To be submitted to NHESS

13 **Abstract.** Explosive eruptions release significant quantities of tephra, which can spread and settle on the ground, potentially
14 leading to various types of damage and disruption to public infrastructure, including road networks. The quantification of
15 the tephra load is, therefore, of significant interest to evaluate and reduce environmental and socio-economic impact, and for
16 managing crises. Tephra dispersal and deposition is a function of multiple factors, including the mass eruption rate (MER),
17 tephra characteristics (size, shape, density), top plume height (H_{TP}), grain size distribution (GSD) and local wind field. In
18 this work we quantified the tephra mass deposited on the main road network on the east-southeast flanks of Mt. Etna (Italy),
19 during lava fountains occurred in 2021, which are lava jets ejected into the air due to the rapid formation and expansion of
20 gas bubbles within the molten rock, also reaching heights of hundreds of metres. We focused on road connections of
21 municipalities significantly affected by these events such as Milo, Santa Venerina and Zafferana Etnea. First, we analysed a
22 sequence of 39 short-lasting and intense Etna's lava fountains detected by the X-band weather radar, applying a volcanic
23 ash radar retrieval approach that permits us to compute the main eruption source parameters (ESPs), such MER, H_{TP} and
24 GSD. When radar measurements were unavailable for a specific event, we analysed images acquired both by the SEVIRI
25 radiometer and by the visible and/or thermal infrared camera of the Istituto Nazionale di Geofisica e Vulcanologia,
26 Osservatorio Etneo (Catania) to derive the main ESPs. Second, we used the computed ESPs as inputs to run two different

numerical models, Tephra2 and Fall3D, and reproduce tephra dispersal and accumulation on the road network. Finally, we produce, for the first time, georeferenced estimates of tephra mass deposited on the whole road network of three municipalities, allowing us to identify the main roads which have been mostly impacted by tephra accumulation, as well as to estimate the total mass of primary tephra that has been removed from roads. Such information represents a valuable input for planning and quick management of the short-term tephra load hazard for future Etna explosive events.

1 Introduction

The estimation of tephra mass deposited on the ground, following a volcanic explosive eruption, remains a key information that is not well-covered in the ~~current~~ literature. In fact, tephra dispersal and fallout is by far the most widespread volcanic hazard affecting both local and distal areas (Jenkins et al. 2015; Barsotti et al., 2018; Bonadonna et al. 2021b) including impact on public health (Baxter, 1990; Horwell and Baxter, 2006), roofs/building collapse (Spence et al., 2005), dangerous road conditions (Blong, 1996; Wilson et al., 2012; Jenkins et al., 2014; Blake et al., 2017), contamination of water reservoirs and vegetation (Wilson et al., 2012; Ágústsdóttir, 2015), damages to electrical infrastructure (Bebbington et al., 2008; Wardman et al., 2012; Wilson et al., 2012; Dominguez et al., 2021), transportation system disruptions (Casadevall, 1994; Guffanti et al., 2009; Wilson et al., 2012), and impact on telecommunication networks (Wilson et al., 2012). Even tephra associated with relatively small intensity eruptions may induce various disrupting effects on transport infrastructure such as aeroplane engine failure and visibility reduction during both primary tephra fall and ash remobilisation (Sarna-Wojcicki et al., 1981; Bonadonna et al., 2021b; Johnston and Daly, 1995; Wilson et al., 2014). In particular, tephra accumulation, although not causing significant physical damage on the road network, can cause wide disruption including reduction of skid resistance, obscuration of road markings and damage to car air filters (Blake et al., 2016, 2017). Tephra particles are also very abrasive with the degree of abrasiveness dependent on the hardness of the material forming the particles and their shape and angularity (Blong, 1984; Johnston, 1997; Labadie, 1994; Heiken et al., 1995; Miller and Casavedall, 1999; Gordon et al., 2005; Wilson et al., 2012; Blake et al., 2017). Road networks are critical for society under normal operating conditions and especially during emergencies (e.g. Bonadonna et al. 2021a; Hayes et al. 2022).

During volcanic eruptions, routes may be required for the evacuation of residents and to allow emergency services and civil protection personnel to access the affected areas. The road network is also crucial for both immediate and long-term recovery, including clean-up and disposal of pyroclastic material, and restoration of services and commerce (Blake et al., 2017).

In this work, for the first time, we quantify the tephra mass accumulated on the road network of east and south-east sectors of Etna, which were **more** affected during the sequence of explosive events of 2021. Usually, the eruptive sequences at Etna are characterised by short-lasting explosive events, with duration of few hours, separated by periods that can last from few hours to few days (Calvari et al., 2018; Andronico et al., 2021; Calvari et al., 2022a). Most studies on exposed critical

58 infrastructure have focussed on larger events and tephra-fallout accumulations greater than 10 kg/m² (Wilson et al., 2012,
59 Blake et al., 2017; Scollo et al., 2013). However, areas around Etna are more frequently impacted by small tephra
60 accumulation (Scollo et al., 2013). Limited quantitative data available for explosive activity have hampered a reliable
61 quantification of the impact of the tephra deposition at Etna. To investigate its impact on road networks and better
62 characterise its behaviour, we analysed a sequence of several lava fountains occurred between February 2021 and October
63 2021, focusing our analysis on 39 events that generated volcanic plumes dispersed by wind mostly towards the east-
64 southeast flanks of the volcano (direction between 90 degrees and 130 degrees from North). These episodes began at the
65 South East Crater (SEC) as initial Strombolian activity that, with time, evolved to lava fountain activity, also named
66 paroxysm.

