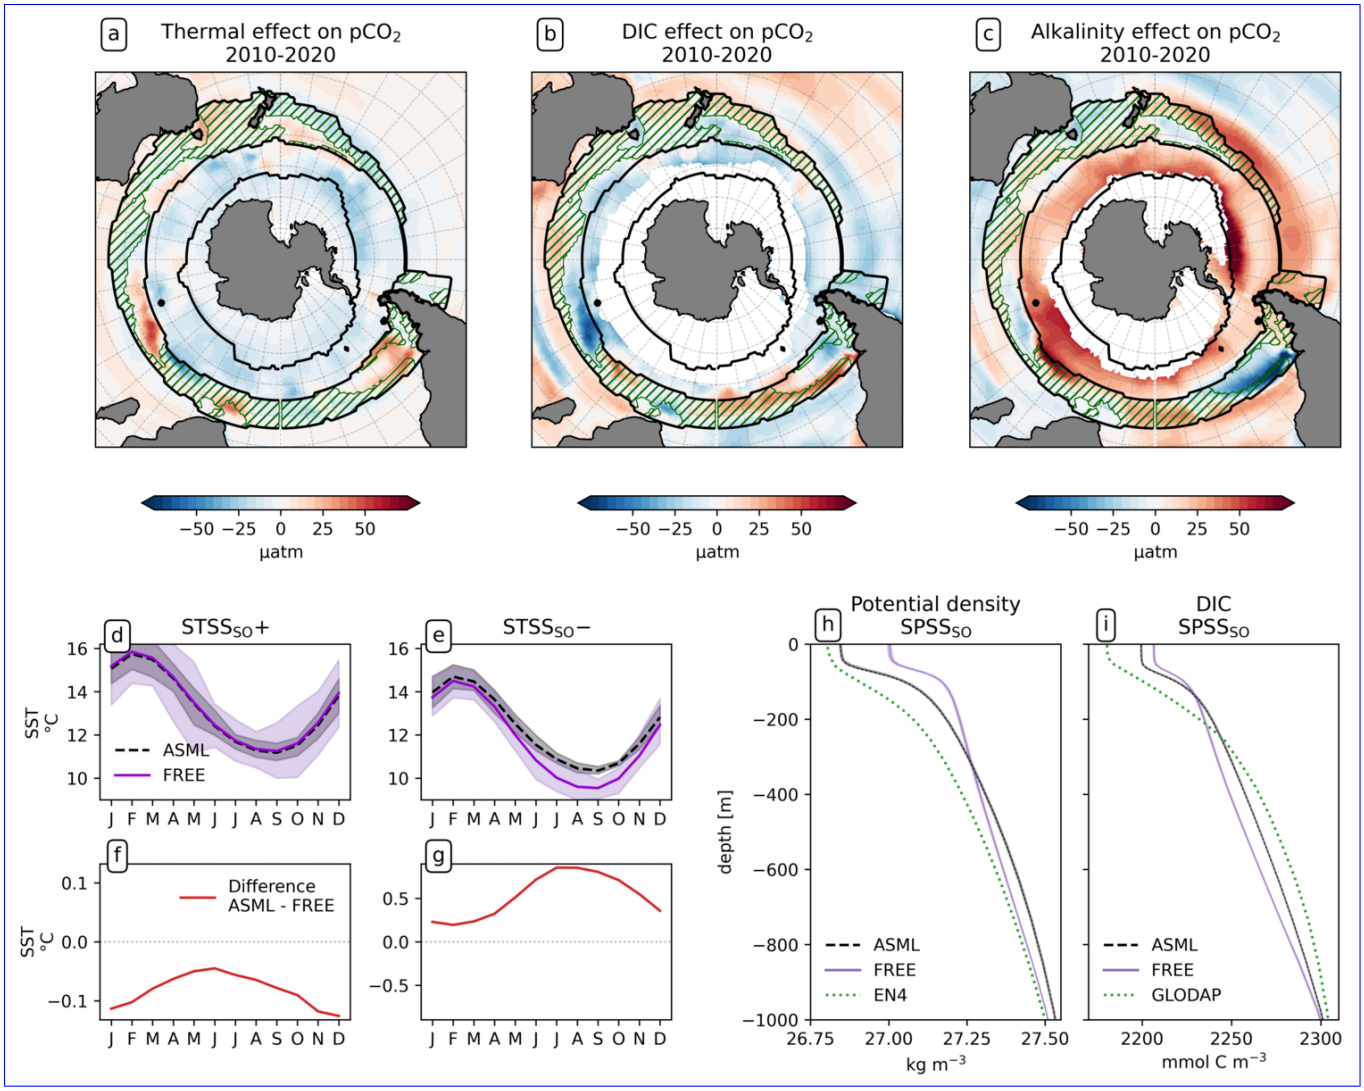

Figure 6. Drivers of the effects of data assimilation on air-sea CO_2 fluxes in the Southern Ocean. Panels a, b and c show the effects of SST, DIC and alkalinity differences between the ASML and FREE simulations on surface pCO_2, where positive denotes an increase in pCO_2. Hatching inside the $STSS_{SO}$ indicates where net pCO_2 is increased through the assimilation ($STSS_{SO}+$). Shading in d, e, h and i indicates the range of ensemble members in the year 2020.

