**Abstract.** Stable water isotopes are important tracers to understand interactions between all compartments of the hydrological cycle. Particularly in groundwater studies they have been used to assess recharge and origin of groundwater. Based on high-density groundwater measurements, we produced a new, interpolated map of the  $\delta^{18}\text{O}$  distribution (i.e. an isoscape) in groundwater of south-east Germany. A comparison of this groundwater isoscape to the regional long-term precipitation isoscape showed differences of up to  $\pm 2\%$  between both compartments. Groundwater was enriched in the light isotope  $^{16}\text{O}$  compared to precipitation in the alpine area where recharge occurs mainly during winter and at recharge areas at higher altitudes. However, groundwater was enriched in the heavy isotope  $^{18}\text{O}$  with respect to precipitation in drier lowland regions where summer recharge, irrigation practices and aquifer types as well as evaporation processes may play a role. Further comparative studies between precipitation and groundwater stable water isotopes by using time series are needed to improve the understanding of spatial and seasonal recharge patterns of groundwater.

## 1 Introduction

20 Stable isotope ratios of oxygen ( $^{18}\text{O}/^{16}\text{O}$ ) and hydrogen ( $^2\text{H}/^1\text{H}$ ) in the water molecule have long been used as tracers in the hydrological cycle (Rozanski et al., 1993; Dansgaard, 1964; Craig, 1961). For groundwater studies, they can provide new information about the origin of precipitation or about surface water-groundwater interactions (e.g., Koeniger et al., 2016). Such insights contribute to improve knowledge about groundwater recharge, both in terms of spatial patterns and seasonality (Bowen et al., 2019). Other benefits include better quantification of infiltration, evaporation, and groundwater vulnerability to surface  
25 pollutants.

For a long time, only localized measurements were available for groundwater isotope studies, although continuous spatial information is needed to reach an overall understanding of flow directions and recharge processes (Bowen, 2010). Maps representing the spatial variation of isotopes, so-called “*isoscapes*”, have been developed and improved since the 2000s with the help of Geographic Information Systems (GIS). Such developments have been made possible with the increased availability  
30 of extensive isotope datasets, mainly in precipitation, and high-resolution climate data. For instance, similar patterns strongly connect isotopes in precipitation to those in the biosphere (Hobson et al., 1999; Bowen et al., 2005; Bowen and Revenaugh,

2003; Gabriel Bowen, 2002; West et al., 2008; Wassenaar and Hobson, 1998; Bowen, 2010). Such isotope relationships offer help in various fields that range from forensics via archaeology, the food and beverage industry, to animal migration investigations (Jason B. West, 2008; Cerling et al., 2016), but also to understand hydrological processes.

35 A global precipitation isoscape was established with the data from the Global Network of Isotopes in Precipitation (GNIP) (Terzer et al., 2013; Terzer et al., 2021). In the interpolation model, effects on isotope ratio variability are accounted for such as latitude, altitude and climate including precipitation quantity, vapor pressure and longwave radiation. Parallel to this global approach, several other local and regional interpolations of isotopes in precipitation have been proposed (Lykoudis and Argiriou, 2007; Delavau et al., 2015; Hollins et al., 2018).

40 Much fewer isoscape investigations exist for groundwater. So far, some regional groundwater isoscapes have been presented for Mexico (Wassenaar et al., 2009), the Baltic region of Estonia, Latvia and Lithuania (Raidla et al., 2016), Ireland (Regan et al., 2017), Poland (Leśniak and Wilamowski, 2019), Croatia (Brkić et al., 2020) and Ethiopia (Bedaso and Wu, 2021). However, comparing precipitation and groundwater isoscapes may reveal groundwater recharge areas and their complex recharge mechanisms that include post depositional evaporation or recharge from surface waters. Such comparisons can also  
45 provide services for interpretations of seasonal or long-term temporal trends in the context of climate change if repeated over time. For example, groundwater isotope values of paleowaters have been used in combination with groundwater mean residence times to reconstruct paleo-recharge conditions and quaternary climate change (Jiráková et al., 2011; Darling, 2011; Edmunds, 2001). So far, such comparisons have only rarely been applied at a larger, regional scales. Most aforementioned groundwater isoscapes underline the need for higher data density and an unbiased and even distributions of datapoints across the study area  
50 and aquifers as well as consistent sampling and analysis methods. This is especially relevant to ensure valid interpolation models across larger investigation areas that take into account regional climatic and geologic particularities (Bedaso and Wu, 2021).

Generally, we expect the isotopes in groundwater to represent a long-term average of the isotopes in precipitation as seasonal patterns are filtered out during infiltration and mixing with the large, long-term reservoir of groundwater. This implies that  
55 groundwater isotope patterns can serve as proxies for precipitation (Wassenaar et al., 2009; Raidla et al., 2016; Bedaso and Wu, 2021). Nonetheless, groundwaters in temperate regions can show a bias towards the lighter isotopes of winter precipitation. This is due to well documented groundwater recharge during winter, mostly because of smaller evapotranspiration during the non-growing season (Riedel and Weber, 2020; Clark, 1997). Studies in Poland, Germany and France have estimated that 0–51% of winter precipitation, but only 0–17% of summer precipitation turn into groundwater (Jasechko et al., 2014; Raidla et  
60 al., 2016).

The opposite situation, when groundwater displays higher isotope composition than precipitation can be explained by several mechanisms. First, evaporation processes can enrich the remaining groundwater in heavy isotopes after precipitation reached the ground. This can happen during water infiltration into the ground, at surface waters (lakes and rivers) that themselves feed

the groundwater, or when large amounts of groundwater are brought back to the surface, for example for irrigation purposes.  
65 Second, a bias in groundwater towards summer precipitation is possible if recharge takes mostly place during the warm season. This is possible in regions where the potential evapotranspiration is roughly equal to the precipitation, i.e. arid areas. In this case, isotopically enriched high intensity rain events taking place during the warm season disproportionately contribute to the low isotope signal observed in groundwater due to preferential flowpaths (H. S. Wheater, 2010). Moreover, a connection of the shallow aquifer to deeper groundwater may change isotope ratios in comparison to precipitation. Finally, isotopes in  
70 groundwater may also show dampened seasonal variations at a local scale in aquifers with short transit times and low dispersivities (Raidla et al., 2016).