67 Remote sensing is routinely used for monitoring the eruptive activity of Etna; the Istituto Nazionale di Geofisica e
68 Vulcanologia, Osservatorio Etneo (INGV-OE) runs a network of different remote sensing sensors both ground-based (such
69 as thermal infrared and visible cameras) and satellite-based sensors (Scollo et al., 2019). An X-band weather radar located
70 in Fontanarossa airport (Catania), which is part of the monitoring network of the Italian Department of Civil Protection
71 (DPC) allows to monitor and analyse the Etna's eruptions as well (Marzano et al. 2020; Mereu et al. 2020). Using these
72 sensors, we can observe in almost all the cases the temporal evolution of explosive activity and characterise it quantitatively
73 in terms of mass eruption rate (MER) and top plume height (H_{TP}). These two parameters are among the main input variables
74 for advection-dispersion models (Scollo et al., 2008a; Biass et al., 2017; Tadini et al., 2022; Takishita et al., 2021), such as
75 Tephra2 and Fall3D (Bonadonna et al., 2005; Costa et al., 2006; Folch et al., 2009, 2020), which have been used in this
76 work to simulate the tephra dispersion and calculate the deposit load at the ground. For each of the 39 events, we estimate
77 the tephra deposited on the road network in order to identify the roads mostly exposed to tephra accumulation and to
78 evaluate the ground mass load that is expected to be removed. Moreover, analysing the simulations done using both models,
79 we investigate their sensitivity to variations of tephra granulometric characteristics and assess the associated uncertainties.
80 The numerical output from a single simulation is a georeferenced map of tephra load, useful to analyse the impact of
81 deposited tephra fallout on roads (Scollo et al., 2009; Scollo et al., 2013; Costa et al., 2012; Bonadonna et al., 2005; Barsotti
82 et al., 2018; Bonadonna et al. 2021a).

83 Analysing tephra accumulation on roads is essential for planning effective responses during volcanic eruptions. By
84 measuring the amount of tephra deposited during both single and multiple eruptions, we can identify which are the roads
85 that are most affected. Moreover, the deposited tephra creates disruptions especially on main roads, considering the large
86 stretches of roadway that may face hazardous driving conditions. This information helps estimate how much material needs
87 to be disposed of and the costs involved in clean up operations. Studying the lava fountain events of Etna in 2021 provides
88 valuable insights for future planning during similar events. By examining the past eruptions, we can predict tephra deposits,
89 providing useful information to decision makers to develop better cleaning up strategies. Indeed, for future eruptions, it is
90 important to consider creating a model that uses real-time data to improve predictions and clean up plans. Overall, this

91 research can help crisis management and enhance safety in volcanic regions. Additionally, recent regional legislation (DA n.
92 8/Gab. 22/04/2024, <https://www.regione.sicilia.it>) permits the use of the volcanic tephra for building applications; in this
93 new framework, this study represents an initial effort to estimate the volume of tephra that may be reused rather than
94 disposed of, transforming a potential problem into a resource.

95 The work is organised as follow: Section 2 provides a brief description of Etna's lava fountain activity; Section 3 presents
96 ground- and satellite-based sensor data, along with the main eruption source parameters (ESPs) retrieved from them, and the
97 methodology employed to analyse the model results; Section 4 validates the results against previously published data for a
98 specific event (February 28th, 2021); Section 5 discusses the modelling outputs and provides conclusive remarks.

99 **2 The lava fountains at Etna in 2021**

100 Etna, one of the most active volcanoes in the world, is a stratovolcano on the east coast of Sicily, Italy. It rises to more than
101 3,300 m in altitude and has four main summit craters: North-East Crater (NEC), Voragine (VOR), Bocca Nuova (BN) and
102 South-East Crater (SEC). Between February 2021 and October 2021, approximately sixty paroxysmal episodes occurred
103 from the SEC. Of these, 39 episodes lasted several hours and were dispersed towards the E-SE (Calvari et al., 2021). Lava
104 fountains, which are formed by a hot inner core consisting of a mix of liquid clots, pyroclasts, and magmatic gases, are often
105 observed during paroxysmal episodes at Etna and can rise several hundred metres above the volcanic vent (Wilson et al.,
106 1995; Taddeucci et al., 2015). Moreover, during those events it is likely that an eruption column of almost 10-15 km above
107 sea level can form above the lava fountains. Usually, lava fountains are divided in three phases (e.g., Alparone et al., 2003;
108 Mereu et al., 2020; Calvari et al., 2022b): 1) Resumption phase, which commonly begins with slow initial effusion from the
109 vent, followed by a progressive increase in explosive activity; 2) Paroxysmal phase, lasting from 10 to 120 minutes, during
110 which there is a rapid transition from Strombolian activity to sustained lava fountains that rise up an altitude of 2-6 km
111 above the vent; 3) Conclusive phase, during which the eruptive episode gradually ceases.

112 **3 Methods**

113 **3.1.1 Sensors and outputs**

114 For the analyses in this work we select all the Etna eruptions characterised by a tephra plume dispersed towards east-
115 southeast flanks of the volcano. These events, listed in Table 1, have been observed using different sensors that are briefly
116 described below:

117 a) X-band Weather Radar (XWR), located in the airport of Catania, 32 km at SSE Etna summit craters (Figure 1). The
118 scanning agility in elevation and azimuth of this sensor allows it to probe the tephra cloud in any weather condition and both
119 during the day and night (Mereu et al., 2022, 2023; Montopoli, 2016; Vulpiani et al., 2016). Applying the Volcanic Ash

120 Radar Retrieval (VARR) methodology (e.g. Marzano et al., 2012, 2020; Mereu et al., 2015, 2020) to measure radar
 121 reflectivity factor, we estimate: i) the top plume height H_{TP} (km) above sea level, which is the maximum height reached by
 122 the eruption column, calculated as the maximum altitude of the radar-detected volume above the volcanic vent contaminated
 123 by the minimum detectable tephra concentration; ii) the mass eruption rate Q_M (kg/s), that is estimated by the time-space
 124 variation of tephra concentration detected above the Etna summit **probing** the volcanic plume; iii) the total erupted mass
 125 TEM (kg), which is the total mass of pyroclastic material erupted during the explosive event; **the** ash-fall rate R_a (kg/m²·h)
 126 **useful** to derive the tephra load integrating this quantity over a time interval and assuming that the radar measurements
 127 closer to the ground are indicative of tephra deposited on the ground from the vertical column above a considered position
 128 (Mereu et al., 2015).