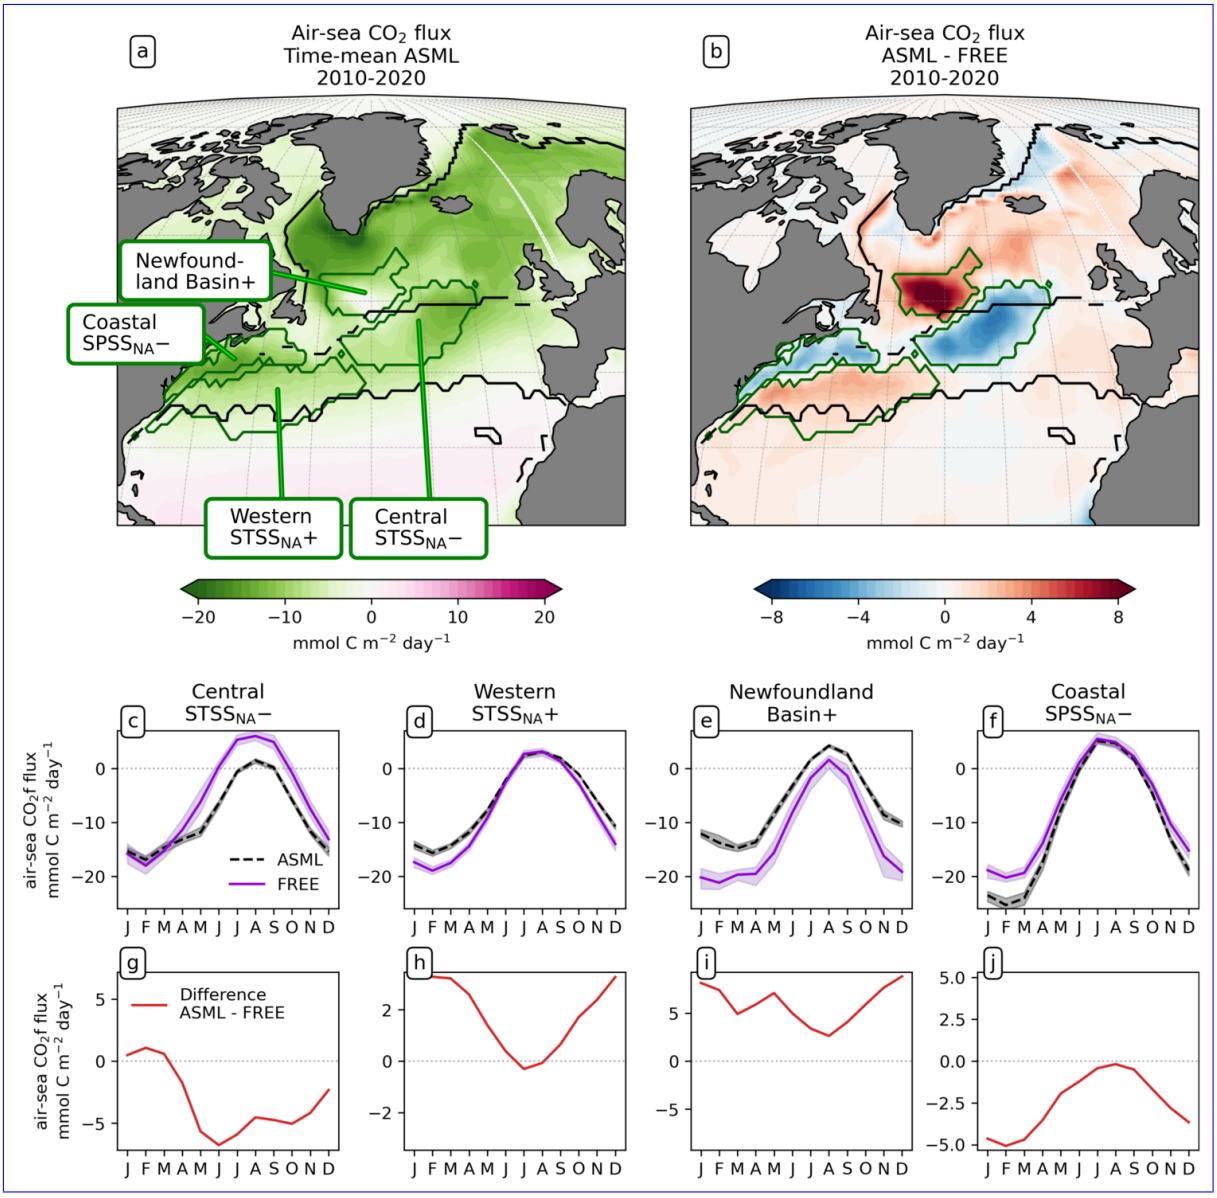

Figure 7. Effect of data assimilation on North Atlantic CO_2 flux and its seasonality averaged over the period 2010-2020. Negative numbers indicate a flux into the ocean. (a) Map of mean CO_2 flux in ASML. (b) Map of difference between CO_2 flux in ASML and FREE. (c - f) Seasonal cycle of air-sea CO_2 flux by region. Shading indicates the range of ensemble members in the year 2020. (g - j) Seasonal difference in air-sea CO_2 flux between ASML and FREE by region. Note different scales.

surface chlorophyll difference between ASML and FREE in Fig. 8e. ~~This is facilitated by more available nutrients through winter mixing in the surface boundary layer, which is deeper in ASML (Fig. 8d).~~ In combination, the higher ~~biological export of carbon~~ alkalinity associated with NAC transport and the higher ~~alkalinity in ASML~~ biological sink of DIC result in lowered surface pCO_2 and higher oceanic uptake.

Western STSS$_{NA}$+ In the Western STSS$_{NA}$+, the DA reduces the CO_2 uptake and increases pCO_2 mainly during winter, as a direct effect of increased SST (Fig. 8a). ~~In this region, the thermal effect of DA, which increases pCO_2,~~ The direct thermal effect is dominant over the combined effect of DIC and alkalinity (relative importance of thermal effect in Fig. A12b). The latter have effects comparable in magnitude to SST, but mostly cancel each other out (Fig. 8b-c). The effect of DA on surface properties (SST, SSS, DIC and alkalinity) in the Western STSS$_{NA}$+ is similar to the effect in the Central STSS$_{NA}$−, which indicates a higher influence of subtropical waters in both regions.

Newfoundland Basin+ In the Newfoundland Basin+, the dominant effect of DA is a reduction of the CO_2 uptake and an increase of pCO_2 mainly during winter, as a direct effect of increased SST (Fig. 8a). In addition, ASML also features ~~shallower winter mixing inside the boundary layer (Fig. 8d) and~~ a more stable stratification due to lower density at the surface than FREE (Fig. 8f)~~. Consequently, DIC and alkalinity in the upper 100 m are slightly reduced . Neverless, some differences to GLODAP-DIC observations remain (DIC in~~ , which mostly affects DIC at 50-400 m depth through reduced subduction of DIC (Fig. 8g). ~~However, the thermal effect of DA, which increases pCO_2, is dominant over the combined effect of DIC and alkalinity on pCO_2 (Fig. 8b and c) , as the latter cancel each other out. Furthermore, surfacenutrients, NPP, export production, biomass and surface chlorophyll are reduced (surface chlorophyll in Fig. 8e)~~Furthermore, ASML represents less surface chlorophyll in the Newfoundland Basin+ (Fig. 8e) as a result of a redistribution of biomass from the surface to 50-400 m depth due to spring mixing (not shown). The downward mixing of biomass results in an increase of the biological sink of DIC above 50 m likely due to more primary production near the surface, ~~probably due to shallower mixing. In the Western Boundary STSS, the increased CO_2 uptake and reduced pCO_2~~ and a decrease of the biological sink at 50-400 m likely due to more remineralization at this depth. However, the differences in the biological sink of DIC are compensated by mixing of DIC (profiles not shown). Overall, differences of the regional DIC profile to the observational GLODAP climatology slightly increase (Fig. 8g).

Coastal SPSS$_{NA}$− In the Coastal SPSS$_{NA}$−, pCO_2 is reduced and the ocean CO_2 uptake is increased in ASML during winter and spring (Fig. 7f and j). The reduction of pCO_2 is facilitated by colder SST (Fig. 8a). This might be due to subpolar water masses penetrating further south along the coast in ASML because the location where the current separates from the coast is further south in ASML (velocities in Fig. A2).

In summary, DA affects the CO_2 flux in the North Atlantic mainly through ~~horizontal and vertical redistribution~~ changes in SST, combined with changes in horizontal advection of DIC and alkalinity near the NAC. Changes in the vertical mixing of DIC and alkalinity ~~, and through changes in SST. However, which~~ are largely compensated by feedbacks in biogeochemical cycles. Which of these effects is dominant, however, varies from region to region.