The non-equilibrium process of evaporation is described quantitatively by the Craig-Gordon model (Craig and Gordon, 1965). According to the C-G model, evaporation effects can typically be seen in the dual-isotope plot ( $\delta^{18}\text{O}$  vs  $\delta^2\text{H}$ ) by sample isotope ratios that plot along a lower slope with respect to the Meteoric Water Line (MWL).

75 A secondary parameter derived from the linear relation of isotope ratios in global precipitation, known as the Global Meteoric Water Line (GWML) (Craig, 1961) is the deuterium excess ( $d$ ) value, introduced by Dansgaard (1964) with:

$$d = \delta^2\text{H} - 8 \delta^{18}\text{O} \quad (1)$$

This parameter is known to vary locally due to kinetic fractionation processes sensitive to relative humidity and advection by winds at the moisture source (Clark, 1997). Globally,  $d$  values range around 10 ‰ worldwide (Craig, 1961). In German precipitation, weighted annual means for  $d$  have been reported between 4.1 and 11.9 ‰ (Stumpp et al., 2014).

80 With this work we investigated similarities and differences between groundwater and precipitation stable water isoscapes in a high-resolution study in southern Germany. The objectives of this study were: (i) to create a high-resolution regional isoscape for shallow groundwater in the south-eastern part of Germany (Bavaria), (ii) to compare this groundwater isoscape to precipitation isotopes in the same area, and (iii) to identify the mechanisms that explain the possible local or regional differences between isotopes in precipitation input and groundwater. The investigated area represents a typical central European temperate  
85 climate with respect to land use, topography, altitudinal gradient, and urbanization. The groundwater data set offers an exceptionally high spatial resolution and covers equally the main shallow aquifers. Thus, this study offers new opportunities to investigate two crucial components of the hydrological cycle, that is precipitation and groundwater. This study therefore provides valuable insights into groundwater recharge patterns on a regional level with high resolution.

## 2 Methods

### 90 2.1 Study area

Our study focuses on the south German state of Bavaria in central Europe (Fig. 1b). It covers 70'500 km<sup>2</sup> from the Alps and alpine foreland in the south (maximum altitude 2'962 m above sea level; a.s.l.), parts of the Danube Basin and the low-lying Main River region in the northwest (about 100 m a.s.l.). The main aquifers in the Alps occur in valley sediments. North of the

Alps, the Molasse Basin covers sandstone and a combination of fracture and pore aquifers. Karst systems are characteristic for  
95 central Bavaria. These are bordered to the east by low permeability crystalline rocks. The region of the Main River in the  
northwest mainly presents fracture aquifers in sand- and limestone formations (Bundesministerium Für Umwelt Naturschutz  
Und Reaktorsicherheit, 2003).

The study area lies in a temperate continental climate with the code Dfb according to the Köppen-climate zones (Beck et al.,  
2020). Average annual precipitation and temperatures are 941 mm and 9.7°C (Bayerisches Staatsministerium Für Umwelt Und  
100 Verbraucherschutz, 2021) with strong regional variations. For instance, the Main River region showed an annual average  
precipitation of 710 mm in the period 1971-2000. This strongly contrasts with the Alps with annual precipitation average of  
1966 mm for the same period.

## 2.2 Groundwater sampling and analysis

Groundwater sampling took place from April to August 2015 in collaboration with the local water management authorities of  
105 Bavaria. A total of 596 water samples were collected in wells ( $n=402$ ) and springs ( $n=194$ ) over the entire study area (Fig. 1a)  
according to standard groundwater sampling protocols. While few deep wells were also sampled, mostly shallow aquifers with  
depth < 40 m below surface were addressed.

All water samples were analysed for stable isotope ratios ( $^{18}\text{O}/^{16}\text{O}$  and  $^2\text{H}/^1\text{H}$ ) with an isotope ratio infrared spectroscopy  
analyzer (Picarro Inc. Santa Clara, CA, USA). Results are denoted in the standard delta-notation for the relative difference of  
110 isotope ratios in permil (‰):

$$\delta^i E = \frac{R(^i E/^j E)_{\text{sample}}}{R(^i E/^j E)_{\text{reference}}} - 1 \quad (1)$$

Where  $R$  represents the dimensionless ratio of heavy isotopes (mass  $i$ ) to light isotope (mass  $j$ ) on an element  $E$  for a sample  
or a reference substance (Coplen, 2011). Raw data values were normalized to the Vienna Standard Mean Ocean Water  
(VSMOW) scale and corrected for sample-to-sample memory as well as instrument drift according to Van Geldern and Barth  
(2012). The long-term measurement precision represented as standard deviation ( $\pm 1 \sigma$ ) on independent control samples was  
115 < 0.1 ‰ and < 1.0 ‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ .

## 2.3 GNIP data acquisition

The monthly water isotope values in precipitation from 2010 to 2018 were retrieved from GNIP stations in and around Bavaria  
(accessible from the WISER database, <https://nucleus.iaea.org/wiser> (IAEA, 2023b) and measured by ourselves (Stumpp et al.,  
2014). The gridded interpolation maps of  $\delta^{18}\text{O}$  values averaged over an entire year were downloaded from the IAEA-Isotope  
120 Hydrology Network (IHN) website in September 2023 (<https://isotopehydrologyneetwork.iaea.org> (Iaea, 2023a). The  
interpolation model for these isoscapes is described in Terzer et al. (2021).