129 b) Etna Catania Visible calibrated camera (ECV), located in Catania about 30 km from Etna summit craters (Scollo et al.,
 130 2019; Aravena et al., 2023, Figure 1); it allows us to monitor the altitude of dispersed plume during the light hours when the
 131 visibility is not compromised by the meteorological cloud cover. In this way, we can derive the time sequence of H_{TP} .

132 c) Spinning Enhanced Visible and InfraRed Imager (SEVIRI), on board of Meteosat Second Generation (MSG) satellites, is
 133 a multispectral radiometer which produces daytime brightness temperature (BT) images with 3 km resolution. Selecting the
 134 BT along the Etna summit in the channel of 10.8 μ m, that is more sensitive to the tephra dielectric signature, we infer H_{TP}
 135 looking for the altitude in which the detected BT can be found in the temperature profile ~~as a function of altitude~~, which is
 136 derived from the hydro-meteorological service of Agenzia Regionale Prevenzione e Ambiente (ARPA) in Emilia Romagna
 137 (Scollo et al., 2009; Romeo et al., 2023).

138 d) Etna Nicolosi Thermal (ENT) infrared camera, located in Nicolosi at about 15 km from Etna summit (Figure 1), which
 139 measures the thermal activity associated with lava fountains. It is worth highlighting that when the radar measurements were
 140 not available and the volcanic plume was not easily detectable by the satellite sensor or by the visible calibrated camera,
 141 analysing the ENT images we have identified the Incandescent Jet Region (IJR), which is a proxy of the lava fountain
 142 height. As described in Mereu et al., (2020), the time sequence of maximum height of IJR area can be converted in exit
 143 velocity v_{ex} (m/s) of pyroclastic material, using the Bernoulli equation under the following approximations: i) most of the
 144 pyroclastic material is sufficiently large to be considered as accelerated projectiles confined in this IJR; ii) atmospheric
 145 density variations and drag effects are negligible. Assuming a trustworthy value of tephra-gas mixture density and of surface
 146 vent, we can deduce Q_M ~~applying~~ the surface flow approach (SFA) described in Marzano et al., (2020) and Mereu et al.,
 147 (2022). It is worth noting that H_{TP} obtained from various sensors, such as XWR, ECV, and SEVIRI, exhibits a comparable
 148 time trend, as shown in Freret-Lorgeril et al. (2021) and Scollo et al. (2019). The complete ESPs dataset for each of the Etna
 149 events considered in this study is displayed in Table 1. Real-time estimation of ESPs can be challenging, especially during
 150 the initial phase, increasing the uncertainty in short-term forecasts of plume dispersal (Scollo et al., 2008a). Furthermore, we
 151 also collected qualitative information about the eruptions, such as plume height (based on VONA reports; Scollo et al.,

2019; Corradini et al., 2018), the presence of tephra fallout and the start and end times of Strombolian and lava fountain activities (based on bulletins and reports available on the INGV-OE website (www.ct.ingv.it)).

Figure 1: (a) Map of South Italy (Sicily and Calabria), with the red square showing the Etna area framed in the right panel; (b) georeferenced map of road network (dark lines) of the Etna volcano area (shape-files with the road data is publicly available from the Regione Sicilia website: <https://www.regione.sicilia.it>). The UTM coordinates (area 33S) are shown in the lower-left part and in the upper-right part of the picture, respectively. The areas of four municipalities, of which three are under examination, and the built environment are highlighted with different colours, whereas each sensor, field data and road points are identified by coloured symbols as listed in the legend in the right side: ground-based sensors employed in this work (the visible camera VSC, the thermal infrared camera ENT and the X-band radar XWR); the South East Carter SEC; 14 field data as derived by Pardini et al. (2021); 8 road points. The rectangle highlighted with the dotted red line identifies the area examined and focused in Figures 3 and 7.

On the other hand, each sensor previously described allows us to measure some features of the lava fountains, which need further elaborations to obtain the ESPs. In this work, H_{TP} (km) and Q_M (kg/s) quantities are directly derived by processing XWR measurements. When it was not possible to determine H_{TP} from XWR, ECV frames or SEVIRI data, we used the ENT images to retrieve the Q_M estimates applying the SFA (Marzano et al. 2020; Mereu et al., 2022). Integrating the SFA in time, we obtain TEM (kg), whereas applying the empirical relation of Mastin et al. (2009), which links Q_M to H_{TP} , we get

the H_{TP} above the Etna summit crater (which is located about 3357 m above sea level). We used the inverse Mastin equation in those cases where the H_{TP} was derived from VSC or SEVIRI imagery to obtain the Q_M time sequence. The starting and ending time for each Etna explosive eruption can be straightly inferred ~~selecting the ends of time range~~ from: i) XWR-based Q_M estimates, where $Q_M > 5 \cdot 10^5$ kg/s; ii) temporal range where ENT camera identifies the lava fountaining feeding the explosive phase; iii) time range in which a quick development of the volcanic cloud is observed by the ECV frames or SEVIRI images. Regarding the wind data, while for Tephra2 simulations we consider a horizontally-constant wind field computed as the mean wind velocity between the Etna summit craters and the maximum value of the H_{TP} sequence, for Fall3D simulations we use the whole meteorological profile. This data, which is used to feed the ash dispersion models, are derived from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5 reanalysis (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>). The grain-size distribution usually refers to the volcanic particle size, indicated by the relation $\phi = -\log_2(D)$, where D stands for sphere-equivalent mean diameter (measured in mm). The ϕ refers to the whole deposit, assumed as a Gaussian distribution characterised by a maximum, minimum, mean and standard deviation. In order to consider all possible cases, in this work we vary the median ϕ value between -1 to +1 with a step of 0.5. The georeferenced location and the elevation of the SEC are considered to complete the set of input parameters used, as listed in Table 1. It is worth noting that for each event listed in Table 1, we consider the UTM coordinates of the vent in easting (500024.03 m) and northing (4177699.5 m), or, equivalently, in longitude (15.000273°E) and latitude (37.746592°N), we assume a ϕ with maximum, minimum and standard deviation values equal to -6, 10 and 3, respectively; we repeat each simulation, varying the median ϕ values, so that we obtain a total of 195 simulations from each numerical model.