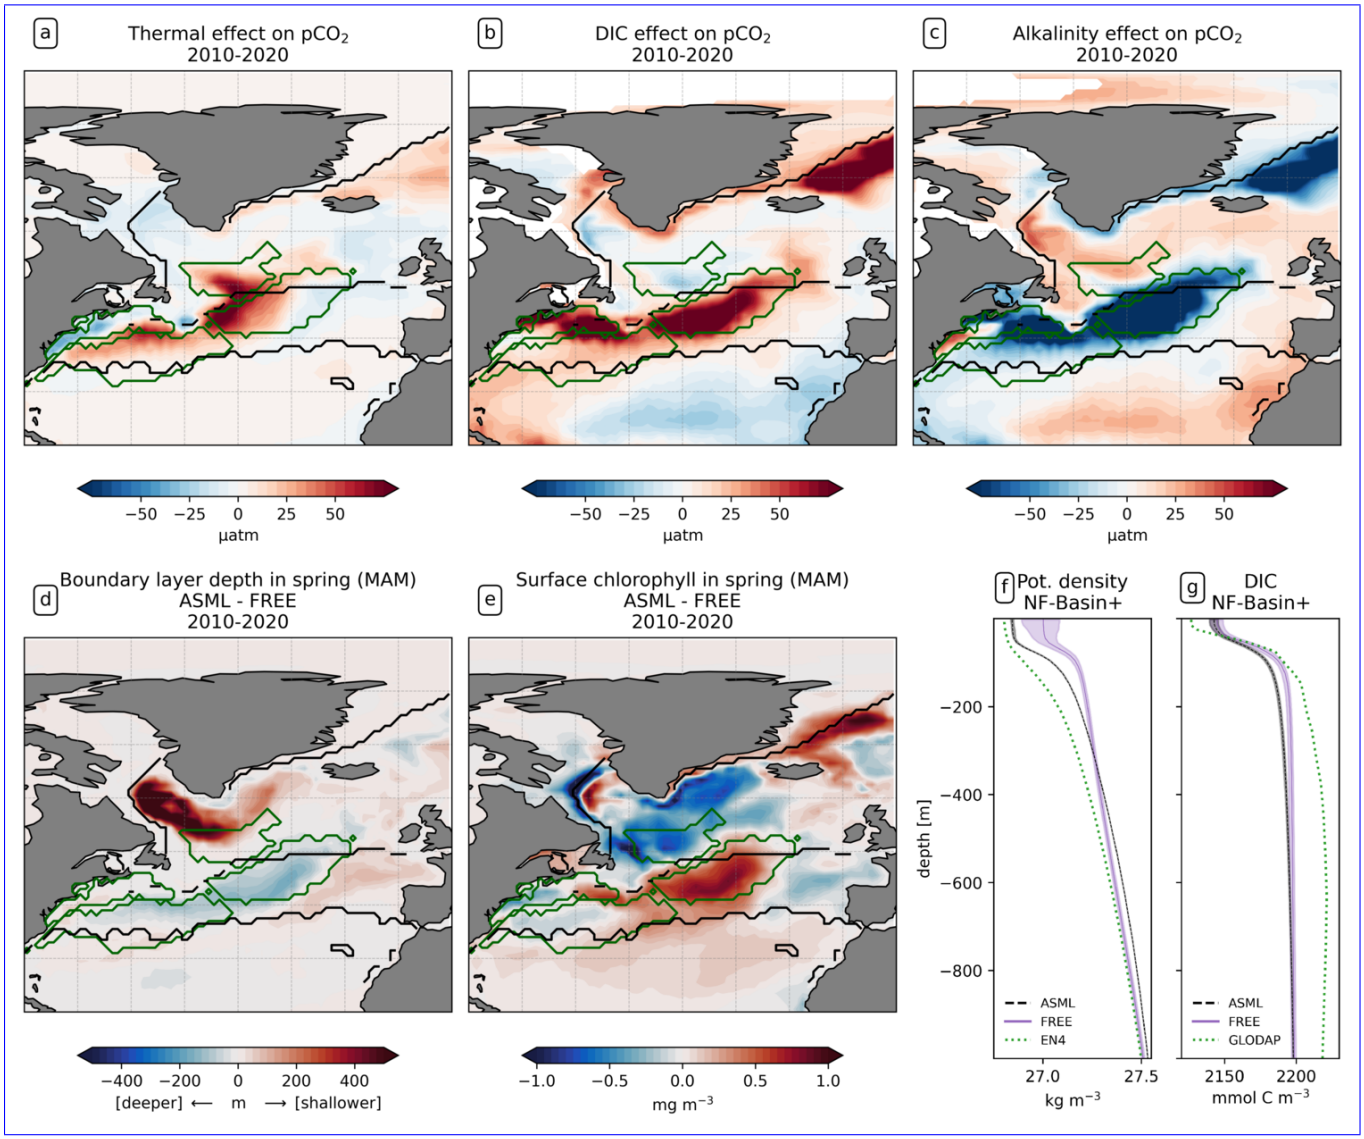

Figure 8. Drivers of the effects of data assimilation on air-sea CO_2 flux in the North Atlantic. Panels a, b and c show the effects of SST, surface DIC and alkalinity differences between ASML and FREE on surface pCO_2. (d) Difference of boundary layer depth (ASML - FREE) for spring (MAM) 2010-2020, where positive denotes a shallower boundary layer in the ASML. (e) Difference of surface chlorophyll (ASML-FREE) for spring (MAM) 2010-2020. (f) Potential density profiles for the Newfoundland Basin+ region, with FREE (violet line) and ASML (dashed black line) based on daily T and S, and with EN4-OA (dotted green line) based on monthly T and S. (g) DIC profiles for the Newfoundland Basin+ region, showing FREE (violet line), ASML (dashed black line) from 2010-2020 and climatological DIC from GLODAP. Shading in f and g indicates the range of ensemble members in the year 2020.

3.3 Comparison with biogeochemical observations

3.3.1 pCO_2 (SOCAT)

To evaluate the modeled air-sea CO_2 flux based on observations, surface pCO_2 is the most informative variable, as it is closely related to the air-sea CO_2 flux. Effects of the DA on the modeled ecosystem and associated carbon fluxes, as well as thermal and dynamical effects that affect the CO_2 flux, are all included in pCO_2. The global mean of absolute monthly model-observation differences to the available SOCAT pCO_2 observations is ~~$27.26\,\mu atm$~~ $27.26\,\mu atm$ for FREE. For ASML, the difference is slightly larger with ~~$27.60\,\mu atm$~~$27.60\,\mu atm$. On global average, pCO_2 is higher than in SOCAT by ~~$3.70\,\mu atm$~~ $3.70\,\mu atm$ in FREE and ~~$4.59\,\mu atm$~~ $4.59\,\mu atm$ in ASML, as regions with positive and negative differences to SOCAT compensate (Fig. 9a). ~~The assimilation changes pCO_2 by a mean absolute value of $8.08\,\mu atm$~~As an illustration of the regional changes through DA, the absolute differences in pCO_2 amount to $8.08\,\mu atm$ (absolute difference ASML-FREE calculated at every grid point then averaged globally), which is $\pm 27\%$ of the mean absolute model-observation difference. A linear offline estimation demonstrates that this change in pCO_2 would lead to an absolute change in the air-sea CO_2 flux by $1.06\,\mathrm{mmol\,C\,m^{-2}\,day^{-1}}$ on average (Eq. (8)).

Overall, FREE and ASML show very similar regional pCO_2 differences compared to SOCAT (difference of FREE and SOCAT in ~~(Fig. 9a)~~Fig. 9a; difference of ASML and SOCAT not shown). In the subtropical and tropical Atlantic and the subtropical Pacific, FREE and ASML have higher pCO_2 than SOCAT, while in the equatorial Pacific, ~~the~~ pCO_2 is lower. At high latitudes, FREE and ASML represent mostly lower pCO_2 than SOCAT.

In the Southern Ocean, the simulations represent lower pCO_2 than SOCAT in the SPSS~~and ICE~~ $_{SO}$ and ICE_{SO} biomes in the annual mean (Fig. 9c), which is dominated by summer differences to SOCAT (not shown) when most observations are available. Through the assimilation, pCO_2 is slightly increased in summer and mostly reduced in winter (not shown), leading to an overall better agreement with SOCAT (Fig. 9e). In contrast, in the STSS, FREE and ASML represent higher pCO_2 than SOCAT, and through the assimilation, the agreement with SOCAT decreases.

In the North Atlantic, the simulations and SOCAT show a similar large-scale pattern, namely that pCO_2 is higher in the subtropics (ASML: around ~~$400\,\mu atm$~~$400\,\mu atm$) than in the subpolar regions (ASML: around ~~$280\,\mu atm$~~$280\,\mu atm$). Yet, this latitudinal difference of pCO_2 is stronger in the simulations compared to SOCAT, meaning that in the subtropics, pCO_2 in the simulations is higher than in SOCAT (Fig. 9d), while it is lower in the subpolar regions. Furthermore, in both simulations there is a pronounced pCO_2 surface gradient in the NAC and North Atlantic Subpolar Gyre region, whose position is changed by the assimilation, and which appears to be further northward in SOCAT. Thereby, the assimilation overall leads to a better agreement with SOCAT, in particular through a decrease of pCO_2 in the Central STSS$_{NA}$~~-~~, where the average difference is reduced from ~~$26\,\mu atm$~~ $26\,\mu atm$ (FREE - SOCAT) to ~~$1\,\mu atm$~~ $1\,\mu atm$ (ASML - SOCAT). However, in the Newfoundland ~~basin~~Basin~~+~~, the average difference is ~~turned from $-17\,\mu atm$~~ reversed from $-17\,\mu atm$ (FREE - SOCAT) into ~~$13\,\mu atm$~~ $13\,\mu atm$ (ASML - SOCAT), which is associated with a larger absolute discrepancy of ASML and SOCAT.