## 2.4 GIS and statistical methods

All maps were produced with ArcGIS Pro 2.9.0 using the Germany Zone 4 projected coordinate reference system (ESRI:31494). Based on the assumption that altitude and temperature differences are negligible in groundwater, that latitude and the distance to oceans are irrelevant on this spatial scale and that our samples were evenly distributed over the entire area, we opted for a purely geostatistical approach to produce a groundwater isoscape. We used the “Empirical Bayesian Kriging” algorithm from the Geostatistical Analyst Toolbox. Input parameters for the algorithm can be found in the supplementary information (Table S1). This algorithm proposes an improvement of traditional Kriging by estimating the uncertainty of the semivariogram model and automating parameters best fit (more information in the ArcGIS Pro documentation (<https://pro.arcgis.com/en/pro-app/2.9/tool-reference/geostatistical-analyst/empirical-bayesian-kriging.htm> (Arcgis pro, 2023)). Compared to traditional Kriging, this improved algorithm proved less sensible to outliers and reduced the number of local artefacts around outlier sampling points. Data transformation and statistics were performed with R (version 4.3.0).

## 2.5 Cluster attribution

To display differences between isotope values in groundwater and precipitation, we subtracted the precipitation isoscape from the groundwater isoscape for both  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  by using the arithmetic raster function built in ArcGIS Pro. Due to the analysis error ( $\pm 0.1 \text{ ‰}$  for  $\delta^{18}\text{O}$ -values) and the uncertainty of the interpolations ( $\pm 0.3 \text{ ‰}$  for groundwater,  $\pm 0.1 \text{ ‰}$  for precipitation), we considered groundwater/precipitation differences under  $|0.5| \text{ ‰}$   $\delta^{18}\text{O}$  ( $|5.0| \text{ ‰}$   $\delta^2\text{H}$ ) as not significant and therefore did not further interpret them. The areas where the difference between groundwater and precipitation exceeded this threshold were grouped into two clusters: a) one in which the isotope values in groundwater were more negative than in the precipitation (blue cluster) and b) one for the opposite situation (yellow cluster). We then attributed the groundwater sampling points to a cluster when the point lay within 25 km to this cluster. To compare to precipitation data, we also considered 13 GNIP stations with at least 8-year monthly time series in and around Bavaria. These were attributed to the clusters based on the same geographic criteria as for groundwater. The location of the considered GNIP stations and their cluster attribution can be found in Fig. 2.

## 3 Results

Here, we present isoscapes of the  $\delta^{18}\text{O}$  values distribution in groundwater and precipitation. Distribution maps of the hydrogen isotopes proved similar and are displayed in the supplementary information (Figure S1).