Table 1. Input parameters used for setting the numerical dispersion model Tephra2 and Fall3D: starting time and ending time of paroxysm (dd:mm:yy, hh:mm), duration Δt (s), top plume height H_{TP} (m) above sea level (a.s.l) and above volcano vent (a.v.v.), total erupted mass TEM (kg).

194 3.2 Models

195 3.2.1 Modelling tephra fallout

196 In this study, we simulate the transport, dispersal and deposition of tephra with two different numerical Eulerian models: a
197 semi-analytical model Tephra2 and a full computational model Fall3D. We run both models on a grid covering the area
198 (14.5° long, 37° lat) and (16° long, 38.5° lat) with a spatial resolution of ~500 m. Tephra2 allows to evaluate the ground
199 tephra deposition employing the advection-diffusion theory (Bonadonna et al., 2005, 2006; Connor and Connor, 2006;
200 Volentik et al., 2009; Biass et al., 2016, 2017) taking as inputs: H_{TP} ; TEM; ϕ ; the density of lithics and juveniles (volcanic
201 particles released from the column, which varies widely from ~500 kg/m³ in highly vesicular clasts to ~2700 kg/m³ in dense
202 ones); the diffusion coefficient (K), which accounts for atmospheric processes including atmospheric diffusion and cloud
203 gravitational spreading; the fall time threshold (FTT), an empirical threshold that defines the transition between two
204 different laws of atmospheric diffusion and the plume ratio (PR), factor describing the mass distribution in the plume, a
205 horizontally uniform wind field. In the Tephra2 model, it is assumed that a vertical eruption column forms above the vent.
206 The column is discretized, and particles fall from every part of its height. The total tephra mass is vertically distributed
207 within the eruption column according to a probability density function that represents mass as a function of height. The
208 model provides three different mass distributions: uniform, log-normal, and beta distribution. The total grain size
209 distribution for the eruption is estimated assuming a normal distribution in ϕ units (Bonadonna et al., 2005).
210 Fall3D (v8.0, Folch et al., 2020) models both the particle concentration in the atmosphere (i.e. tephra cloud evolution) and
211 the particle loading at ground level, based on a 3-D time-dependent Eulerian scheme (Costa et al., 2006; Folch et al., 2009;
212 ~~Folch et al., 2012~~). The model solves the advection-diffusion-sedimentation (ADS) equation over a topographical 3D
213 domain, with several modelling options, including particle aggregation and source terms, among others. The meteorological
214 data used in the simulations are obtained by interpolating the outputs of a meteorological model into the simulation domain.
215 The simulations conducted for this work were performed with no aggregation, using the one-dimensional buoyant plume
216 theory (Folch et al., 2016) as a model for the source term. The meteorological data were retrieved from the ECMWF ERA5-
217 Reanalysis database (Hersbach et al., 2018). This methodology has the potential to track the evolution of particle
218 concentration during an eruption, but the main limitation is the computational cost (Costa et al., 2006). Fall3D uses the same
219 ESP's inputs listed in Table 1, but instead of TEM, it considers Q_M . Figure 2 shows the simulated tephra load (kg/m²) maps
220 for two among the largest-TEM eruptions (10⁸ kg and 10⁹ kg), assuming $\phi=0.5$. Generally, we note a greater spreading of
221 tephra deposition to the ground simulated by Tephra2 with respect to Fall3D. Both numerical models generate output files
222 in netCDF format (e.g. <https://www.unidata.ucar.edu/software/netcdf/>) containing geo-referenced data on tephra load
223 (kg/m²) on the ground in UTM coordinates (zone 33-S for Etna) with a grid spacing of 500 m. The limitations of both
224 models, as a function of variation of input parameters listed in Table 1, as well as and considerations of topography, column

225 mass distribution models, bulk particle shape, and particle terminal fall velocity, are described in detail in Scollo et al.
226 (2008b).

Figure 2: Maps of tephra load (kg/m^2) for the Etna lava fountain event of 17 February 2021 (a-b)) and of 23 October 2021 (c-d)), using the Tephra2 (a-c)) and Fall3D (b-d)) models. Tephra deposition is plotted as uniform iso-mass contour lines in grayscale, ranging from black for values lower than 10 kg/m^2 to light white for values greater than $5 \cdot 10^3 \text{ kg/m}^2$. The colour scale is the same in all panels. Global Self-Consistent Hierarchical High-Resolution Geography (GSHHG) map of Matlab.

3.2.2 Calculating the tephra load and mass on the road network

Since our main interest in this work is to calculate the tephra load in the road network, we increase the grid spacing of the tephra load data to 5 m using linear interpolation. Afterwards, we use the Quantum Geographical Information System (QGIS) tool to determine the intersection between the downscaled tephra load data and the areas covered by the road network. While the tracks of road network in the study area is publicly available (geospatial vector data in shapefile format, as shown in Figure 1, from the Regione Sicilia; website <https://www.regione.sicilia.it/>), an accurate estimate of area of roads is not still available. In order to estimate the area of the roads, we selected several roads in the study area and measured their width using both QGIS integrating an OpenStreetMap layer (<https://wiki.openstreetmap.org/wiki/QGIS>), and satellite images from GoogleEarth (<https://earth.google.com/web/>), obtaining an average width of approximately 6 m. Assuming that the roads are generally composed of two carriageways, this value is in agreement with the prescribed widths for urban and extra-urban roads according to the Italian law on roads (art. 2 del Testo Unico, which ranges from 2.8 m and 4 m per carriageway). To consider an uncertainty in this gross measurement, we set the road width to $6 \pm 0.5 \text{ m}$. The case study is focused on the road networks located within the municipal area of Milo, Santa Venerina and Zafferana Etnea towns. For a given road segment we calculate the corresponding road area (m^2) and then using the tephra load (kg/m^2) we calculate the total mass (kg) deposited on each road segment. Figure 3 (which covers the area in the rectangle shown with a dotted red line in Figure 1) shows the simulated tephra load (kg/m^2) on the geo-referenced road network within the Milo (light orange area), Santa Venerina (light pink area) and Zafferana Etnea (light green area) municipalities for the event on 28 February 2021.