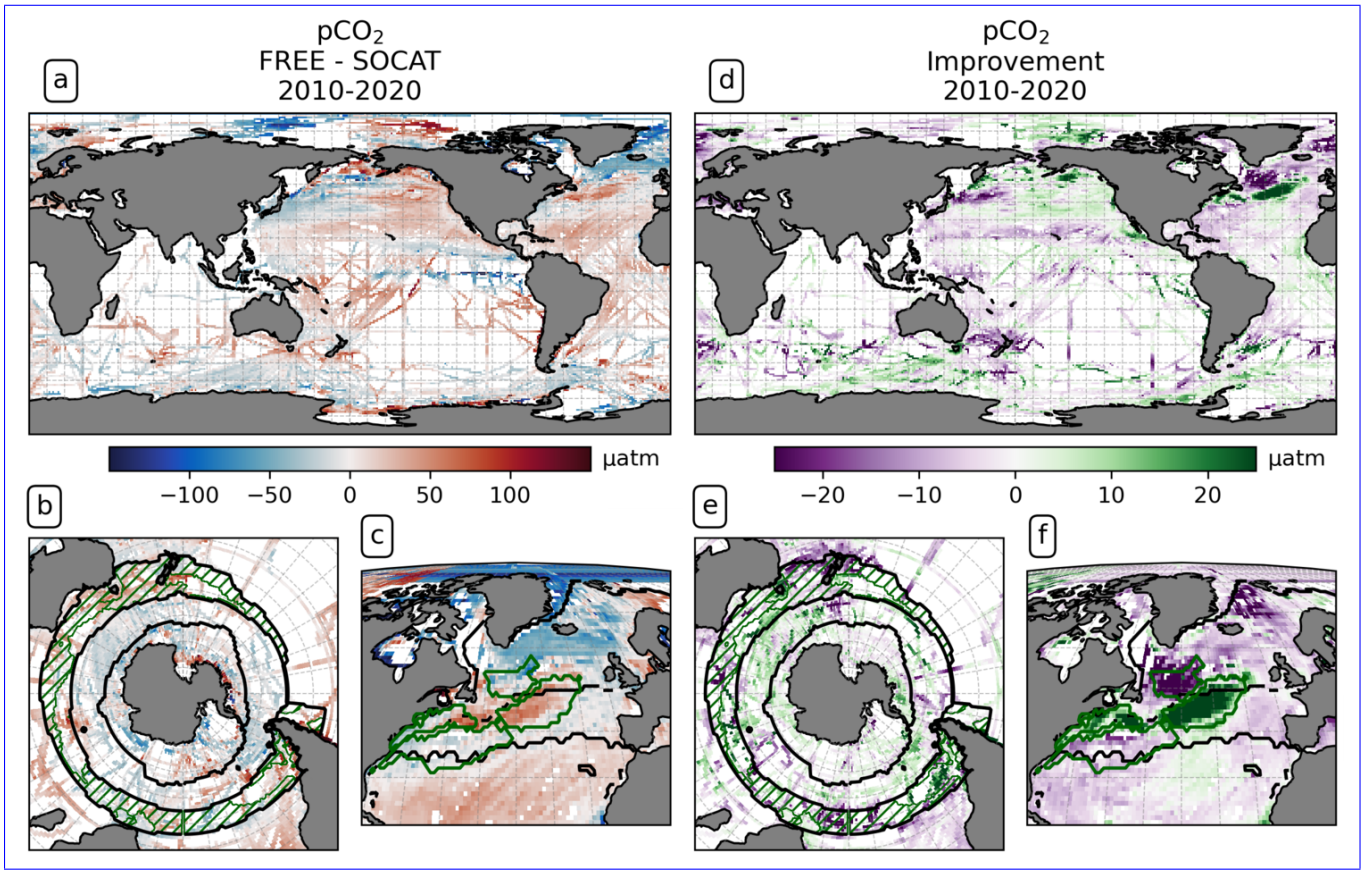

Figure 9. Partial pressure of CO_2 (pCO_2) at the surface averaged over the years 2010-2020. Panels (a-c) show the difference between FREE and SOCAT observations in (a) the global ocean, (b) Southern Ocean and (c) North Atlantic; panels (d-f) show the impact of the assimilation as 'improvement' relative to SOCAT observations computed from monthly mean pCO_2 in the same regions. Positive values (green color) denote a reduced difference to SOCAT.

3.3.2 DIC and alkalinity (GLODAP)

DIC and alkalinity are two of the most important variables from which pCO_2 is derived (Section 3.2). Comparing them with observations provides more insights into the strengths and weaknesses of the modeled carbonate system than a comparison with pCO_2 observations alone. The FESOM-REcoM simulations represent higher surface DIC than GLODAP bottle observations (Lauvset et al., 2024a, gridded monthly-means) on average (Fig. 10a), with a global mean surface difference FREE-GLODAP of $6.46\,\mathrm{mmol\,C\,m^{-3}}$ for DIC. Although fewer DIC observations are available than pCO_2 observations, similarities between the respective model-observations differences for DIC and pCO_2 can be recognized. For example, DIC in the model is lower in the tropical and subtropical Atlantic than GLODAP, and higher in the polar Atlantic. This is consistent with SOCAT pCO_2 observations in the same areas. The model-observation differences to GLODAP DIC and SOCAT pCO_2 are also consistent with each

other in the north Pacific. The assimilation induces absolute changes in surface DIC of $6.33\,\mathrm{mmol\,C\,m^{-3}}$ on global average, with regional differences in sign. These changes slightly reduce the mean absolute difference to the surface observations from $32.78\,\mathrm{mmol\,C\,m^{-3}}$ to $32.15\,\mathrm{mmol\,C\,m^{-3}}$, and yield a mixed picture of the improvement (Fig. 10b).

While the trend in surface DIC due to anthropogenic input makes it necessary to compare the model with contemporaneous observations at the ocean surface, a comparison with climatological data is meaningful below a depth of approximately 200 m. In fact, the modeled global distribution of DIC at depth is overall similar to that in the GLODAP climatology ~~(~~for both simulations (zonal mean DIC surface to 1000 m depth in Fig. A17). For example, the model results and GLODAP data sets show that DIC is lowest in the isopycnals of the subtropical gyres ($2050 - 2150\,\mathrm{mmol\,C\,m^{-3}}$; Fig. A17a) and that DIC mostly increases with depth and is higher in the Pacific ($2420\,\mathrm{mmol\,C\,m^{-3}}$ at 1000 m in the North Pacific) than in the Atlantic ($2320\,\mathrm{mmol\,C\,m^{-3}}$ below 3000 m in the South Atlantic). Yet, depending on the ocean basin and depth, there can be both negative and positive differences between the simulations and the GLODAP climatology, which are in the order of $20\,\mathrm{mmol\,C\,m^{-3}}$ (Fig. A17c). On a global average, the assimilation leads to an increase in DIC between 200-600 m depth and a reduction of DIC between the surface and 200m, with the largest effect in the upper 400 m (Fig. A17b). This leads to an improved agreement with the GLODAP climatology, with the largest global mean improvement at a depth of 400 m ($2.5\,\mathrm{mmol\,C\,m^{-3}}$; ~~(~~Fig. A17d). Below 1000 m depth, the global mean absolute difference FREE-ASML of DIC and alkalinity is only $1 - 2\,\mathrm{mmol\,m^{-3}}$ and is therefore substantially smaller than at the surface.

The comparison with GLODAP bottle alkalinity at the surface shows a similar spatial patterns as for DIC (see Fig. 10a and c). The magnitude of the bias is also comparable ($14\,\mathrm{mmol\,Alk\,m^{-3}}$). The global mean of the absolute difference ASML-FREE of surface alkalinity is $7.72\,\mathrm{mmol\,Alk\,m^{-3}}$. The assimilation leads to a reduction of the absolute difference of the model alkalinity to GLODAP from $34.34\,\mathrm{mmol\,Alk\,m^{-3}}$ to $32.60\,\mathrm{mmol\,Alk\,m^{-3}}$. Since the effects of physics assimilation on alkalinity and DIC are regionally consistent, regions of improved or deteriorated agreement with GLODAP often coincide for both variables (compare Fig. 10b and d). ~~Since~~ Because changes of DIC and alkalinity have an opposing effect on the CO_2 flux, it is likely that their correlation results in compensating effects. A linear estimate shows that the joint effect of DIC and alkalinity changes is responsible for a change in the CO_2 flux in the order of $1.22\,\mathrm{mmol\,C\,m^{-2}day^{-1}}$ on average, and, globally integrated, the assimilation-induced changes in DIC and alkalinity lead to an estimated net increase of the air-sea CO_2 flux ~~by~~ in the order of $0.50\,\mathrm{Pg\,C\,yr^{-1}}$ (Eqs. (3), (4) and (8)). However, this linear offline estimate is subject to a large uncertainty because regionally large effects with opposite sign lead to uncertainty in the global mean.

3.3.3 Surface chlorophyll (OC-CCI)

The representation of chlorophyll by the model is of interest as a ~~pCO_2-independent~~ proxy for primary production. Surface chlorophyll reflects the phytoplankton state and biomass, and therefore, effects of the DA on the biological model state can be seen in the total surface chlorophyll concentration. A comparison of the modeled surface chlorophyll with remotely-sensed chlorophyll from OC-CCI reveals that ~~the simulations capture the global distribution of chlorophyll well (Fig. 11). The simulations show the seasonal maxima in each hemisphere around one month earlier in the year (not shown). FREE features~~ both simulations feature a higher surface chlorophyll concentration than OC-CCI ~~by~~ (FREE-OBS in Fig. 11a and c). In FREE,