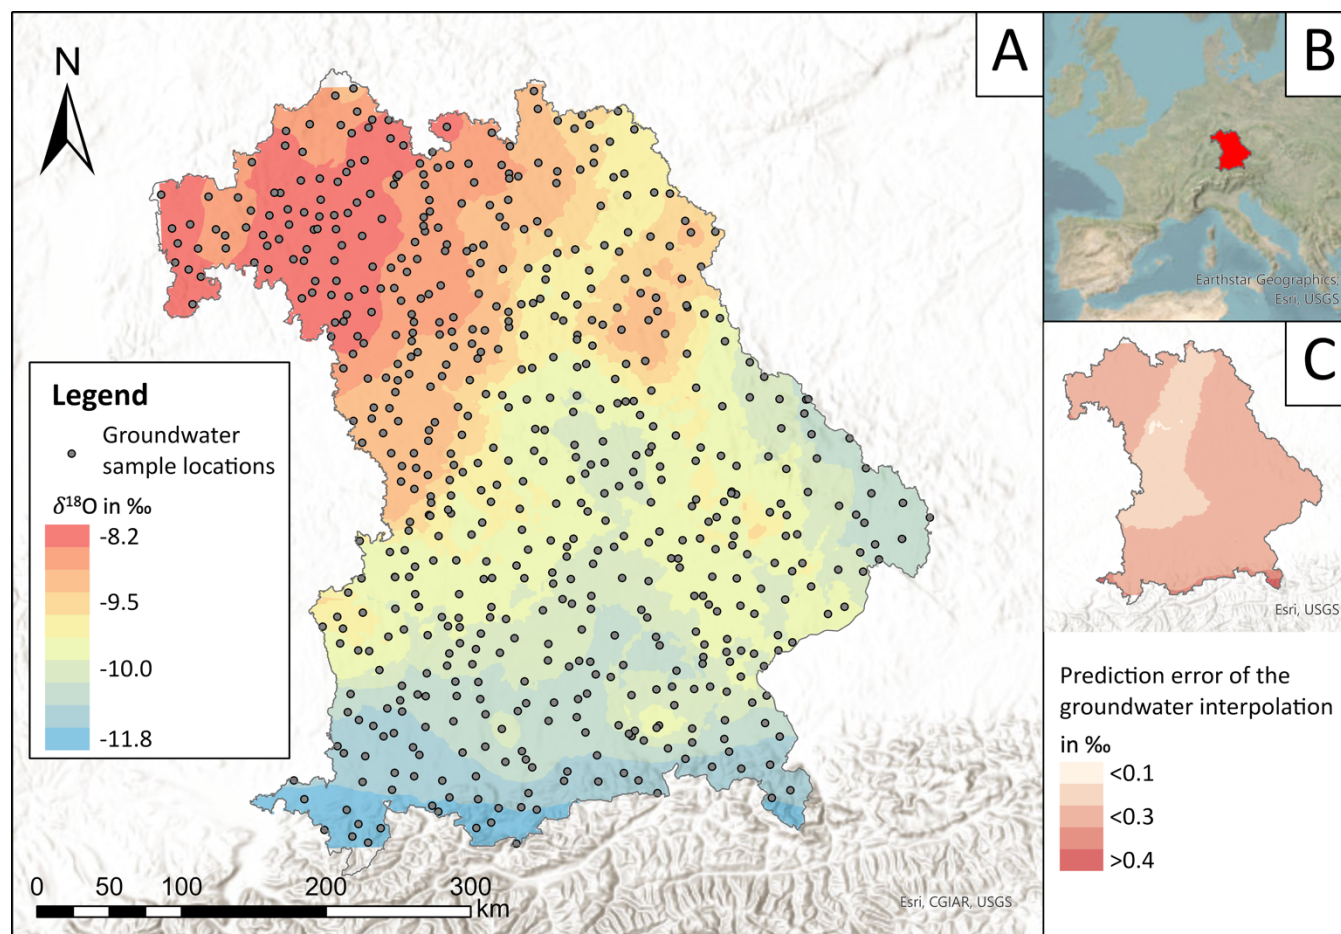

### 3.1 Groundwater and precipitation data

Figure 1a presents the  $^{18}\text{O}$ -isoscape of Bavarian shallow groundwaters. The groundwater  $\delta^{18}\text{O}$  values ranged from -12.9 to -6.8 ‰ with a mean value of -9.6 ‰. We observe a clear trend of more negative isotope values in the south (alpine region) to less negative values in the north-western (Main region). The standard error of the interpolation ranged from 0.1 ‰ to 0.55 ‰

but lies under 0.3 ‰ in >95% of the area (Fig. 1c). The interpolation error lies in the same order of magnitude as the analytical error.

155 Figure 1: (a) groundwater  $\delta^{18}\text{O}$  isoscape with sample locations. (b) Location of the study area in Europe. (c) Standard error of the interpolation in ‰.