Figure 3: Tephra load (kg/m²) on the road network of Milo, Santa Venerina and Zafferana Etnea municipalities computed for the Etna explosive event on 28 February 2021, assuming $\phi = 0.5$ and using both Tephra2 (a) and Fall3D (b) models. The tephra deposits in the road graph are shown in red scale for selected threshold levels of the tephra load values (as shown in

the legend). Georeferenced map of road network (dark lines) of the Etna volcano area (shape-files with the road data is publicly available from the Regione Sicilia website: <https://www.regione.sicilia.it/>).

4. Results

4.1 Validation: case study on February 28, 2021

In order to verify the results obtained in this study, we focus our attention on the case study of the event on 28 February 2021, which has been observed by the XWR and analysed by Pardini et al. (2021). Table 2 shows the coordinates (longitude, latitude) of 14 points in which field measurements of tephra load are available (from literature, e.g., Pardini et al., 2021) in the selected municipalities (see Figure 1) as well as the results of tephra load derived from the Tephra2 and Fall3D models, fixing the ϕ to 0.5. The XWR retrievals are obtained considering the tephra load rate ($\text{kg/m}^2 \text{ s}$) related to the first four elevations, which is equal to a few km of altitude with respect to the ground, and integrating it for the whole time sampling of the radar. In this way we can retrieve the tephra load (kg/m^2) related to the whole lava fountain. The correlation between the ground field data (Pardini et al., 2023) and the estimated values using Tephra2, Fall3D, and XWR are plotted, respectively, in Figure 4a, 4b, and 4c. We observe that taking as reference the observed values reported by Pardini et al., 2023, Tephra2 tends to overestimate while Fall3D tends to underestimate the tephra load values. This is evident from the majority of the points dispersed above and below the bisector, as well as from the differences in the slope of the regressive curves with respect to the bisector shown in Figures 4a and 4b. These discrepancies could be due to different dispersal settings used in the numerical model. In contrast, a good correlation between field data and XWR data is observed (Figure 4c), where the points mostly distribute around the bisector and the regressive straight line is almost parallel to it. To evaluate the degree of agreement between filed data and tephra load estimates, we implemented a non-parametric test (namely the Kendall's tau correlation). Table 3 summarises Kendall's tau coefficients, the p-values for testing the null hypothesis of no correlation against the alternative hypothesis of a non-zero correlation; moreover, we estimate the mean absolute percentage error (MAPE) between predicted/estimated data and the observed field data. A Kendall's tau value closer to 1 indicates a better correlation between the field data and the model/estimate data, whereas a low p-value ($<1\%$) indicates a significant correlation. This test confirms that the estimates of both XWR and Tephra2 exhibit a better correlated variation with the field measurements, as indicated by the respective higher tau and lower p-values. The MAPE calculation further supports this conclusion.

Table 2. Etna eruption on February 28, 2021: tephra load (kg/m^2) on 14 sites, each one identified by the latitude and longitude, as deduced by Pardini et al. (2021), and in the same points as derived by Tephra2 and Fall3D models (fixing $\phi = 0.5$) and retrieved by XWR.

Figure 4: Tephra load correlation: the coloured points represent the field data (Pardini et al., 2023) as a function of the results from Tephra2, Fall 3D and XWR results (blue, red and green dots), as listed in Table 2 and respectively shown in panel a), b), and c). The dashed dark represents the bisector, while the magenta line represents the regressive straight line.

Table 3. Kendall’s tau correlation coefficient, p-value, and Mean Absolute Percentage Error (MAPE) computed for the Etna eruption on February 28, 2021

Kendall method	τ	p-value	MAPE
T2-Field data	0.73	$2.8 \cdot 10^{-3}$	48
F3-Field data	0.54	$4.56 \cdot 10^{-2}$	$3.7 \cdot 10^4$
XWR-Field data	0.84	$1.3 \cdot 10^{-4}$	34

Assuming the width of (6 ± 0.5) m for each road, we convert the tephra load to tephra mass (kg) for the event of 28 February 2021, assuming $\phi = 0.5$. We selected a few roads, characterised by their larger extension, for each municipality: Via Bellini and Corso Italia in Milo; via Mazzini, via Galimberti and via Stabilimenti in Santa Venerina; via Libertà, via Zafferana Milo and via delle Rose in Zafferana Etnea. We summarise in Table 4 the total tephra mass for streets of Milo, Santa Venerina and Zafferana Etnea as derived from Tephra2 and Fall3D models. The total mass computed for the selected roads in Milo by Tephra2 and Fall3D shows a comparable order of magnitude (10^7 kg), whereas for two selected roads in Zafferana Etnea reveals a disagreement of one order of magnitude. However, the values computed for all municipalities show a maximum variability between approximately five times the tephra deposit collected on the ground (Scollo et al., 2007). The Tephra2 outcomes are generally larger than those of Fall3D, with the ratio between Fall3D and Tephra2 ranging

344 from 0.3 to 1.4 for the roads and from 0.3 to 1.1 for towns. The variability in road width corresponds to a variability in
 345 tephra mass of approximately $\pm 9\%$. The last three rows in Table 4 show the total mass computed on the whole road
 346 network of the three municipalities, highlighting the comparable results (same order of magnitude of about 10^9 kg). It is
 347 worth noting that the total mass derived from Tephra2 in Zafferana Etnea municipality is four times larger than the total
 348 mass derived from Fall3D. This variability can be observed in Figure 3. Not all roads are affected by tephra load, as shown
 349 in Figure 3b, and this can be attributed to dissimilarity in the dispersal laws implemented in each model (Scollo et al., 2008;
 350 Bonadonna et al., 2005; Folch et al., 2012, 2016). It is important to note that during a typical explosive event at Etna, only a
 351 few kilograms of tephra accumulate on a limited number of streets across the three municipalities. This aspect is closely
 352 related to the intensity of the explosive event, the amount of pyroclastic material erupted, and the wind dispersal pattern.
 353

