To be submitted to NHESS

13    **Abstract.** Explosive eruptions release significant quantities of tephra, which can spread and settle on the ground, potentially  
14    leading to various types of damage and disruption to public infrastructure, including road networks. The quantification of the  
15    tephra load is, therefore, of significant interest to evaluate and reduce environmental and socio-economic impact, and for  
16    managing crises. Tephra dispersal and deposition is a function of multiple factors, including the mass eruption rate (MER),  
17    tephra characteristics (size, shape, density), top plume height ( $H_{TP}$ ), grain size distribution (GSD) and local wind field. In this  
18    work we quantified the tephra mass deposited on the main road network on the east-southeast flanks of Mt. Etna (Italy), during  
19    lava fountains occurred in 2021, which are lava jets ejected into the air due to the rapid formation and expansion of gas bubbles  
20    within the molten rock, also reaching heights of hundreds of metres. We focused on road connections of municipalities  
21    significantly affected by these events such as Milo, Santa Venerina and Zafferana Etnea. First, we analysed a sequence of 39  
22    short-lasting and intense Etna's lava fountains detected by the X-band weather radar, applying a volcanic ash radar retrieval  
23    approach that permits us to compute the main eruption source parameters (ESPs), such MER,  $H_{TP}$  and GSD. When radar  
24    measurements were unavailable for a specific event, we analysed images acquired both by the SEVIRI radiometer and by the  
25    visible and/or thermal infrared camera of the Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etneo (Catania) to  
26    derive the main ESPs. Second, we used the computed ESPs as inputs to run two different numerical models, Tephra2 and

27 Fall3D, and reproduce tephra dispersal and accumulation on the road network. Finally, we produce, for the first time,  
 28 georeferenced estimates of tephra mass deposited on the whole road network of three municipalities, allowing us to identify the  
 29 main roads which have been mostly impacted by tephra accumulation, as well as to estimate the total mass of primary tephra  
 30 that has been removed from roads. Such information represents a valuable input for planning and quick management of the  
 31 short-term tephra load hazard for future Etna explosive events.

## 32 **1 Introduction**

33 The estimation of tephra mass deposited on the ground, following a volcanic explosive eruption, remains a key information  
 34 that is not well-covered in the current literature. In fact, tephra dispersal and fallout is by far the most widespread volcanic  
 35 hazard affecting both local and distal areas (Jenkins et al. 2015; Barsotti et al., 2018; Bonadonna et al. 2021b) including impact  
 36 on public health (Baxter, 1990; Horwell and Baxter, 2006), roofs/building collapse (Spence et al., 2005), dangerous road  
 37 conditions (Blong, 1996; Wilson et al., 2012; Jenkins et al., 2014; Blake et al., 2017), contamination of water reservoirs and  
 38 vegetation (Wilson et al., 2012; Ágústsdóttir, 2015), damages to electrical infrastructure (Bebbington et al., 2008; Wardman et  
 39 al., 2012; Wilson et al., 2012, Dominguez et al., 2021), transportation system disruptions (Casadevall, 1994; Guffanti et al.,  
 40 2009; Wilson et al., 2012), and impact on telecommunication networks (Wilson et al., 2012). Even tephra associated with  
 41 relatively small intensity eruptions may induce various disrupting effects on transport infrastructure such as aeroplane engine  
 42 failure and visibility reduction during both primary tephra fall and ash remobilisation (Sarna-Wojcicki et al., 1981; Bonadonna  
 43 et al., 2021b; Johnston and Daly, 1995; Wilson et al., 2014). In particular, tephra accumulation, although not causing  
 44 significant physical damage on the road network, can cause wide disruption including reduction of skid resistance, obscuration  
 45 of road markings and damage to car air filters (Blake et al., 2016, 2017). Tephra particles are also very abrasive with the degree  
 46 of abrasiveness dependent on the hardness of the material forming the particles and their shape and angularity (Blong, 1984;  
 47 Johnston, 1997; Labadie, 1994; Heiken et al., 1995; Miller and Casavedall, 1999; Gordon et al., 2005; Wilson et al., 2012;  
 48 Blake et al., 2017). Road networks are critical for society under normal operating conditions and especially during  
 49 emergencies (e.g. Bonadonna et al. 2021a; Hayes et al. 2022).

50 During volcanic eruptions, routes may be required for the evacuation of residents and to allow emergency services and civil  
 51 protection personnel to access the affected areas. The road network is also crucial for both immediate and long-term recovery,  
 52 including clean-up and disposal of pyroclastic material, and restoration of services and commerce (Blake et al., 2017).