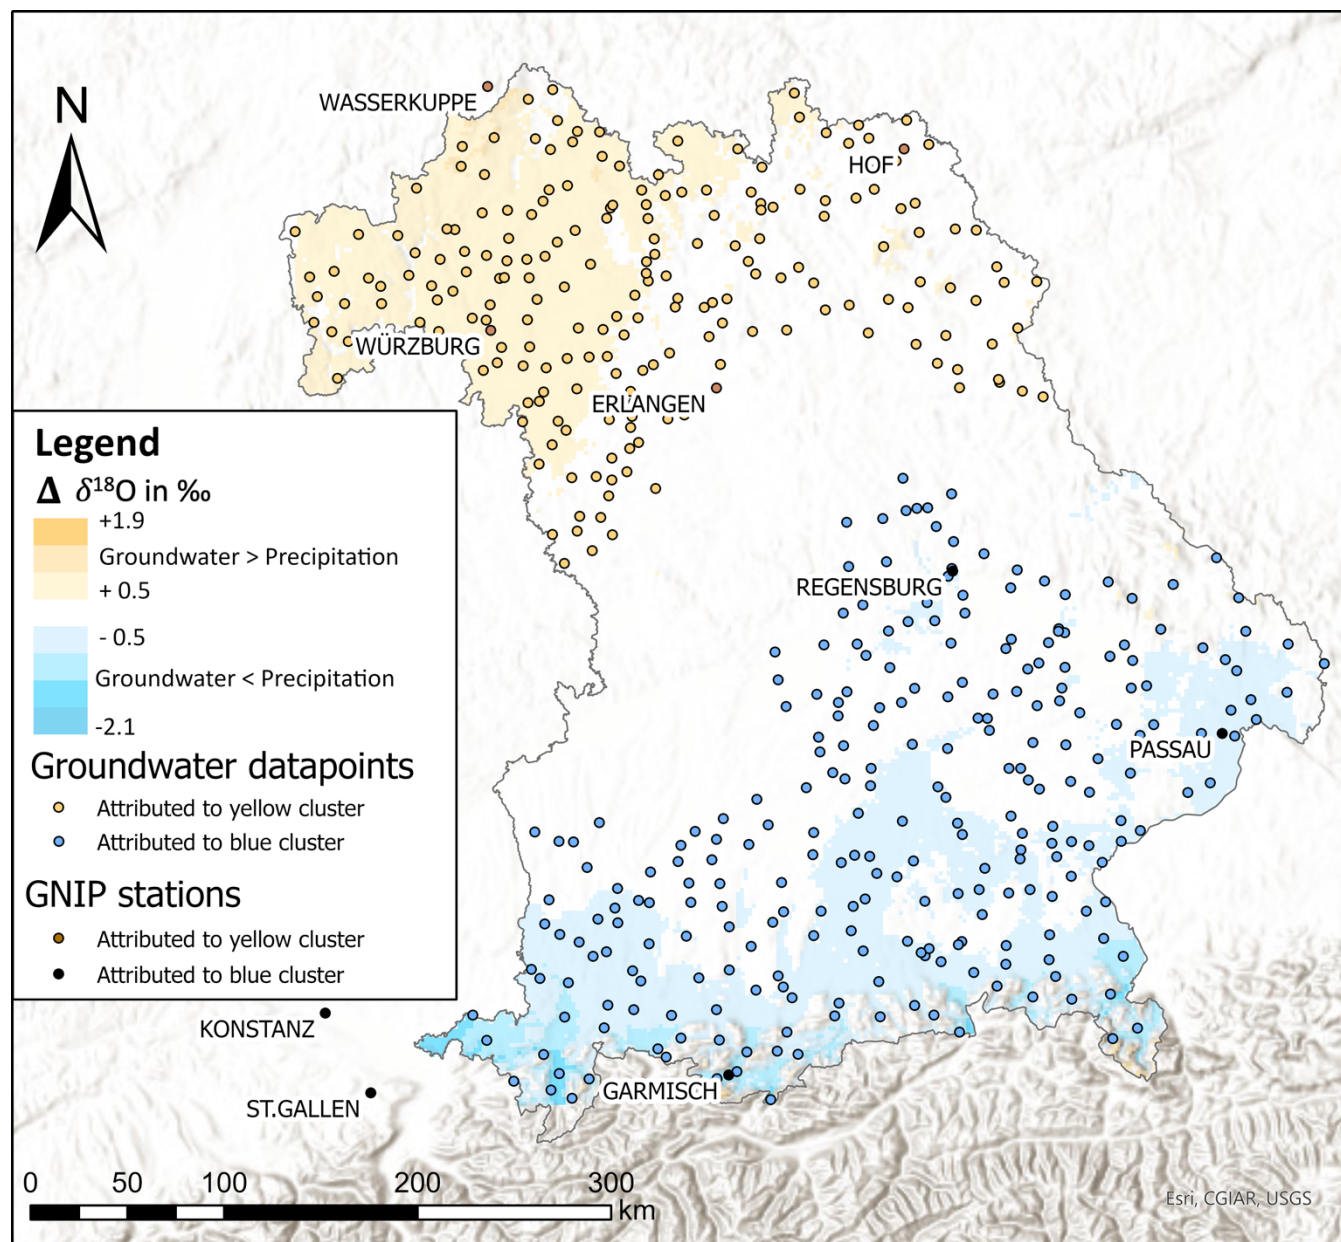

The distribution of  $\delta^{18}\text{O}$  values in precipitation obtained by the interpolation by Terzer et al. (2021) is shown in the supplementary information (Figure S2). The data range from -13.4 to -8.8 ‰. The distribution pattern in precipitation depends on the altitude with the lowest values in the Alps and the eastern regions bordering the study area.

### 3.3 Groundwater–precipitation comparison

160 Figure 2 displays the difference of  $\delta^{18}\text{O}$  values between groundwater and precipitation. About 67 % of our investigation area, mainly central Bavaria, showed less than  $\pm 0.5$  ‰ difference between groundwater and precipitation. When this was the case, we concluded that precipitation recharges groundwater equally throughout the year with little or no alteration of the isotope signal and did not further consider these regions in the subsequent discussion that focuses on isotope differences ( $\Delta\delta$ -values).

165 Areas with substantial differences between isotopes in precipitation and groundwater include the Alps, alpine foreland and molasse basin (19.3 % of the study area) with groundwaters having more negative values than the local precipitation, with a maximum difference of 2.1 ‰. In contrast, the north-western part of Bavaria that roughly corresponds to the Main region (13.3 % of the study area) showed more negative values in precipitation than in groundwater, with a maximum difference of 1.9 ‰.

170 Figure 2: Differences between  $\delta^{18}\text{O}$  values groundwater and precipitation isoscapes ( $\Delta\delta$ ). Areas with differences smaller than  $|0.5 \text{ ‰}|$  are transparent. The yellow and blue areas mark the clusters with groundwater–precipitation differences  $> |0.5 \text{ ‰}|$ . The groundwater sampling points and GNIP stations attributed to one cluster according to Sect. 2.5 are also shown.

### 3.4 Meteoric water lines and d-excess

175 Figure 3 shows the regional meteoric waterlines (RMWL) for (a) the groundwater and precipitation data in the southern (blue) cluster and (b) groundwater and precipitation data in the northern (yellow) cluster.

In the southern region (Fig. 3a) the groundwater samples ( $n=262$ ) plot along a trendline with the following equation:

$$\delta^2H_{gw,Alps} = (6.47 \pm 0.1) \delta^{18}O - (7.75 \pm 1.06) \quad (2)$$

The Southern Meteoric Water Line of the monthly precipitation values between 2010 and 2018 in the corresponding GNIP stations ( $n=420$ ):

$$\delta^2H_{prec,Alps} = (7.87 \pm 0.06) \delta^{18}O + (6.47 \pm 0.6) \quad (3)$$

180 This is similar to the MWL (meteoric water line) reported by Stumpp et al. (2014) for the precipitation in Germany with  $\delta^2H = 7.09 \delta^{18}O - 0.31$ .

In the northern region of Bavaria (Fig. 3b) the groundwater samples ( $n=202$ ) plot along a trendline with the following equation:

$$\delta^2H_{gw,Main} = (6.1 \pm 0.17) \delta^{18}O - (8.99 \pm 1.53) \quad (4)$$

The monthly precipitation values between 2010 and 2018 in the corresponding GNIP stations ( $n=432$ ) are:

$$\delta^2H_{prec,Main} = (7.78 \pm 0.07) \delta^{18}O + (5.95 \pm 0.65) \quad (5)$$

185 The reduced spread of groundwater isotope values in comparison to the corresponding precipitation values is most likely the result of subsurface mixing processes along the flow paths and with different water sources from different recharge areas and seasons.

When comparing the groundwater samples in the southern and northern clusters, we observe a clear trend towards less negative values going from south to north with minimum, maximum and mean  $\delta^{18}O$  values of -12.9, -6.8, and -10.1 ‰ and -10.6, -7.7, and -9.0 ‰, respectively. This observation reflects the same south-north trend as in the groundwater isoscape (Fig. 1).

190 The  $d$ -values in groundwater displayed in Fig. 4 range from 6.0 to 10.3 ‰ with higher values preferentially found at higher altitudes, although not consistently.