354 **Table 4. Total tephra mass (kg) computed on main roads selected of Milo, Santa Venerina and Zafferana Etnea for the Etna**
 355 **eruption on 28 February 2021 as derived from the results obtained using Tephra2 and Fall3D models (fixing $\phi=0.5$ and assuming**
 356 **a road width of 6 ± 0.5 m). The total mass on the road network of Milo, Santa Venerina and Zafferana, for three road widths (5.5**
 357 **m, 6 m, and 6.5 m), is presented in the last three rows. On the right column the mass ratio between Fall3D and Tephra2 results.**

Santa Venerina	129.6, 141.4, 153.2	144.1, 157.2, 170.3	1.1
Zafferana Etnea	659.1, 719.0, 779.0	165.2, 180.2, 195.2	0.3

359

360 4.2. Tephra mass on specific road-points

361 We investigate how the tephra load, derived from both models, can be used to assess the accumulated tephra mass on the
362 road network for the selected municipalities, assuming a cell size of (5×5) metres in the interpolated tephra load map. It is
363 important to highlight that deposited tephra causes disruptions on main roads, specifically in terms of the kilometres of
364 roadways that may face critical driving conditions. The location of the Etna volcano, along with the prevailing westerly and
365 northwesterly winds at high altitude, favours the tephra fallout and dispersal primarily toward east (31%), southeast (35%)
366 and north-west (29%) ~~Etna flanks~~, and only (6%) directed towards south. These patterns are derived from the analysis of
367 ERA5 reanalysis wind data during 39 eruptive events that occurred in 2021. These results are consistent with the historical
368 statistical distribution of wind direction and ~~relative~~-velocity from the 1990-2007 period at altitudes between 5 and 10 km,
369 as derived from meteorological forecast data (Barsotti et al., 2010; Scollo et al., 2013). The deposited tephra mass, derived
370 from two models, is computed by selecting eight road-points (shown in Figure 1) across different roads in the municipalities
371 of Milo, Santa Venerina (Sven), Zafferana Etnea (Zaff) and Giarre municipalities: provincial roads (SP41, SP92, SP8 and
372 SP59); the highway (E45); and the state road (SS114). To increase the number of road-points on the southeast flank of Etna,
373 we also include road-points from the E45 and SP114 in the municipality of Giarre. In Figure 5 we show the time cumulative
374 tephra mass for different median ϕ values at specific points in the selected roads, as computed by Tephra2 (Figure 5a) and
375 Fall3D (Figure 5b). Generally, increasing the median ϕ increases the deposited tephra mass and vice versa. Obviously, this
376 estimate depends on the collection point, because for a given ϕ , if the mass deposited in the proximal area increases, it
377 decreases in the distal one, since the total mass deposited is conserved. The highest simulated tephra mass values from both
378 models are found at SP59 in Milo, with Tephra2 recording **between** 2750 and 3375 kg and Fall3D showing **between** 3000
379 and 4250 kg at the end of the paroxysm sequence. This location is approximately 12 km from the summit of Etna, making it
380 the closest among the analysed points. In contrast, SP92 in Zafferana Etnea shows lower ash loads, with Tephra2 reporting
381 **about** 725 to 800 kg and Fall3D indicating **between** 250 and 450 kg at the end of the paroxysm sequence. While Zafferana
382 Etnea is also near Etna (12.2 km away), it is situated further south than Milo. We can evaluate these results taking into
383 account the tolerance boundaries, usually considered as more/less five times the estimated values (Scollo et al., 2007).
384 Indeed, the variability of tephra mass for all the road-points computed with Tephra2 ranges between limit values of 750-
385 3375 kg, whereas the variability derived from Fall3D is between 250-4250 kg. The time-cumulative function derived from
386 Tephra2 presents larger steps in concomitance with events of 14 March, 22 and 28 May, **1** July 2021 for SP59 in Milo, E45,
387 SP49 and SS114 in Santa Venerina and SP8 in Zafferana Etnea **whereas** E45 and SS114 in Milo show a larger step during
388 the event on 24 May 2021. During the other events, the tephra mass is not large enough to generate major steps in the time-
389 cumulative function. For most road-points, the total accumulated tephra mass stabilises at values between 500 kg and 1250
390 kg after the paroxysm of 20 July 2021, with the exception of SP59 in Milo. The time-cumulative function obtained with
391 Fall3D shows larger steps during the events of 28 May, 2 and 27 June, 31 July 2021 for SP59 in Milo. E45 and SS114 in
392 Milo show a larger step on 27 June 2021, whereas SP41, E45 and SS114 in Santa Venerina exhibit a large step on 29

393 August 2021, and SP92 in 17 June 2021. In Zafferana Etnea, SP8 shows a time increase of tephra mass, whereas in
 394 Zafferana Etnea the tephra mass stabilises at values between 250 kg and 500 kg by the end of June. The time-cumulative
 395 tephra mass on SP41, E45 and SS114 in Santa Venerina and SS114 on Milo stabilises between 1325 kg and 2075 kg starting
 396 from the beginning of August. Also in the case of Fall3D, SP59 in Milo is confirmed as the most impacted road-point due to
 397 accumulation of tephra in time where the time-cumulated tephra increases more than at the other target points, with larger
 398 steps, and then stabilises starting from August. These results suggest that, following the 2021 cluster of Etna lava fountains,
 399 the roads of Milo and Santa Venerina municipalities have been the most impacted from tephra deposition in time.
 400

401

Figure 5: The time series of cumulative tephra mass simulated by the Tephra2 (a) and Fall3D (b) models for all analysed explosive events at Etna in 2021, which shows plumes dispersing to the east and southeast. Each road-point is represented by a unique colour and symbol. We display the cumulative tephra mass corresponding to each road-point and varying the median value of ϕ . The larger the mean grain size, the higher the accumulated load for that road-point, as indicated on the right side of each figure.