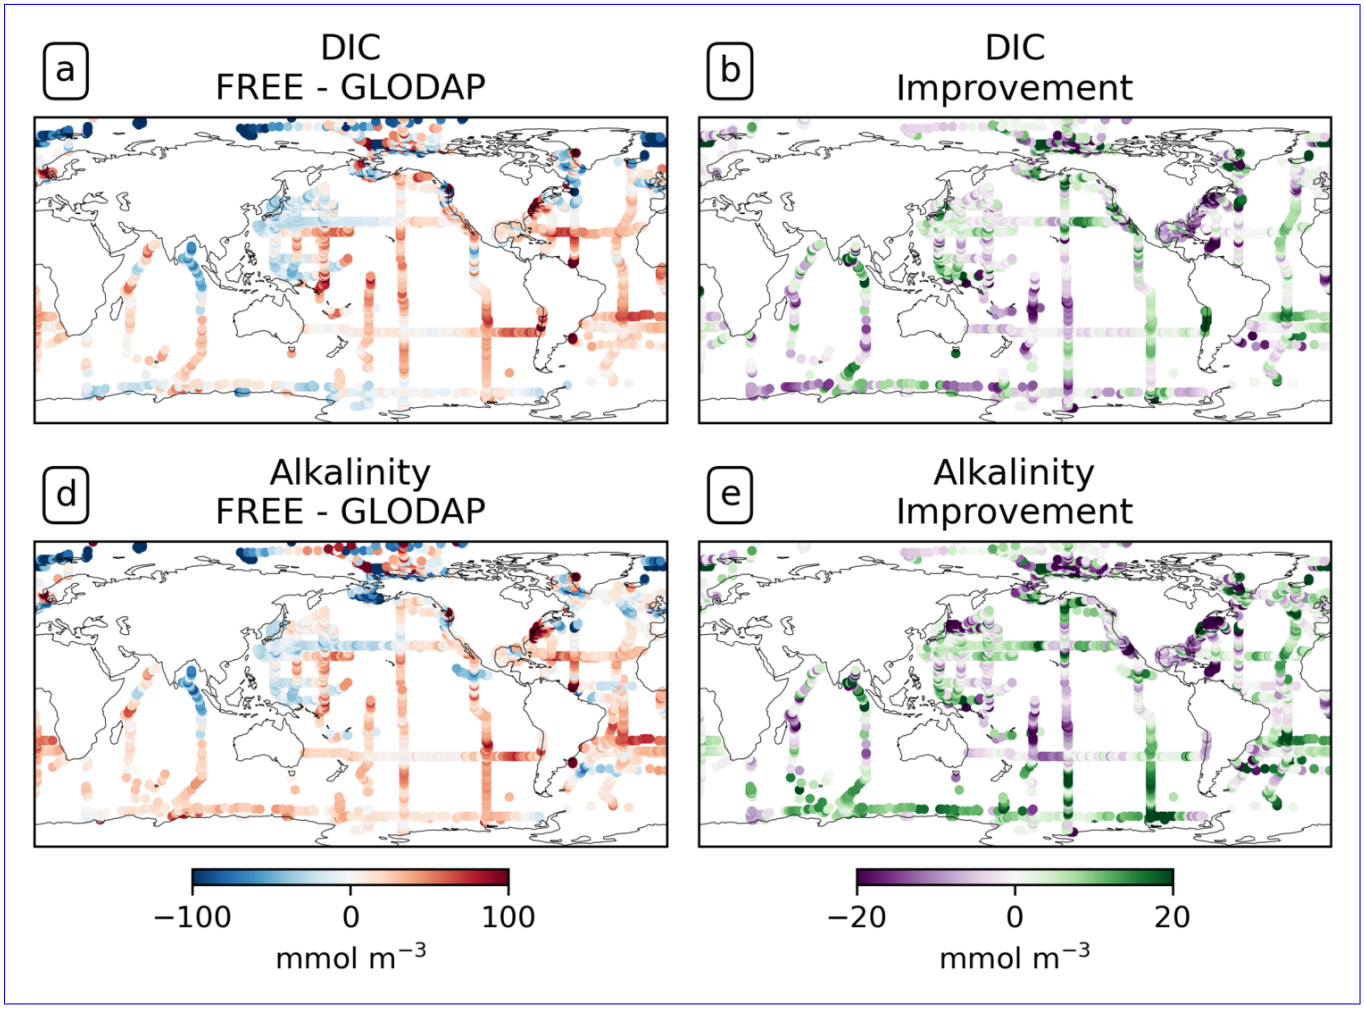

Figure 10. Comparison of the model result with surface DIC and alkalinity bottle observations from GLODAP over the years 2010 to 2020. (a) Difference of DIC between FREE and GLODAP. (b) Improvement of monthly surface DIC relative to GLODAP. (c and d) For alkalinity.

the difference to OC-CCI is $0.02\,\mathrm{mg\,m^{-3}}$ on global average, with low deviations in the tropics and an enhanced difference north of $30\,^{\circ}\mathrm{N}$ ($0.12\,\mathrm{mg\,m^{-3}}$) and south of $30\,^{\circ}\mathrm{S}$ ($0.24\,\mathrm{mg\,m^{-3}}$)~~(Fig. 11a~~. Apart from this, both simulations capture the global distribution of chlorophyll well. The simulations show the seasonal maxima in each hemisphere around one month earlier in the year (not shown). South of $30\,^{\circ}\mathrm{S}$, FREE is in better agreement with chlorophyll-a from Johnson et al.'s (2013) Southern Ocean specific chlorophyll product (Fig. 11~~a~~b) than with OC-CCI data (Fig. 11a).

On global average, the assimilation slightly reduces the differences between model and OC-CCI data, from a global mean absolute difference of $0.31\,\mathrm{mg\,m^{-3}}$ to $0.29\,\mathrm{mg\,m^{-3}}$. The assimilation changes the chlorophyll concentration by an absolute value of $0.05\,\mathrm{mg\,m^{-3}}$ on average, which is 15% of the global mean absolute difference to OC-CCI. There are regions in which assimilation leads to a reduction in chlorophyll and thus to better agreement with the satellite products, for example in the North Atlantic Subpolar Gyre and the Southern Ocean SPSS~~(Fig. 11b and e~~ $_{\mathrm{SO}}$ (Fig. 11e and f). In contrast, the model reacts to the DA with an increase in chlorophyll in the North Atlantic Central STSS$_{\mathrm{NA}}$ – and the Argentine Basin~~(Fig. 11b and f)~~, which leads to poorer agreement.

4 Discussion

~~The assimilation of physics has different effects on BGC surface variables , though the major effects~~

The improvement in temperature and salinity overall leads to a heterogeneous picture in biogeochemistry. While near-surface temperature and salinity fields are improved through DA almost everywhere, the global mean absolute difference of modeled surface pCO_2 to SOCAT remains similar in ASML compared to FREE, and this also applies to the model-observation differences for surface chlorophyll, DIC and alkalinity (Section 3.3). Where improvements in one BGC variable occur, these do not necessarily lead to consistent improvement in all BGC variables. For example, the representation of pCO_2 improves while that of chlorophyll deteriorates in the North Atlantic Central STSS$_{\mathrm{NA}}$ – (Fig. 11f and Fig. 9f). In the Southern Ocean SPSS$_{\mathrm{SO}}$, the reduction of modeled surface chlorophyll in spring and the increase of pCO_2 in summer lead to a better agreement with pCO_2 observations, yet the available observations of DIC and alkalinity do not resolve the regional scales to evaluate the corresponding changes in these variables (Fig. 9, Fig. 10 and Fig. 11f). The uncertainty represented by the ensemble is reduced by the DA, which has the most obvious effect on the directly assimilated fields (SST in Fig. 6d and e and density in Fig. 8f). The ensemble standard deviation of the CO_2 flux, where it is large in FREE, is constrained by the DA to globally more uniform and smaller values (Fig. 5c-f, Fig. 7c-f and Fig. A1). Only in the North Pacific, the standard deviation of CO_2 fluxes is equally high in ASML and FREE, precisely in a region that also presents a challenge for pCO_2 products (compare Fig. A1 and Mayot et al., 2024, Figure 5a). In the rest of the ocean, the reduced uncertainty represented by the ensemble does not necessarily coincide with improved agreement with BGC observations. One possible reason for improvement of model-data mismatch in one variable with worsening in another may lie in inconsistencies between the observational datasets. Another reason may be missing processes in the model and the use of constant BGC model parameters. Those parameters are responsible for linking changes between ecosystem variables and in reality, they vary across space and time depending on species composition in the ecosystem (Mamnun et al., 2023, Chapter 3). Overly simplified links between ecosystem variables