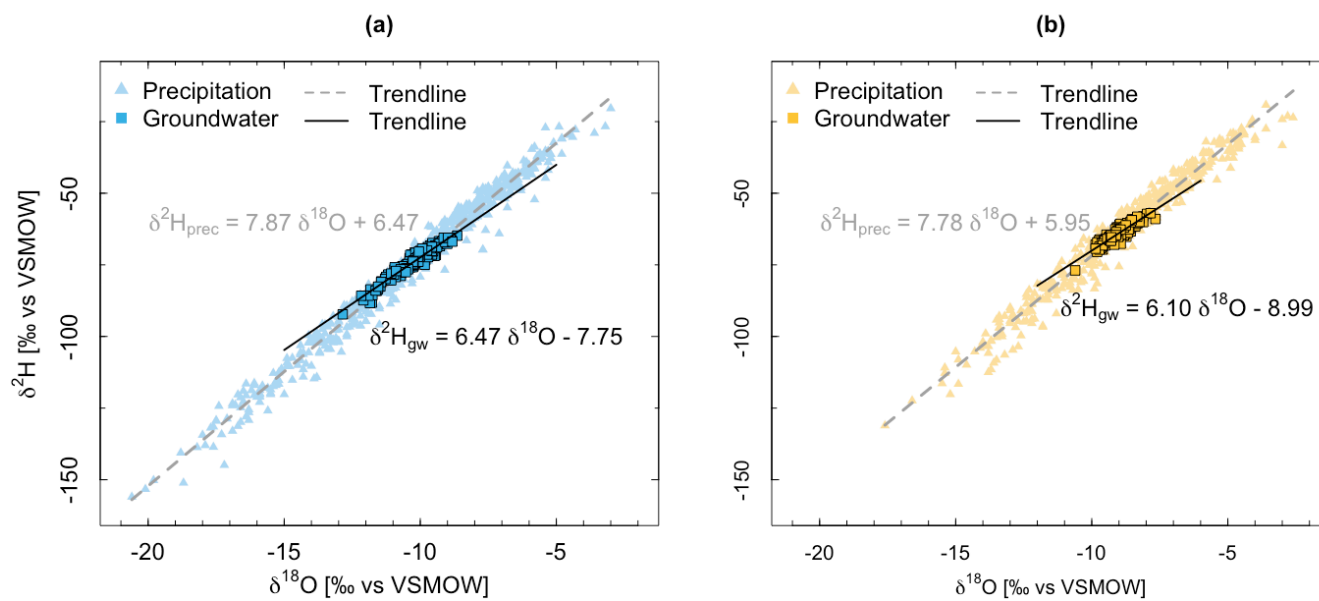

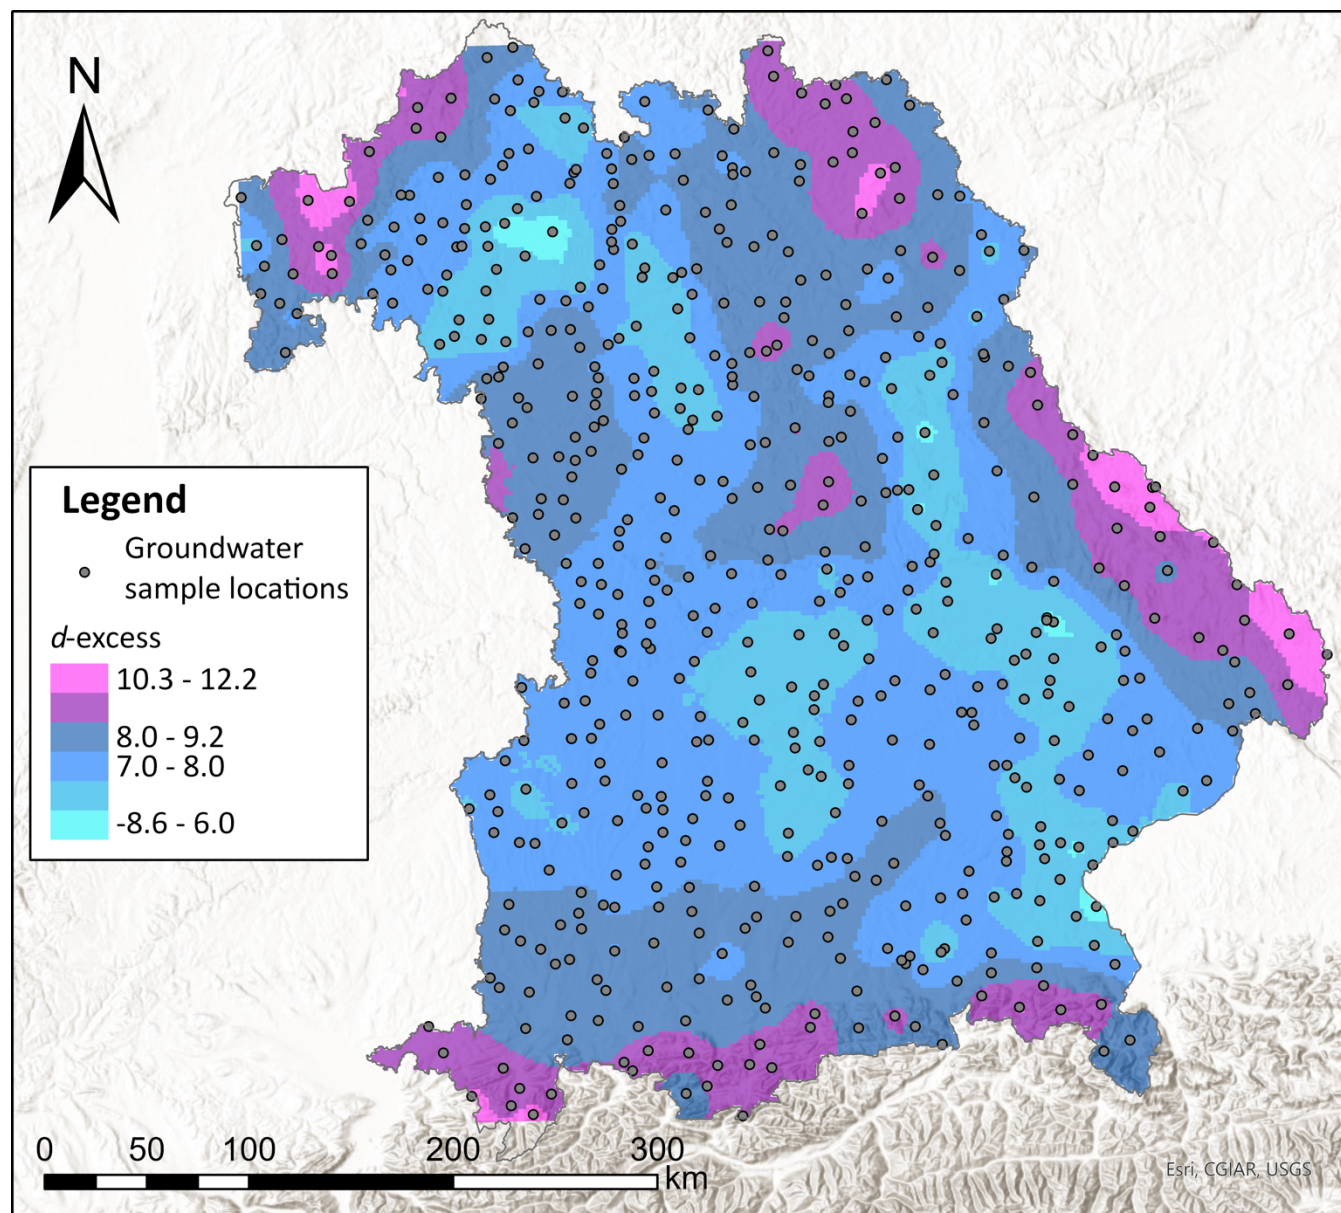

Figure 3: Regional meteoric waterlines (RMWL) in groundwater (squares) and precipitation (triangles) (a) in the southern alpine and (b) northern Main regions.

195

Figure 4: Interpolated *d*-values in Bavarian groundwaters with sample locations.

#### 4 Discussion

##### 4.1 Isoscape comparison

With an average of 0.0084 wells/km<sup>2</sup>, the presented groundwater dataset shows an exceptionally high density of points. For comparison, the isoscape produced by Regan et al. (2017) for Ireland is based upon 0.0025 wells/km<sup>2</sup> (factor 4 less) and the

data density of large scale groundwater isoscapes for Mexico or Ethiopia lies one order of magnitude below (Wassenaar et al., 2009; Bedaso and Wu, 2021). Another advantage of our groundwater dataset is the even distribution of the sampling points across the study area that covers all major aquifer types in Bavaria, climatic regions, and altitudes up to 953 m a.s.l. It has to be noted that all groundwater sampling points lie strictly within the boundaries of Bavaria and the interpolation shows higher prediction errors at the edges of the study site due to a lack of information outside of Bavaria. This disadvantage of strict boundary cutoff is not present with the precipitation isoscape because it is retrieved from a Europe-wide interpolation.

205

The groundwater was sampled only once, within a short time frame (July 2015). The different groundwater values are therefore comparable. The isotope ratios in groundwater are expected to be representative for the annual average of isotopes in precipitation because neighbouring wells showed similar values across all regions. Additionally, the attenuation of seasonality is expected to take place in the unsaturated zone due to long enough travel times and even further dampened when infiltrating water is mixed with a much larger reservoir of existing groundwater with a wide range of ages. Nevertheless, we cannot confirm that all sampled stations are representative for the annual averages of isotopes in precipitation. Therefore, we recommend investigating the seasonality of the isotope signal in shallow groundwater aquifers with quarterly sampling campaigns.

210

215

Nevertheless, the observed trends remain robust because of the high number of consistent results across all regions and the generally low prediction error of the interpolation ( $< 0.3 \text{ ‰ } \delta^{18}\text{O}$ ). Thus, we can compare the produced groundwater isoscape to the precipitation map proposed by (Terzer et al., 2021). However, if there was a long-time trend in the isotope ratios in the precipitation, repeated groundwater measurements would be needed to assess such a trend.