53 In this work, for the first time, we quantify the tephra mass accumulated on the road network of east and south-east sectors of  
 54 Etna, which were more affected during the sequence of explosive events of 2021. Usually, the eruptive sequences at Etna are  
 55 characterised by short-lasting explosive events, with duration of few hours, separated by periods that can last from few hours  
 56 to few days (Calvari et al., 2018; Andronico et al., 2021; Calvari et al., 2022a). Most studies on exposed critical infrastructure  
 57 have focussed on larger events and tephra-fallout accumulations greater than  $10 \text{ kg/m}^2$  (Wilson et al., 2012, Blake et al., 2017;

58 Scollo et al., 2013). However, areas around Etna are more frequently impacted by smaller tephra accumulation (Scollo et al.,  
 59 2013). Limited quantitative data available for explosive activity have hampered a reliable quantification of the impact of the  
 60 tephra deposition at Etna. To investigate its impact on road networks and better characterise its behaviour, we analysed a  
 61 sequence of several lava fountains occurred between February 2021 and October 2021, focusing our analysis on 39 events that  
 62 generated volcanic plumes dispersed by wind mostly towards the east-southeast flanks of the volcano (direction between 90  
 63 degrees and 130 degrees from North). These episodes began at the South East Crater (SEC) as initial Strombolian activity that,  
 64 with time, evolved to lava fountain activity, also named paroxysm.

65 Remote sensing is routinely used for monitoring the eruptive activity of Etna; the Istituto Nazionale di Geofisica e  
 66 Vulcanologia, Osservatorio Etneo (INGV-OE) runs a network of different remote sensing sensors both ground-based (such as  
 67 thermal infrared and visible cameras) and satellite-based sensors (Scollo et al., 2019). An X-band weather radar located in  
 68 Fontanarossa airport (Catania), which is part of the monitoring network of the Italian Department of Civil Protection (DPC)  
 69 allows to monitor and analyse the Etna's eruptions as well (Marzano et al. 2020; Mereu et al. 2020). Using these sensors, we  
 70 can observe in almost all the cases the temporal evolution of explosive activity and characterise it quantitatively in terms of ma  
 71 ss eruption rate (MER) and top plume height ( $H_{TP}$ ). These two parameters are among the main input variables for advection-  
 72 dispersion models (Scollo et al., 2008a; Biass et al., 2017; Tadini et al., 2022; Takishita et al., 2021), such as Tephra2 and  
 73 Fall3D (Bonadonna et al., 2005; Costa et al., 2006; Folch et al., 2009, 2020), which have been used in this work to simulate the  
 74 tephra dispersion and calculate the deposit load at the ground. For each of the 39 events, we estimate the tephra deposited on  
 75 the road network in order to identify the roads mostly exposed to tephra accumulation and to evaluate the ground mass load that  
 76 is expected to be removed. Moreover, analysing the simulations done using both models, we investigate their sensitivity to  
 77 variations of tephra granulometric characteristics and assess the associated uncertainties. The numerical output from a single  
 78 simulation is a georeferenced map of tephra load, useful to analyse the impact of deposited tephra fallout on roads (Scollo et  
 79 al., 2009; Scollo et al., 2013; Costa et al., 2012; Bonadonna et al., 2005; Barsotti et al., 2018; Bonadonna et al. 2021a).

80 Analysing tephra accumulation on roads is essential for planning effective responses during volcanic eruptions. By measuring  
 81 the amount of tephra deposited during both single and multiple eruptions, we can identify which are the roads that are most  
 82 affected. Moreover, the deposited tephra creates disruptions especially on main roads, considering the large stretches of  
 83 roadway that may face hazardous driving conditions. This information helps estimate how much material needs to be disposed  
 84 of and the costs involved in clean up operations. Studying the lava fountain events of Etna in 2021 provides valuable insights  
 85 for future planning during similar events. By examining the past eruptions, we can predict tephra deposits, providing useful in  
 86 formation to decision makers to develop better cleaning up strategies. Indeed, for future eruptions, it is important to consider  
 87 creating a model that uses real-time data to improve predictions and clean up plans. Overall, this research can help crisis  
 88 management and enhance safety in volcanic regions. Additionally, recent regional legislation (DA n. 8/Gab.  
 89 22/04/2024, <https://www.regione.sicilia.it>) permits the use of the volcanic tephra for building applications; in this new

framework, this study represents an initial effort to estimate the volume of tephra that may be reused rather than disposed of, transforming a potential problem into a resource.