4.3 Total mass accumulated on selected roads

In this section we quantify the total tephra mass deposited on selected main roads previously listed in Table 3 for each municipality. Three panels in Figure 6a, 6b and 6c are related, respectively, to the time-cumulative mass on Milo (a), Santa Venerina (b) and Zafferana Etnea (c) computed on selected roads of known area. Analysing the panels in Figure 6 we observe some rapid increases in the cumulative trend of tephra mass mainly for the Fall3D simulations (grey dashed line) with respect to Tephra2 (dark continuous line) simulations. These rapidly increasing trends are found in Milo on 12 March, 28 May (18:10-21:10 UTC), 27 June 2021, in Santa Venerina on 30 May, 17 June 2021 and in Zafferana Etnea. Generally, all the selected roads show a large step in the estimated cumulative tephra mass on 19 February, regardless of the model used. The largest step of total mass is found around June and July, as confirmed by the plots shown in Figure 6a.

416

417

Figure 6: Cumulative tephra mass on selected roads for Milo (a), Santa Venerina (b) and Zafferana Etnea (c), respectively, for all Etna explosive events here analysed and simulated using the Tephra2 (dark continuous line) and Fall3D (grey dashed line) models. Each road is plotted with different symbols and identified by the relative area (m^2 , assuming a road width of 6 m), as listed in the legend.

In Table 5 we summarise the total tephra mass deposited during the 39 Etna events in 2021 for the selected roads in each municipality. The last three rows show the total tephra mass computed for the complete road network of each town. The Fall3D estimates are generally larger than those from Tephra2, with the ratio ranging from 1.5 to 3.8 for the roads and from 2.0 to 5.0 for the towns, though the variability can be as much as a factor of five in either direction. We observe that during about one year of Etna's paroxysms, in the nearest municipalities under examination, the estimated value of total tephra mass accumulated in the main streets ranges between 10^6 - 10^9 kg. A difference of at most one order of magnitude in the total accumulated mass according to the two models is found. It is worth noting that these values are computed under the worst condition, i.e. without considering the tephra mobilisation due to external factors, such as rain or wind, during the complete time range, as well as assuming not road cleaning after each event. Therefore, this tephra mass represents a computed estimate of the total amount of tephra mass that theoretically had to be removed to the roads and disposed of during and after the 2021 crisis.

435 **Table 5. Total mass accumulated over 39 Etna events on the selected roads for Milo, Santa Venerina and Zafferana Etnea**
 436 **municipalities, as simulated by Tephra2 and Fall3D models (fixing $\phi=0.5$ and assuming a road width of (6 ± 0.5) m). The total**
 437 **mass on the whole road network of Milo, Santa Venerina and Zafferana, for three road widths (5.5 m, 6 m, 6.5 m), is in the last**
 438 **three rows. On the right column the mass ratio between Fall3D and Tephra2 results.**
 439

Location	Mass (10 ⁷ kg)		
	Tephra2 (5.5, 6, 6.5 m-width road)	Fall3D (5.5, 6, 6.5 m-width road)	Mass Ratio

449 **Figure 7: Cumulative tephra load (kg/m²) for all 39 Etna lava fountains analysed in this work, computed on the whole road**
 450 **network of Milo, Santa Venerina and Zafferana Etnea using (a) Tephra2 and (b) Fall3D models, assuming $\phi=0.5$. The road graph**
 451 **is bold highlighted and in red scale coloured in function of deposited tephra values. Georeferenced maps of road network (dark**
 452 **lines) of the Etna volcano area (shape-files with the road data is publicly available from the Regione Sicilia website:**
 453 **<https://www.regione.sicilia.it/>).**

454 Considering the area of each road, we compute the time-cumulative tephra mass (kg) relative to Milo, Santa Venerina and
 455 Zafferana, over the whole road network, as computed by both numerical models (Figure 8). Normally, the cumulative tephra
 456 mass derived from Tephra2 (dark continuous line) after an initial rapid growth tends to stabilise, in contrast with the trends
 457 obtained using Fall3D (grey dashed line), which present rapid increases in estimates throughout the sequence. These leaps
 458 in Milo are for the events on 28 May, 23 June (17:40-19:00 UTC) and 27 June 2021, in Santa Venerina on 28 February, 23
 459 and 27 June 2021, and in Zafferana Etnea on 28 February and 17 June 2021. The maximum value of tephra mass deposited
 460 on the whole road network in the three municipalities ranges between 10^{10} to 10^{12} kg.

461

462 **Figure 8: Cumulative tephra mass for all the 2021 Etna lava fountains analysed in this work, simulated using Tephra2 (dark**
 463 **continuous line) and Fall3D (grey dashed line) models, for the whole road network in Milo, Santa Venerina and Zafferana Etnea.**
 464