#### 4.2 Alpine region

The pattern observed in the southern region of Bavaria displays consistently more depleted  $\delta^{18}\text{O}$  values in groundwater than in precipitation. This difference can be caused by predominant groundwater recharge during the colder season. Higher groundwater recharge rates in winter are expected for temperate climates, regions where snow melt is the dominating recharge process and because of little impact of evapotranspiration on the soil water balance in winter (Jasechko et al., 2014; Clark, 1997; Jasechko et al., 2017). Several studies in Europe have discussed a bias in groundwater isotopes towards winter recharge on local and regional levels (Raidla et al., 2016; Regan et al., 2017; Darling et al., 2003). Additionally, altitude effects are easily recognisable in alpine regions. When groundwater recharge areas lie at higher altitudes than the valley aquifers, groundwater is recharged with  $\delta^{18}\text{O}$ -depleted water. On a global average, altitude effects have been reported to affect the  $\delta^{18}\text{O}$  value by  $-0.2 \text{ ‰}$  per 100 meters elevation increase worldwide (Clark, 1997; Hemmerle et al., 2021) but even higher rates of  $-0.47 \text{ ‰}$  per 100 m have been reported in Germany (Stumpp et al., 2014). Moreover, a large part of the precipitation at higher altitudes falls as snow which further reduces its  $\delta^{18}\text{O}$  values (Clark, 1997).

225

230

In the alpine regions it is therefore plausible that a combination of cold season groundwater recharge, snow melt dominated recharge, altitude and temperature effects explain the differences of up to  $2.1 \text{ ‰}$  between the  $\delta^{18}\text{O}$  values in precipitation and groundwater. These differences range between findings from the Italian alpine region (no differences between the medians in

groundwater and precipitation, Cervi et al. (2017) and British Columbia, Canada (groundwater enriched by about 4.5 ‰ in  $^{18}\text{O}$  than precipitation in average, Wassenaar et al. (2011).

### 235 4.3 Main River region

In the northwest part of Bavaria, the Main River region, the groundwater displayed more positive  $\delta^{18}\text{O}$  values when compared to precipitation. One possible explanation for this situation is evaporation that occurs after precipitation reached the ground. One factor that supports this hypothesis is the presence of widespread cropland in need for irrigation (43 % of the area in the Main Region opposed to 35 % in the alpine region according to the land use in European Space Agency (2020)). This implies  
240 potentially large amounts of groundwater that is spread on the surface and becomes subject to evaporation.