The work is organised as follow: Section 2 provides a brief description of Etna's lava fountain activity; Section 3 presents ground- and satellite-based sensor data, along with the main eruption source parameters (ESPs) retrieved from them, and the methodology employed to analyse the model results; Section 4 validates the results against previously published data for a specific event (February 28th, 2021); Section 5 discusses the modelling outputs and provides conclusive remarks.

## 2 The lava fountains at Etna in 2021

Etna, one of the most active volcanoes in the world, is a stratovolcano on the east coast of Sicily, Italy. It rises to more than 3,300 m in altitude and has four main summit craters: North-East Crater (NEC), Voragine (VOR), Bocca Nuova (BN) and South-East Crater (SEC). Between February 2021 and October 2021, approximately sixty paroxysmal episodes occurred from the SEC. Of these, 39 episodes lasted several hours and were dispersed towards the E-SE (Calvari et al., 2021).

Lava fountains, which are formed by a hot inner core consisting of a mix of liquid clots, pyroclasts, and magmatic gases, are often observed during paroxysmal episodes at Etna and can rise several hundred metres above the volcanic vent (Wilson et al., 1995; Taddeucci et al., 2015). Moreover, during those events it is likely that an eruption column of almost 10-15 km above sea level can form above the lava fountains.

Usually, lava fountains are divided in three phases (e.g., Alparone et al., 2003; Mereu et al., 2020; Calvari et al., 2022b): 1) Resumption phase, which commonly begins with slow initial effusion from the vent, followed by a progressive increase in explosive activity; 2) Paroxysmal phase, lasting from 10 to 120 minutes, during which there is a rapid transition from Strombolian activity to sustained lava fountains that rise up an altitude of 2-6 km above the vent; 3) Conclusive phase, during which the eruptive episode gradually ceases .

## 3 Methods

### 3.1.1 Sensors and outputs

For the analyses in this work we select all the Etna eruptions characterised by a tephra plume dispersed towards east-southeast flanks of the volcano. These events, listed in Table 1, have been observed using different sensors that are briefly described below:

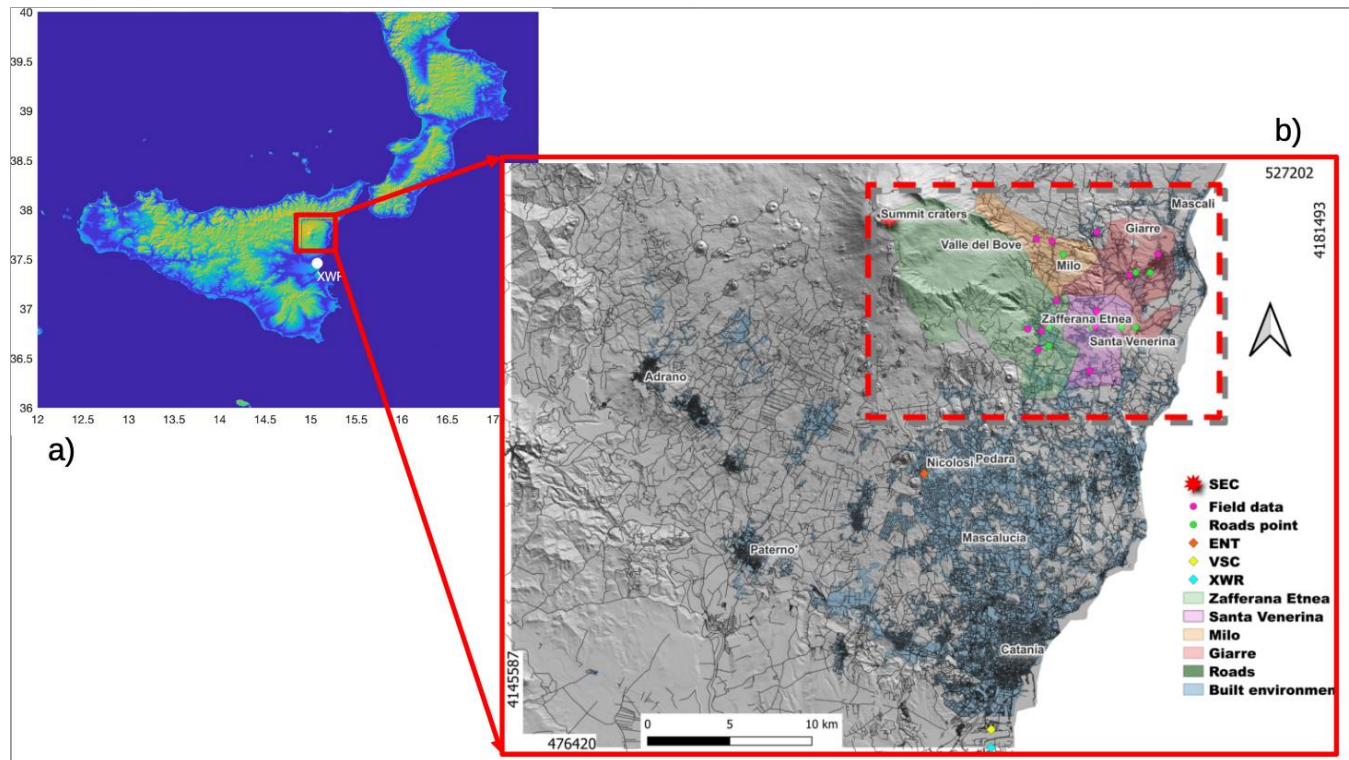

a) X-band Weather Radar (XWR), located in the airport of Catania, 32 km at SSE Etna summit craters (Figure 1). The scanning agility in elevation and azimuth of this sensor allows it to probe the tephra cloud in any weather condition and both during the day and night (Mereu et al., 2022, 2023; Montopoli, 2016; Vulpiani et al., 2016). Applying the Volcanic Ash Radar Retrieval (VARR) methodology (e.g. Marzano et al., 2012, 2020; Mereu et al., 2015, 2020) to measure radar reflectivity factor, we

estimate: i) the top plume height  $H_{TP}$  (km) above sea level, which is the maximum height reached by the eruption column, calculated as the maximum altitude of the radar-detected volume above the volcanic vent contaminated by the minimum detectable tephra concentration; ii) the mass eruption rate  $Q_M$  (kg/s), that is estimated by the time-space variation of tephra concentration detected above the Etna summit probing the volcanic plume; iii) the total erupted mass TEM (kg), which is the total mass of pyroclastic material erupted during the explosive event; the ash-fall rate  $R_a$  (kg/m<sup>2</sup>·h) useful to derive the tephra load integrating this quantity over a time interval and assuming that the radar measurements closer to the ground are indicative of tephra deposited on the ground from the vertical column above a considered position (Mereu et al., 2015).

b) Etna Catania Visible calibrated camera (ECV), located in Catania about 30 km from Etna summit craters (Scollo et al., 2019; Aravena et al., 2023, Figure 1); it allows us to monitor the altitude of dispersed plume during the light hours when the visibility is not compromised by the meteorological cloud cover. In this way, we can derive the time sequence of  $H_{TP}$ .

c) Spinning Enhanced Visible and InfraRed Imager (SEVIRI), on board of Meteosat Second Generation (MSG) satellites, is a multispectral radiometer which produces daytime brightness temperature (BT) images with 3 km resolution. Selecting the BT along the Etna summit in the channel of 10.8  $\mu$ m, that is more sensitive to the tephra dielectric signature, we infer  $H_{TP}$  looking for the altitude in which the detected BT can be found in the temperature profile as a function of altitude, which is derived from the hydro-meteorological service of Agenzia Regionale Prevenzione e Ambiente (ARPA) in Emilia Romagna (Scollo et al., 2009; Romeo et al., 2023).