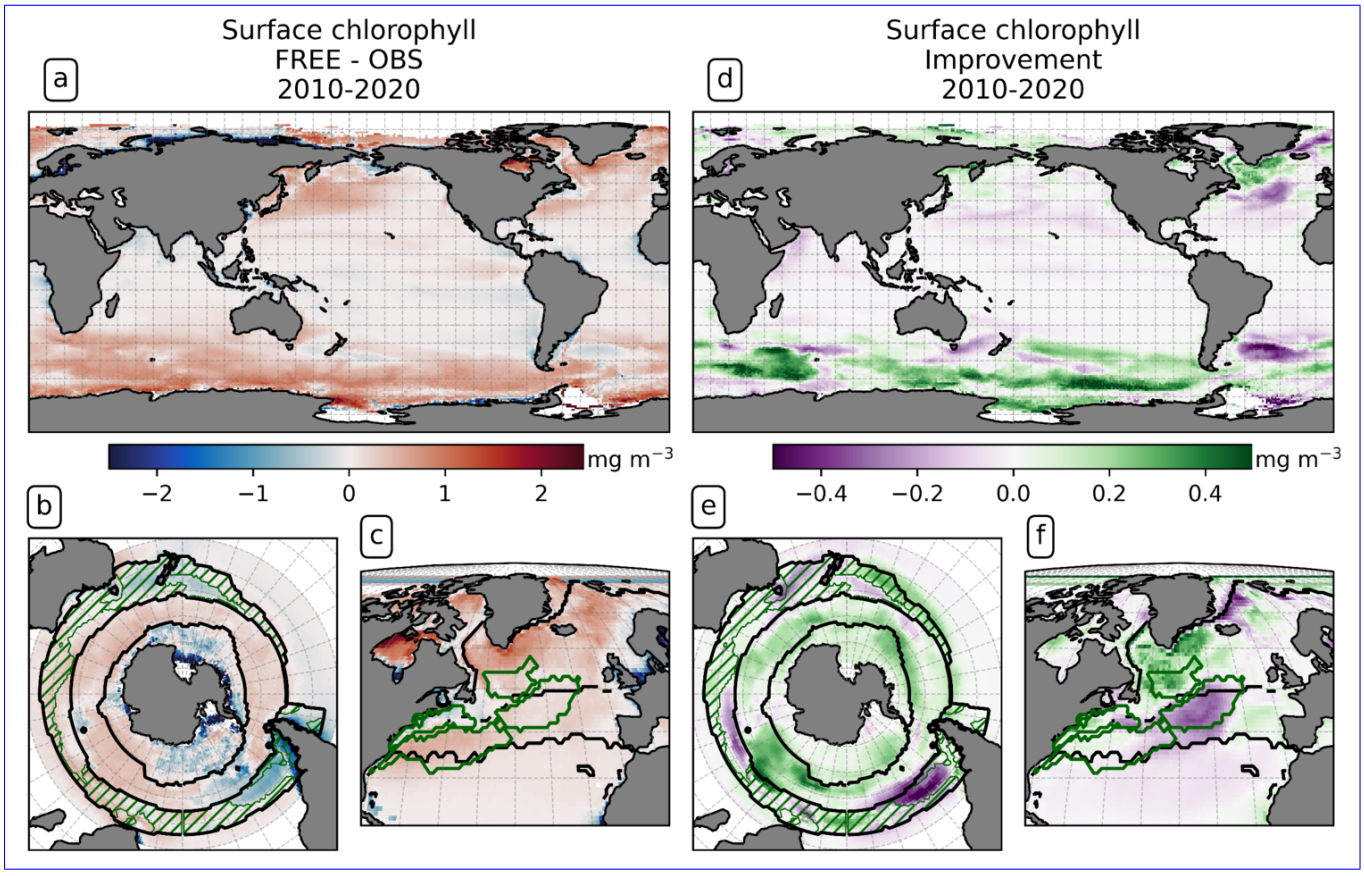

Figure 11. Surface chlorophyll averaged over the years 2010-2020: (a-c) difference between FREE and SOCAT observations in (a) the global ocean, (b) the Southern Ocean and (c) the North Atlantic; (d-f) impact of the assimilation as 'improvement' relative to the observations in the same regions. Panels (a, c, d) and (f) compare to monthly OC-CCI observations, panels (b) and (e) refer to the climatology for 1998-2019 by Johnson et al. (2013).

can lead to cancelling errors, which means that the state of one variable may worsen as a result of improving the other through DA (as in Ford and Barciela, 2017).

The major effects of physics DA on BGC variables seem to be related to changes of SST and are largely uniform over the full period of DA (Section 3.3). Surface chlorophyll changes follow SST changes (~~Fig. 11 and Fig. 1), as the~~ Figs. 1 and 11). The modeled phytoplankton growth is temperature-dependent (Gürses et al., 2023). Furthermore, indirect temperature effects on plankton dynamics due to stratification and mixing changes contribute, albeit those can have heterogeneous effects and the correlation of chlorophyll and boundary-layer depth is less clear (not shown). The changes of surface DIC and alkalinity show similar spatial patterns with regional heterogeneity (Section 3.2), again with the major changes being coherent with the changes in SST (Fig. 1). Furthermore, the effects of the assimilation on DIC and on temperature in the upper 1000 m correlate regionally~~. Cooling~~ : Cooling through DA at intermediate depth (Fig. 2b) is usually accompanied by higher DIC

(Fig. A17in ASML (Fig. A17b), while warming through DA near the surface co-occurs occurs together with reduced DIC in ASML. An overall more stable ocean stratification in the upper hundreds of meters explains why; on . On global average, the assimilation leads to lower DIC above 200 m and higher DIC between 200-600 m depth. In regions of substantial DA effects on vertical transport of DIC, as for example in the Central $STSS_{NA}$– or in the $SPSS_{SO}$ (Section 3.2), the modelled biogeochemical cycles adjust dynamically to the altered vertical transport. The resulting changes in biological sources and sinks of DIC compensate for 20-70% of the changes in vertical transport of DIC (Fig. A13a). In addition to changes in stability and mixing, the assimilation affects the distribution of DIC and alkalinity through changes in horizontal and vertical advection, with changes in the horizontal advection being about an order of magnitude larger than in the vertical. The horizontal local changes in near-surface horizontal transport. As the horizontal distribution of surface DIC, alkalinity and SST is governed by latitudinal gradients and common pathways of advective transport , so that transport (Figs. A10 and A15), all of them undergo similar changes as the SST field is modified. The An exception to this is the Southern Ocean STSS, where changes in the horizontal transport in the $STSS_{SO}$, where regional shifts along contrasting surface gradients of DIC, alkalinity and temperature along contrasting surface gradients affect the respective variables differently (Section 3.2, Fig. A10, Fig. A18). The physics assimilation affects pCO_2 directly through the thermal effect, but also indirectly through changes of DIC and alkalinity, among other factors. Globally, changes in). These shifts change the spatial pattern of air-sea CO_2 fluxes. With the exception of the Southern Ocean, zonally averaged changes in surface pCO_2 are dominated by changes in DIC and alkalinity, but regionally, also the thermal effect can the combined effects of surface alkalinity and DIC on pCO_2 (Fig. A9a). Because alkalinity and DIC are usually modified according to the same pattern through mechanisms acting on both, their effects on pCO_2 are anticorrelated (Fig. A9b). The direct thermal effect on pCO_2 can still be the largest locally, for example in the North Atlantic Newfoundland Basin(Fig. A12+ (Fig. A12b). While the DA dynamically induces changes in surface pCO_2 globallyeverywhere, the strongest effects on the air-sea CO_2 flux are at high latitudes, where the pCO_2 changes are amplified by high wind velocities.

The improvement in ocean physics overall leads to a more heterogeneous picture in biogeochemistry. While near-surface temperature and salinity fields are improved through DA almost everywhere, the global net effect of DA on the global air-sea CO_2 flux varies from year to year between $-0.12\,\mathrm{PgC\,yr^{-1}}$ and $0.15\,\mathrm{PgC\,yr^{-1}}$, which is small compared to the changes in regional CO_2 fluxes. The global net effect of lateral redistribution of alkalinity and DIC at the ocean surface is a result of compensation between regions where alkalinity and DIC are added and removed. Similarly, regional SST effects on surface pCO_2 mostly balance out globally, because DA primarily induces a correction of regional SST biases, reducing the mean absolute difference of modeled surface pCO_2 to SOCAT remains similar in ASML compared to FREE, and this also applies to the model-observation differences for surface chlorophyll, DIC and alkalinity (Section 3.3). Where improvements in one BGC variable occur, these do not necessarily lead to consistent improvement in all BGC variables. For example, the representation of pCO_2 improves while that of chlorophyll deteriorates in the North Atlantic Central STSS (Fig. 11f and Fig. 9f). In the Southern SPSS, the reduction of modeled surface chlorophyll and the summer increase of pCO_2 in the Southern Ocean SPSS lead to a better agreement with observations, yet the available observations of DIC and alkalinity do not resolve the regional scales to evaluate the corresponding changes in these variables (Fig. 9, Fig. 10 and Fig. 11). One possible reason for improvement of model-data mismatch in one variable with worsening in another may lie in inconsistencies between the observational datasets.

~~Another reason may be missing processes in the model or the use of constant BGC model parameters. Those parameters are responsible for linking changes between ecosystem variables and in reality, they vary across space and time depending on species composition in the ecosystem (Mamnun et al., 2023, Chapter 3)~~the observations from 0.59 °C to 0.32 °C, rather than changing the global mean SST, which differs by only 0.02 °C between FREE and ASML. DA-induced differences in vertical transport of DIC are comparably large south of 50 °S, but approximately 95% of them are balanced globally by opposing changes in vertical transport further north (vertical transport of DIC in Fig. A13a). In particular, the effect of DA on subduction of DIC through vertical advection into the ocean's deeper layers (not shown), which is the rate-limiting step on oceanic uptake of anthropogenic CO_2 emissions (DeVries, 2022), appears small, which may be due to an insufficient amount of deep observations. Besides, experiments on longer time scales might be necessary to generate a visible effect of deep circulation changes on the ocean's carbon cycle (Cao et al., 2009), which could however lead to imbalances in the CO_2 flux (Lebehot et al., 2019; Kriest et al., 2020; Primeau and Deleersnijder, 2009). Another possible reason why the DA effect on the global CO_2 flux in our simulation is small, is the variable stoichiometry in REcoM. The dynamic biological functioning reduces the sensitivity of critical fields, like DIC, to physical changes (Buchanan et al., 2018). Furthermore, negative feedback effects between surface alkalinity, DIC, atmospheric pCO_2 and air-sea fluxes might reduce the overall response (Bunsen et al., 2024).