Another is the presence of the surface water body of the Main River which in turn partly feeds the groundwater. However, a 2013 study of the Main River shows that the  $\delta^{18}\text{O}$  values vary between -10.0 ‰ in winter and -9.0 ‰ in summer and cannot explain the groundwater  $\delta^{18}\text{O}$  values as far as 40 km from the river course (Türk, 2013).

The much drier climate in the Main region compared to the rest of Bavaria also reinforces evaporation mechanisms. The origin  
245 and quantity of the water used for irrigation could not be quantified, but none of those aspects alone are likely to enrich the groundwater  $\delta^{18}\text{O}$  by up to 2 ‰. Even more so that evaporation is barely seen in the RMWL and  $d$  values. The regional groundwater line indeed displays a smaller slope than the precipitation line and indicates that evaporation might take place after precipitation reaches the ground. This slope difference is larger in the Main region than in the Bavarian Alps, and further supports the hypothesis of a more pronounced evaporation effect in the Main region. However, the statistical differences do  
250 not allow to conclude on a significant evaporation effect.

The  $d$  values isoscape shows higher  $d$  values with higher elevations. Nonetheless, no spatial correlations to the southern alpine or northern Main region could be observed. The distribution of  $d$  values does not allow to conclude on different evaporative conditions between the Main region and the rest of the study area. This suggests that evaporation alone is not likely to be the main explanation for the 2 ‰ more positive  $\delta^{18}\text{O}$  signal in the groundwater compared to precipitation in the Main Region. A  
255 bias of the groundwater isotope signal towards the warm season precipitation due to summer groundwater recharge is not expected in our study area since the main groundwater recharge season in temperate central Europe is winter. Nevertheless, the contribution of winter precipitation to groundwater is less important in the Main region than in the rest of the study area both in terms of proportion and isotope signature. The yearly distribution of precipitation and the absence of a significant snow cover and less distinctive summer and winter isotope signals together with shorter winters may lead to a reduced winter bias  
260 in the groundwater. Finally, a connection of the upper aquifer to deeper groundwater is unlikely in the Main region, as no deep aquifer is found under Northwest Bavaria (Büttner, 2003).

One further explanation for the isotopically heavier groundwater in the Main region can be attributed to the sampling time during the month of July 2015. Overall, stable isotopes in groundwater are assumed to show only little seasonal variations. Nonetheless, a lysimeter study by Stumpp et al. (2012) performed with Bavarian soils and climate reported that water isotopes  
265 show seasonality throughout the unsaturated zone; at least until a depth of 2 m below ground surface. On larger scales, Regan

et al. (2017) also observed seasonal variation in groundwater at local scales in regions with rapid groundwater recharge. In the Main region, it is possible that the isotope signal in precipitation produces seasonal patterns in the groundwater because our sampling focused on shallow aquifers and the region is characterized by karst and fracture aquifers that provide favourable conditions for rapid transit times and low dispersivities. This might be an important and a so far hardly acknowledged reason  
270 for the up to 2 ‰ more positive groundwater  $\delta^{18}\text{O}$  values when compared to precipitation. To investigate this aspect of groundwater isotopes, longer timeseries and at least quarterly sampling campaigns of both groundwater, surface water and precipitation would be necessary. So far, our data indicate scarce but potentially critical seasonality of large-scale groundwater recharge processes.

## 5. Conclusion and Outlook

275 In this study, we produced a high-resolution regional groundwater isoscape of  $\delta^{18}\text{O}$  values in southern Germany. The observed spatial pattern shows  $\delta^{18}\text{O}$ -depleted values in the southern alpine region and  $\delta^{18}\text{O}$ -enriched values in the Main region in the northwest of Bavaria. Further, comparisons between groundwater and precipitation isoscapes showed local and regional differences between these connected hydrologic compartments.

Differences in the southern Alpine region can be explained by the winter groundwater recharge, altitude effects and important  
280 snow cover. On the other hand, the more positive groundwaters in the northern Main River are more difficult to explain and hypotheses for this situation include evaporation after precipitation reached the ground, reduced winter groundwater recharge, possible connection to a deep-water aquifer and, importantly, a bias due to the sampling season of the groundwater samples. Especially this last hypothesis would benefit from quarterly groundwater sampling campaigns in order to investigate seasonality of stable isotopes in the first aquifer on a regional scale. In addition, better documentation of irrigation practices  
285 and surface waters via stable isotopes would provide insights into the regional water balance.

This study shows that consideration of stable isotope values of both precipitation and groundwater are promising to outline and understand regional recharge mechanisms. Our results highlight the need for a better understanding of the seasonality of large-scale groundwater recharge patterns, based on quarterly or monthly sampling campaigns of all compartments of the hydrologic cycle. Such investigations are gaining more importance with changing weather and groundwater recharge patterns and may  
290 help to outline influences of recharge pathways and how they may have to be controlled for instance via managed aquifer recharge strategies.

## Code and Data availability

Original isotope data is available up on request.

## Competing Interests

295 The authors declare that they have no conflict of interest.

## Author contribution

Aixala Gaillard prepared the manuscript with contributions from all co-authors. Robert van Geldern and Johannes A. C. Barth supervised the groundwater sampling and laboratory analyses. Christine Stumpp performed and provided the precipitation data. Aixala Gaillard applied the model and statistics.

## 300 Acknowledgment

This research was funded within the funding measure "Sustainable Groundwater Management" (LURCH) by the German Bundesministerium für Bildung und Forschung (BMBF, Project 'IsoGW', FKZ 02WGW1671A). We thank the We thank the Bayerisches Landesamt für Umwelt and 17 Bavarian water management authorities for their participation as well as Tobias Juhlke for the logistic and organization of the sampling.