d) Etna Nicolosi Thermal (ENT) infrared camera, located in Nicolosi at about 15 km from Etna summit (Figure 1), which measures the thermal activity associated with lava fountains. It is worth highlighting that when the radar measurements were not available and the volcanic plume was not easily detectable by the satellite sensor or by the visible calibrated camera, analysing the ENT images we have identified the Incandescent Jet Region (IJR), which is a proxy of the lava fountain height. As described in Mereu et al., (2020), the time sequence of maximum height of IJR area can be converted in exit velocity  $v_{ex}$  (m/s) of pyroclastic material, using the Bernoulli equation under the following approximations: i) most of the pyroclastic material is sufficiently large to be considered as accelerated projectiles confined in this IJR; ii) atmospheric density variations and drag effects are negligible. Assuming a trustworthy value of tephra-gas mixture density and of surface vent, we can deduce  $Q_M$  applying the surface flow approach (SFA) described in Marzano et al., (2020) and Mereu et al., (2022). It is worth noting that  $H_{TP}$  obtained from various sensors, such as XWR, ECV, and SEVIRI, exhibits a comparable time trend, as shown in Freret-Lorgeril et al. (2021) and Scollo et al. (2019). The complete ESPs dataset for each of the Etna events considered in this study is displayed in Table 1. Real-time estimation of ESPs can be challenging, especially during the initial phase, increasing the uncertainty in short-term forecasts of plume dispersal (Scollo et al., 2008a). Furthermore, we also collected qualitative information about the eruptions, such as plume height (based on VONA reports; Scollo et al., 2019; Corradini et al., 2018), the presence of tephra fallout and the start and end times of Strombolian and lava fountain activities (based on bulletins and reports available on the INGV-OE website ([www.ct.ingv.it](http://www.ct.ingv.it))).

**Figure 1: (a) Map of South Italy (Sicily and Calabria), with the red square showing the Etna area framed in the right panel; (b) georeferenced map of road network (dark lines) of the Etna volcano area (shapefiles with the road data is publicly available from the Regione Sicilia website: <https://www.regione.sicilia.it/>). The UTM coordinates (area 33S) are shown in the lower-left part and in the upper-right part of the picture, respectively. The areas of four municipalities, of which three are under examination, and the built environment are highlighted with different colours, whereas each sensor, field data and road points are identified by coloured symbols as listed in the legend in the right side: ground-based sensors employed in this work (the visible camera VSC, the thermal infrared camera ENT and the X-band radar XWR); the South East Carter SEC; 14 field data as derived by Pardini et al. (2021); 8 road points. The rectangle highlighted with the dotted red line identifies the area examined and focused in Figures 3 and 7.**

On the other hand, each sensor previously described allows us to measure some features of the lava fountains, which need further elaborations to obtain the ESPs. In this work,  $H_{TP}$  (km) and  $Q_M$  (kg/s) quantities are directly derived by processing XWR measurements. When it was not possible to determine  $H_{TP}$  from XWR, ECV frames or SEVIRI data, we used the ENT images to retrieve the  $Q_M$  estimates applying the SFA (Marzano et al. 2020; Mereu et al., 2022). Integrating the SFA in time, we obtain TEM (kg), whereas applying the empirical relation of Mastin et al. (2009), which links  $Q_M$  to  $H_{TP}$ , we get the  $H_{TP}$  above the Etna summit crater (which is located about 3357 m above sea level). We used the inverse Mastin equation in those cases where the  $H_{TP}$  was derived from VSC or SEVIRI imagery to obtain the  $Q_M$  time sequence. The starting and ending time

for each Etna explosive eruption can be straightly inferred selecting the ends of time range from: i) XWR-based  $Q_M$  estimates, where  $Q_M > 5 \cdot 10^5$  kg/s; ii) temporal range where ENT camera identifies the lava fountaining feeding the explosive phase; iii) time range in which a quick development of the volcanic cloud is observed by the ECV frames or SEVIRI images. Regarding the wind data, while for Tephra2 simulations we consider a horizontally-constant wind field computed as the mean wind velocity between the Etna summit craters and the maximum value of the  $H_{TP}$  sequence, for Fall3D simulations we use the whole meteorological profile. This data, which is used to feed the ash dispersion models, are derived from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5 reanalysis (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>). The grain-size distribution usually refers to the volcanic particle size, indicated by the relation  $\phi = -\log_2(D)$ , where  $D$  stands for sphere-equivalent mean diameter (measured in mm). The  $\phi$  refers to the whole deposit, assumed as a Gaussian distribution characterised by a maximum, minimum, mean and standard deviation. In order to consider all possible cases, in this work we vary the median  $\phi$  value between -1 to +1 with a step of 0.5. The georeferenced location and the elevation of the SEC are considered to complete the set of input parameters used, as listed in Table 1. It is worth noting that for each event listed in Table 1, we consider the UTM coordinates of the vent in easting (500024.03 m) and northing (4177699.5 m), or, equivalently, in longitude (15.000273°E) and latitude (37.746592°N), we assume a  $\phi$  with maximum, minimum and standard deviation values equal to -6, 10 and 3, respectively; we repeat each simulation, varying the median  $\phi$  values, so that we obtain a total of 195 simulations from each numerical model.