The ~~global~~ overall impact of the DA on the air-sea CO_2 flux on a global scale is modest ($0.05\,\mathrm{Pg\,C\,yr^{-1}}$) compared to the differences between other estimates (e.g., a standard deviation of $0.45\,\mathrm{Pg\,C\,yr^{-1}}$ of GOBMs in DeVries et al., 2023). The global air-sea CO_2 flux estimates of FREE and ASML fall in the range of previous model estimates and in the range of previous pCO_2 products (Fig. 4a and b) for the period 2010-2018, during which comparable estimates are available (DeVries et al., 2023). ~~Thus, the overall impact of the DA on the air-sea CO_2 flux on a global scale is modest ($0.05\,\mathrm{Pg\,C\,dec^{-1}}$) compared to the differences between other estimates (e.g., a standard deviation of $0.20\,\mathrm{Pg\,C\,dec^{-1}}$ in DeVries et al., 2023). However, regionally, the effects of DA are more pronounced.~~

~~There are~~ We compare here to two other data assimilating BGC model approaches, namely ECCO-Darwin (global; Carroll et al., 2020) ~~)~~ and B-SOSE, which is restricted to the Southern Ocean (Verdy and Mazloff, 2017). Both approaches use Linearized Least Squares Optimization data assimilation methods (4D-var/adjoint and Green's function, Wunsch, 1996; Menemenlis et al., 2005). However, the largest difference to our study is probably that they assimilate BGC observations in addition to physical data. Thus, as expected, the effect on pCO_2 in our study is smaller (3%) than in ECCO-Darwin and B-SOSE where a reduction in pCO_2 ~~model data~~ model-data misfit of 6% and 64% was reported, respectively (here given as quadratic misfit).

The global CO_2 flux (2010-2018) is smaller in FESOM2.1-REcoM3-PDAF (~~$-2.73\,\mathrm{Pg\,C\,dec^{-1}}$~~$-2.73\,\mathrm{Pg\,C\,yr^{-1}}$ in FREE and $-2.78\,\mathrm{Pg\,C\,yr^{-1}}$ in ASML) than in ECCO-Darwin (~~$-3.13\,\mathrm{Pg\,C\,dec^{-1}}$)(2010-2018). The global CO_2 flux in ASML is similar to FREE and does not drive the estimate closer towards the higher estimates of the ECCO-Darwin or the observation-based pCO_2-products ($-2.87\,\mathrm{Pg\,C\,dec^{-1}}$). Similarly, the trend and interannual variability of the CO_2 flux is hardly changed by the assimilation, suggesting that a flawed representation of ocean physics as an argument for the models underestimating the CO_2 flux trend is unlikely.~~

$-3.13\,\mathrm{Pg\,C\,yr^{-1}}$). The discrepancy between the CO_2 flux estimates based on models and pCO_2-products is an area of active research and ~~is~~ not fully resolved (Friedlingstein et al., 2023; DeVries et al., 2023). On the one hand, model biases in the

~~AMOC~~Atlantic Meridional Overturning Circulation, in Southern Ocean ventilation and possibly biases in the surface ocean carbonate chemistry were suggested as reasons why models might underestimate the global mean CO_2 uptake in recent decades (Friedlingstein et al., 2023; Terhaar et al., 2024, 2022). On the other hand, the sparsity of observations is a concern for the pCO_2 products. According to one testbed simulation, the pCO_2 products reflect the global mean and the seasonal cycle relatively well, while the decadal variability may be overestimated (Gloege et al., 2021). An overestimation of the decadal trend, as suggested by Hauck et al. (2023b), could explain the high estimates of the pCO_2 products for the present-day global mean CO_2 flux. In contrast, for the North Atlantic, it was argued that pCO_2 is comparatively well constrained by observations in the last decade but not in the 1980s, which has an erroneous influence on the long-term trend (Pérez et al., 2024).

The effects of data assimilation on the CO_2 flux are most pronounced in the Southern Ocean STSS~~and SPSS~~ $_{SO}$ and $SPSS_{SO}$ in winter. Verdy and Mazloff (2017) also found the largest effects of assimilation on the CO_2 flux in this region. Although the region is of crucial importance for the global ocean carbon sink, it also has the greatest uncertainty due to the lack of ship-based winter observations (Friedlingstein et al., 2023; Hauck et al., 2020). In the last decade, the number of winter observations has increased due to the introduction of biogeochemical Argo floats (Johnson et al., 2017; Williams et al., 2017), although the float-based pCO_2 derived from pH measurements and estimated alkalinity is subject to higher uncertainty compared to direct pCO_2 measurements (Williams et al., 2017; Bakker et al., 2016). Machine learning approaches incorporating BGC Argo float observations suggest a stronger winter outgassing around Antarctica, particularly south of $50\,°S$ in the SPSS~~and ICE~~ $_{SO}$ and ICE_{SO} biomes, for 2015-2017 (Bushinsky et al., 2019; Gray et al., 2018). This results in a lower estimate of annual Southern Ocean CO_2 uptake in the float products. One suggestion in the literature ~~was~~ is that model inadequacies in the representation of mixing and upwelling in the Southern Ocean ~~could~~ might cause the discrepancy between float products and models (Gray et al., 2018). However, improvements in the modeled ocean physics and changes in mixing through data assimilation do not lead to ~~not lead to~~ closer agreement between the FESOM-REcoM estimate and the float products (comparison of FESOM-REcoM, float products and B-SOSE in Fig. A14). In contrast, ASML shows even weaker winter outgassing and stronger summer uptake south of $50\,°S$ than FREE, which brings the FESOM-REcoM estimate further away from the float products. However, ASML is brought close to B-SOSE in terms of winter outgassing in the Antarctic polar ocean ~~(~~south of $60\,°S$ ~~)~~ and winter uptake in the STSS~~(at~~ $_{SO}$ around $40\,°S$~~)~~. Additionally, airborne CO_2 flux estimates and direct pCO_2 measurements stemming from a sail drone have questioned the estimates of winter outgassing based on the BGC floats, either attributing the high pCO_2 values to possible biases in the floats' measuring devices or to anomalously high pCO_2 in the years 2015-2016 (Long et al., 2021; Sutton et al., 2021). ~~Based on the assumption of preindustrial steady state conditions, a larger natural CO_2 outgassing in the Southern Ocean needs to be compensated by other ocean regions (Gray et al., 2018). The regional differences caused by the data assimilation in the Southern Ocean and elsewhere largely balance out globally and appear to be shifts in the areas where outgassing occurs. These regional shifts follow shifts in sea surface temperature and the distribution of dissolved inorganic carbon (DIC) and alkalinity.~~

~~The comparably small effect of physics DA on the air-sea CO_2 flux suggests that the physical processes are already well-represented in FREE when compared to the uncertainties arising from the biogeochemistry model. The response of REcoM to changes in model physics might be small due to its variable stoichiometry, as the study by (Buchanan et al., 2018)~~

~~indicated that dynamic biological functioning reduces the sensitivity of critical fields, like carbon, to physical changes. Furthermore, negative feedback effects between alkalinity, DIC, atmospheric pCO_2, and air-sea fluxes might reduce the overall response (Bunsen et al., 2024). While surface physics are well constrained in the ASML run, questions remain about the dynamics of the mixed layer and deep ocean. Experiments on decadal or longer time scales might be necessary to represent the adjustment of the ocean's carbon cycle to changes in the circulation (Cao et al., 2009). In ASML though, the effect on the CO_2 flux is already as strong in the first two years as at the end of the period, and it appears to be governed by interannual variability rather than showing a continuous adjustment. Despite the higher resolution in dynamic regions of the North Atlantic and the Arctic, strong currents and their exact locations, such as the North Atlantic Current and Antarctic Circumpolar Current, are challenging for the model to resolve. These are improved through the assimilation, which is the basis for realistically modeling biogeochemistry in these regions as well.~~