465 4.5. Analysis of variability in tephra mass results

466 The estimates of tephra mass, as a function of uncertainty variation related to ESPs used as input to train both numerical
467 models and the specific limitations of the two dispersal models, are already well-documented in the literature (Scollo et al.,
468 2008b). In the present work, we evaluated the potential mass load and total mass accumulated on the road networks of
469 several target towns. Due to the complexity of the Fall3D model, requiring significant computational resources compared to
470 Tephra2, the number of simulations considered for each analysed eruption was limited to the GSD variability. However, the
471 comparison between the results provided by the two models allows a first analysis of the variability in tephra mass
472 estimates. The evaluation of the results for the case study on 28 February 2021, observed by the XWR and analysed by
473 Pardini et al. (2021), allowed us to confirm Tephra2 as a useful numerical model for rapid assessment of tephra dispersal
474 and deposition on road points, and for quickly evaluating the relative tephra fallout hazard. These results are consistent with
475 the distribution of field data in relation to XWR measurements and model outcomes shown in Figure 4a, 4b, and 4c. The
476 Kendall's tau correlation coefficient and the MAPE presented in Table 4 further support our findings. We also highlight the
477 high performance of XWR in measuring these quantities, although these observations are not always available in real-time.
478 By shifting focus from individual road points to selected roads for the same Etna eruption event on 28 February 2021, we
479 observe that the Fall3D estimates are approximately comparable with those of Tephra2, as confirmed by a ratio ranging
480 from 0.3 to 2. When considering the entire sequence of 39 Etna eruptive events, Fall3D estimates are higher than Tephra2
481 for the main roads in the three municipalities and for the entire road network selected in this work. Furthermore, assuming a
482 variability of road width (± 0.5 m) in our computations, we estimate a variability in tephra mass of approximately $\pm 9\%$. All
483 of this information allows us to outline a more comprehensive framework for estimating the mass of tephra accumulated on
484 roads, which is essential for managing the impact of volcanic eruptions.

485 5. Discussion and conclusions

486 Considering the question about the quantification of the total tephra mass deposited in a given infrastructure of interest
487 following an (or a series of) explosive volcanic eruption(s), in this work we assessed, for the first time, the cumulated tephra
488 mass on the road networks in three selected towns on Etna's eastern flank during several paroxysms that occurred in 2021.
489 This accumulated mass is a theoretical estimate of the amount of material that had to be removed from the roads and
490 disposed of during the 2021 volcanic activity. We have focussed on three target municipalities located on the east flank, i.e.
491 Milo, Santa Venerina and Zafferana Etnea. According to the law at the time of the eruption, such material had to be handled
492 and disposed of as special waste (Art. 35 decreto legge 77/2021). At the time of writing this paper a new law allows the use
493 of this material for other purposes (DA n.8/Gab. 22/04/2024, <https://www.regione.sicilia.it>) as, for example, building
494 construction. Processing measurements derived from visible and thermal cameras of INGV-OE, and, when available, from
495 SEVIRI images and the XWR data, we can retrieve the main ESPs, useful inputs to run numerical models. In this way we

can simulate and evaluate the cumulated tephra load on roads in time. Processing these results with the QGIS tool, we are able to identify the roads more exposed to tephra deposition. We consider that the results of this analysis can be a valuable source of information to support the management of volcanic crises and for planning the reinstatement of road networks after a crisis.

It is known that effective and realistic transport management strategies are essential into volcanic contingency planning in sectors where key infrastructure are at risk, such as the road networks. Evaluating tephra mass using ~~two (or more)~~ different models allows assessing epistemic uncertainty, to estimate the ~~different~~ sensitivity of each model to same input ESPs and the variability of the median ϕ . It is worth highlighting that in this work, we have neglected the uncertainties in the ESP values (such as Q_M , TEM and H_{TP}), but this analysis is already available in literature (see e.g., Scollo et al., 2008b). However, these values are affected by various sources of uncertainty, including pre- and post-processing of data, as well as instrument sensitivity and accuracy, all of which can significantly impact the model outputs (see e.g., Mereu et al, 2023). This can lead to larger uncertainties in the simulated tephra load in addition to those related to the different model settings and the physical assumptions implemented in each numerical model.

In this work we are not considering the effect of rain which can remain trapped in the tephra deposit. Furthermore, depending on the rain's intensity, the road traffic safety can worsen (e.g., by making the transport network particularly slippery) or can be improved (e.g., by washing the road surface from the ash deposit). Specific thresholds of tephra load that can damage the main roads system, and the necessary actions to mitigate the tephra effects are defined and known in the literature (e.g. Jenkins et al. 2015; Bonadonna et al. 2021b; Table 8 in Bonadonna et al., 2021a).

As a final consideration, we point out the importance of the validation of the results of tephra load simulation obtained with two different numerical models by comparing their output with ground sampling data (in our case available from Pardini et al., 2023) as well as with the XWR retrievals for the Etna explosive activity on February 28, 2021. The tephra deposit estimations, as listed in Tables 2 and 3, highlight the good agreement among the ground sampling, XWR retrievals and the output of numerical models. This observation makes us confident to use the two different models in evaluating not only qualitatively but also quantitatively the tephra deposited during recent Etna paroxysms. In this way it is possible to provide plausible values of ground cumulated tephra mass on roads, and identify which routes in the road network of the target towns may be most impacted in next eruptions.

We consider that the analyses and the results proposed in this paper provide interesting inputs for supporting decision making and crisis management. Indeed, such analyses may support planning for clean-up following volcanic eruptions, which is essential for effective volcanic risk management (Hayes et al., 2019). Post-eruption clean-up of tephra deposits on roads is a widespread and costly activity, both in terms of time and resources, and frequently it is an unplanned activity (Hayes et al., 2019). Combining different cleaning methods, such as sweeping, suction, spraying and air blasting, could help speed up tephra fallout removal from high-priority roads used in the management of these events, especially before markings are fully covered (with thickness ranging from 1 to 10 mm), in order to ensure safety during cleaning operations.

529 Understanding the economic impact on affected areas (Hayes et al., 2015; Magill et al., 2006) also contributes to better risk
530 management. Geospatial analysis methods are well-documented in the literature for estimating the duration of roads
531 cleaning-up (Hayes et al., 2017), although these operations are influenced by complex interactions between physical factors
532 (e.g. erupted volume, column height, grain-size, wind speed and direction, and rainfall) and social factors (e.g. social
533 priorities, prior planning, previous experience, and infrastructure interdependencies) (Hayes et al., 2015). Moreover, the
534 presented results may support decision makers in different ways e.g. for planning and consequently for better management
535 of a future volcanic crisis due to explosive activity of Etna volcano, as well as for getting valuable information about the
536 order of magnitude of the total mass of tephra available for preparing the subsequent disposal and/or reuse.