**Table 1. Input parameters used for setting the numerical dispersion model Tephra2 and Fall3D: starting time and ending time of paroxysm (dd:mm:yy, hh:mm), duration  $\Delta t$  (s), top plume height  $H_{TP}$  (m) above sea level (a.s.l.) and above volcano vent (a.v.v.), total erupted mass TEM (kg).**

## 190 3.2 Models

### 191 3.2.1 Modelling tephra fallout

192 In this study, we simulate the transport, dispersal and deposition of tephra with two different numerical Eulerian models: a  
 193 semi-analytical model Tephra2 and a full computational model Fall3D. We run both models on a grid covering the area ( $14.5^\circ$   
 194 long,  $37^\circ$  lat) and ( $16^\circ$  long,  $38.5^\circ$  lat) with a spatial resolution of  $\sim 500$  m. Tephra2 allows to evaluate the ground tephra  
 195 deposition employing the advection-diffusion theory (Bonadonna et al. 2005, 2006; Connor and Connor, 2006; Volentik et al.  
 196 2009; Biass et al. 2016, 2017) taking as inputs:  $H_{TP}$ ; TEM;  $\phi$ ; the density of lithics and juveniles (volcanic particles released  
 197 from the column, which varies widely from  $\sim 500$  kg/m<sup>3</sup> in highly vesicular clasts to  $\sim 2700$  kg/m<sup>3</sup> in dense ones); the diffusion  
 198 coefficient (K), which accounts for atmospheric processes including atmospheric diffusion and cloud gravitational spreading;  
 199 the fall time threshold (FTT), an empirical threshold that defines the transition between two different laws of atmospheric  
 200 diffusion and the plume ratio (PR), factor describing the mass distribution in the plume, a horizontally uniform wind field. In  
 201 the Tephra2 model, it is assumed that a vertical eruption column forms above the vent. The column is discretized, and particles  
 202 fall from every part of its height. The total tephra mass is vertically distributed within the eruption column according to a  
 203 probability density function that represents mass as a function of height. The model provides three different mass distributions:  
 204 uniform, log-normal, and beta distribution. The total grain size distribution for the eruption is estimated assuming a normal  
 205 distribution in  $\phi$  units (Bonadonna et al., 2005).

206 Fall3D (v8.0, Folch et al., 2020) models both the particle concentration in the atmosphere (i.e. tephra cloud evolution) and the  
 207 particle loading at ground level, based on a 3-D time-dependent Eulerian scheme (Costa et al., 2006; Folch et al., 2009; Folch  
 208 et al., 2012). The model solves the advection-diffusion-sedimentation (ADS) equation over a topographical 3D domain, with  
 209 several modelling options, including particle aggregation and source terms, among others. The meteorological data used in the  
 210 simulations are obtained by interpolating the outputs of a meteorological model into the simulation domain. The simulations  
 211 conducted for this work were performed with no aggregation, using the one-dimensional buoyant plume theory (Folch et al.,  
 212 2016) as a model for the source term. The meteorological data were retrieved from the ECMWF ERA5-Reanalysis database  
 213 (Hersbach et al, 2018). This methodology has the potential to track the evolution of particle concentration during an eruption,  
 214 but the main limitation is the computational cost (Costa et al., 2006). Fall3D uses the same ESP's inputs listed in Table 1, but  
 215 instead of TEM, it considers  $Q_M$ . Figure 2 shows the simulated tephra load (kg/m<sup>2</sup>) maps for two among the largest-TEM  
 216 eruptions ( $10^8$  kg and  $10^9$  kg), assuming  $\phi=0.5$ . Generally, we note a greater spreading of tephra deposition to the ground  
 217 simulated by Tephra2 with respect to Fall3D. Both numerical models generate output files in netCDF format (e.g.  
 218 <https://www.unidata.ucar.edu/software/netcdf/>) containing geo-referenced data on tephra load (kg/m<sup>2</sup>) on the ground in UTM  
 219 coordinates (zone 33-S for Etna) with a grid spacing of 500 m. The limitations of both models, as a function of variation of  
 220 input parameters listed in Table 1, as well as and considerations of topography, column mass distribution models, bulk particle  
 221 shape, and particle terminal fall velocity, are described in detail in Scollo et al.(2008b).