5 Conclusion

We apply data assimilation of temperature and salinity into a global ocean-biogeochemical model to improve the physical state for the years 2010-2020. The simulation is then assessed with regard to the effects on the biogeochemical variables. The experiments show that the effect of data assimilation (DA) on biogeochemical variables is mostly related to temperature changes. While the air-sea CO_2 flux and pCO_2 are directly affected by sea surface temperature, the DA also ~~induced~~ induces indirect changes to pCO_2 through dissolved inorganic carbon (DIC) and alkalinity. Globally integrated, these are more relevant for pCO_2 than the direct temperature effect. Yet, which of these factors has a dominant effect on pCO_2 varies locally. The assimilation leads to ~~changes in the horizontal advection of DIC and alkalinity, thereby regionally shifting~~ regional shifts in areas of CO_2 outgassing and uptake. Local effects on the air-sea CO_2 flux are particularly large in dynamic regions such as the North Atlantic Current and near the Subantarctic Front, whose pathways are challenging for the model to resolve without DA. The largest effect on the air-sea CO_2 flux occurs in the Southern Ocean during winter. In the simulation with assimilation, the uptake south of $50\,^{\circ}\mathrm{S}$ is increased due to shallower mixing and surface cooling, and the uptake northward of that (40-$50\,^{\circ}\mathrm{S}$) is weakened. In this ~~part~~ area of the ocean, the uncertainty in current estimates of CO_2 fluxes is particularly high. ~~Furthermore, the assimilation has locally strong effects in the area of the North Atlantic current.~~ Overall, the uncertainty inherent to the biogeochemical model appears to be larger than the uncertainties induced through physical biases in the free running model. Locally, the changes in surface pCO_2, chlorophyll, alkalinity, and DIC caused by the assimilation ~~are of the magnitude of 15-30~~range between about 15 and 30% of the mean absolute model-observation difference. Yet, local improvements in one variable do not necessarily come along with improvements across other observed biogeochemical variables. Therefore, globally, physics DA does not generally improve the difference between the model and observations. In total, the effect of physics DA on the global ocean carbon uptake is ~~small~~ with $0.05\,\mathrm{Pg\,C\,yr^{-1}}$ small compared to the spread between previous estimates of models, pCO_2 products and other DA estimates. While the assimilation of temperature and salinity improves the ~~physical state,~~ representation of these two and also of mixed-layer depth, sea-ice concentration and horizontal near-surface velocities, possible errors in the ~~mixed layer depth~~ vertical velocities and overturning circulation are not ~~fully~~ eliminated. Further biogeochemical variables are

only indirectly affected. To this end, the additional assimilation of biogeochemical observations is an obvious next step to reduce the uncertainty stemming from the ecosystem model and to improve the ~~model observation~~ model-observation differences for biogeochemical variables.

Code and data availability. The code used to perform the free simulation and the data assimilation is available at 10.5281/zenodo.11495274. This code archive additionally contains a notebook to produce the manuscript figures from the model output. The processed model output data underlying the figures of this manuscript are available at 10.5281/zenodo.11495081.

Appendix A

Table A1. List of tracers in REcoM3

Tracers in REcoM3
Dissolved inorganic nitrogen and carbon (DIN, DIC)
Dissolved organic nitrogen and carbon (DON, DOC)
Alkalinity
Oxygen
Iron
Silicate
Intracellular concentrations of nitrogen, carbon, chlorophyll, and calcium in small phytoplankton (PhyN, PhyC, PhyChl, PhyCalc)
Intracellular concentrations of nitrogen, carbon, chlorophyll, and silicate in diatoms (DiaN, DiaC, DiaChl, DiaSi)
Intracellular concentrations of nitrogen and carbon in each of two zooplankton groups (HetN, HetC, Zoo2N, Zoo2C)
Two size classes of detritus for nitrogen, carbon, silicate, and calcium (DetN, DetC, DetSi, DetCalc; and DetZ2N, DetZ2C, DetZ2Si, DetZ2Calc)

Transport terms include advection and diffusion of DIC and alkalinity. Meridional transport is averaged across bins of 5° latitude. In panel b, vertical and horizontal transport are summed up for readability. Biological terms for DIC are the sum of: photosynthesis, respiration, remineralization of dissolved organic carbon, and formation and dissolution of calcite. Biological terms for alkalinity are the sum of: nitrogen assimilation and remineralization, and formation and dissolution of calcite.

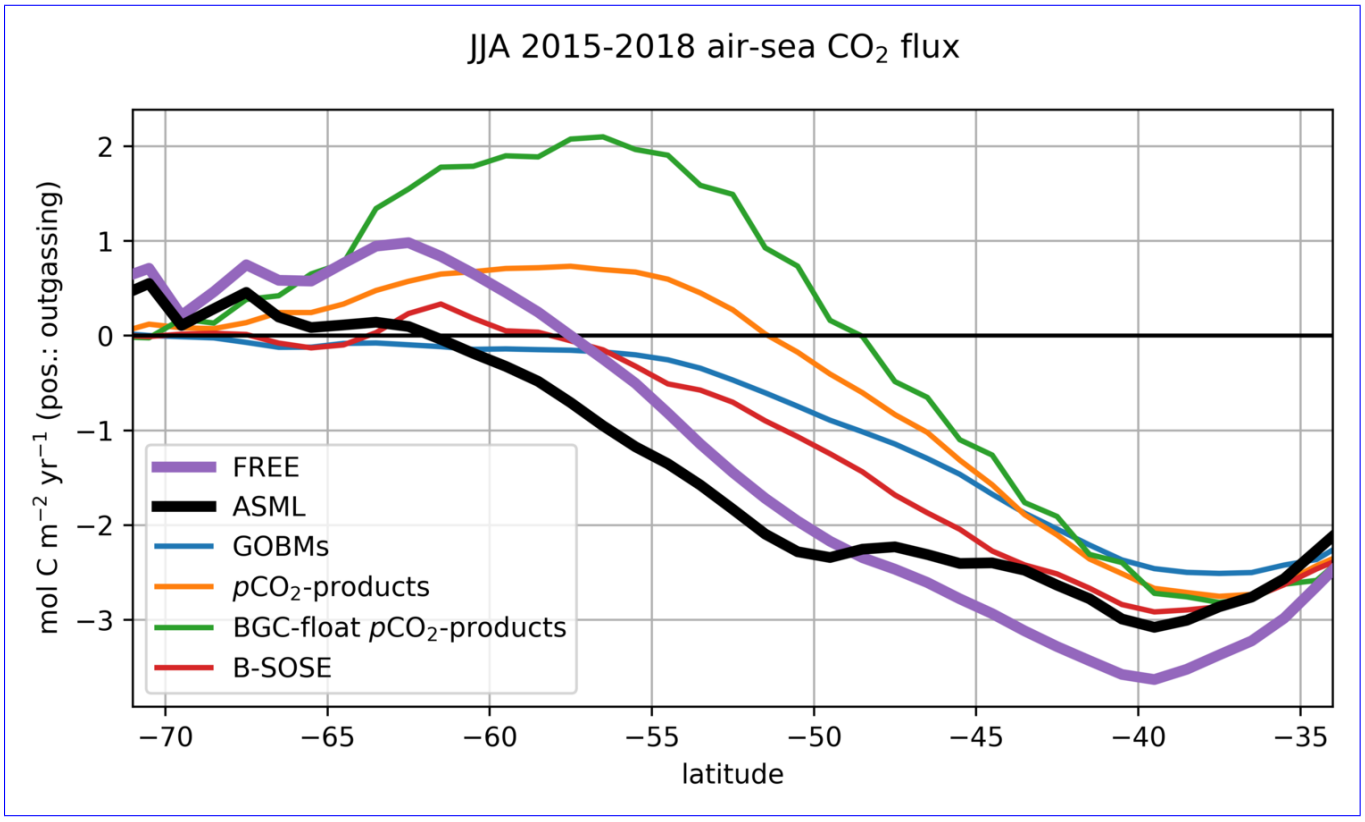

Figure A14. Zonally averaged winter (JJA) air-sea CO_2 flux in FREE, ASML and previous estimates (Hauck et al., 2023a; Verdy and Mazloff, 2017).

~~**Text A1: Velocity field** A problem with deep equatorial vertical velocities is indicated by artifacts of the meridional overturning in ASML. Throughout the assimilation period, spurious, spatially limited and often deep overturning structures emerge, evolve through several months or years, and disappear in the tropical Indian, Pacific and Atlantic basin (not shown). Thereby, the surface overturning cell sometimes breaks apart where it should extend over the equator, exposing the bottom cell to the surface. One possible cause is the effect of data assimilation on the eddy parameterisation (Gent and Mcwilliams, 1990). The parameterised eddy activity is relevant for the dynamics in the deep ocean, and corrupting it can have a negative impact on the large-scale oceanic circulation, as described in Sidorenko (2004, Chapter 5.5 onwards) for a previous version of the ocean model FESOM.~~

Author contributions. JH and LN conceptualized the research idea and provided supervision of the work. FB worked on the code for the model binding, for which LN provided supervision, and performed formal analysis of the data and figure production. FB prepared the initial paper draft with conceptional inputs from all authors. All authors contributed to the review and editing of the final manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We acknowledge the Global Carbon Project, which is responsible for the Global Carbon Budget and ~~RECCAP~~ RECCAP2 and we thank the ocean modeling and fCO_2-mapping groups for producing and making available their model and fCO_2-product output; in particular Cara Nissen for providing the files. Further, we thank Longjiang Mu who provided code for a PDAF-model binding within the FESOM model family in order to modify it for our study. At last, we acknowledge the use of DeepL Free (DeepL SE, https://www.deepl.com/translator) for translations and of ChatGPT 3.5 (Open AI, https://chat.openai.com) to provide rewording suggestions for the text.

FB has received funding from the AWI INSPIRES programme, and JH from the Helmholtz Young Investigator Group Marine Carbon and Ecosystem Feedbacks in the Earth System (MarESys, Grant VHNG-1301), and from the European Research Council Starting Grant ERC2022-STG OceanPeak (Grant 101077209). The work reflects only the authors' view; the European Commission and their executive agency are not responsible for any use that may be made of the information the work contains.