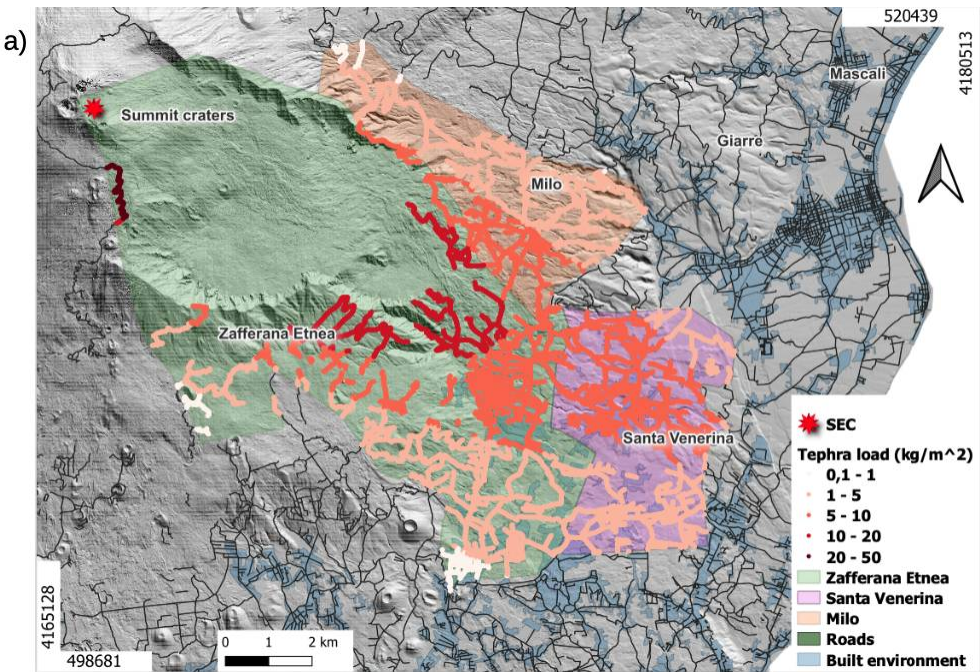

**Figure 2: Maps of tephra load (kg/m<sup>2</sup>) for the Etna lava fountain event of 17 February 2021 (a-b)) and of 23 October 2021 (c-d)), using the Tephra2 (a-c)) and Fall3D (b-d)) models. Tephra deposition is plotted as uniform iso-mass contour lines in grayscale, ranging from black for values lower than 10 kg/m<sup>2</sup> to light white for values greater than 5 · 10<sup>3</sup> kg/m<sup>2</sup>. The colour scale is the same in all panels.**

247 **3.2.2 Calculating the tephra load and mass on the road network**

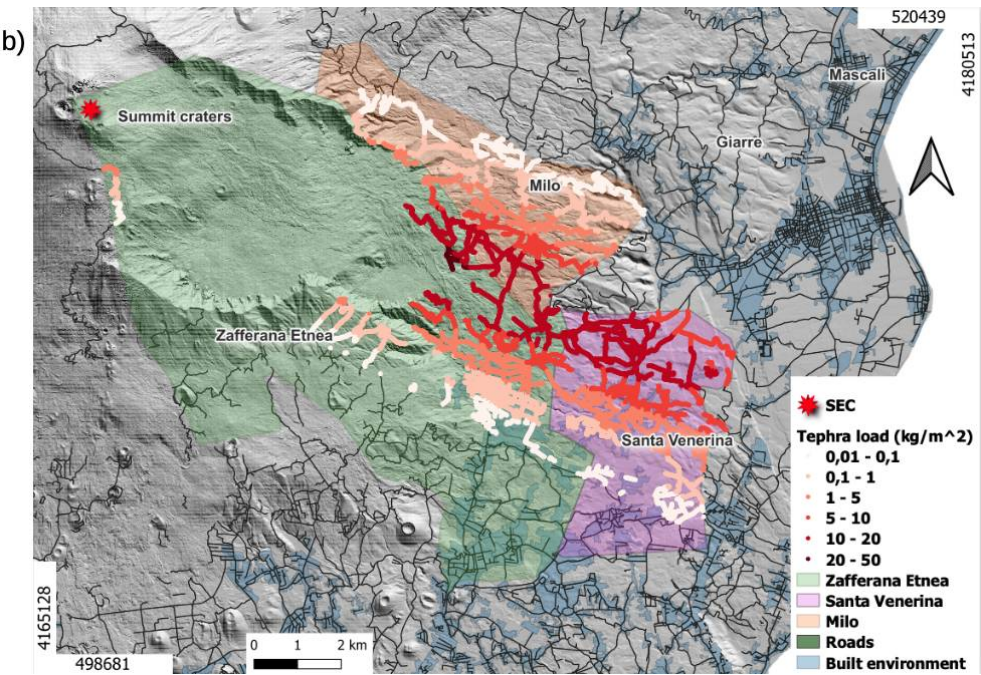

248 Since our main interest in this work is to calculate the tephra load in the road network, we increase the grid spacing of the  
249 tephra load data to 5 m using linear interpolation. Afterwards, we use the Quantum Geographical Information System (QGIS)  
250 tool to determine the intersection between the downscaled tephra load data and the areas covered by the road network. While  
251 the tracks of road network in the study area is publicly available (geospatial vector data in shapefile format, as shown in Figure  
252 1, from the Regione Sicilia; website <https://www.regione.sicilia.it/>), an accurate estimate of area of roads is not still available  
253 . In order to estimate the area of the roads, we selected several roads in the study area and measured their width using both QG  
254 IS integrating an OpenStreetMap layer (<https://wiki.openstreetmap.org/wiki/QGIS>), and satellite images from GoogleEarth  
255 (<https://earth.google.com/web/>), obtaining an average width of approximately 6 m. Assuming that the roads are generally  
256 composed of two carriageways, this value is in agreement with the prescribed widths for urban and extra-urban roads  
257 according to the Italian law on roads (art. 2 del Testo Unico, which ranges from 2.8 m and 4 m per carriageway). To consider an  
258 uncertainty in this gross measurement, we set the road width to  $6 \pm 0.5$  m. The case study is focused on the road networks  
259 located within the municipal area of Milo, Santa Venerina and Zafferana Etnea towns. For a given road segment we calculate  
260 the corresponding road area ( $m^2$ ) and then using the tephra load ( $kg/m^2$ ) we calculate the total mass (kg) deposited on each road  
261 segment. Figure 3 (which covers the area in the rectangle shown with a dotted red line in Figure 1) shows the simulated tephra  
262 load ( $kg/m^2$ ) on the geo-referenced road network within the Milo (light orange area), Santa Venerina (light pink area) and  
263 Zafferana Etnea (light green area) municipalities for the event on 28 February 2021.

264

265

**Figure 3: Tephra load ( $\text{kg/m}^2$ ) on the road network of Milo, Santa Venerina and Zafferana Etnea municipalities computed for the Etna explosive event on 28 February 2021, assuming  $\phi = 0.5$  and using both Tephra2 (a) and Fall3D (b) models. The tephra deposits in the road graph are shown in red scale for selected threshold levels of the tephra load values (as shown in the legend).**

#### 4. Results

##### 4.1 Validation: case study on February 28, 2021

In order to verify the results obtained in this study, we focus our attention on the case study of the event on 28 February 2021, which has been observed by the XWR and analysed by Pardini et al. (2021). Table 2 shows the coordinates (longitude, latitude) of 14 points in which field measurements of tephra load are available (from literature, e.g., Pardini et al., 2021) in the selected municipalities (see Figure 1) as well as the results of tephra load derived from the Tephra2 and Fall3D models, fixing the  $\phi$  to 0.5. The XWR retrievals are obtained considering the tephra load rate ( $\text{kg/m}^2 \text{ s}$ ) related to the first four elevations, which is equal to a few km of altitude with respect to the ground, and integrating it for the whole time sampling of the radar. In this way we can retrieve the tephra load ( $\text{kg/m}^2$ ) related to the whole lava fountain. The correlation between the ground field data (Pardini et al., 2023) and the estimated values using Tephra2, Fall3D, and XWR are plotted, respectively, in Figure 4a, 4b, and 4c. We observe that taking as reference the observed values reported by Pardini et al., 2023, Tephra2 tends to overestimate while Fall3D tends to underestimate the tephra load values. This is evident from the majority of the points dispersed above and

below the bisector, as well as from the differences in the slope of the regressive curves with respect to the bisector shown in Figures 4a and 4b. These discrepancies could be due to different dispersal settings used in the numerical model. In contrast, a good correlation between field data and XWR data is observed (Figure 4c), where the points mostly distribute around the bisector and the regressive straight line is almost parallel to it.

To evaluate the degree of agreement between field data and tephra load estimates, we implemented a non-parametric test (namely the Kendall's tau correlation). Table 3 summarises Kendall's tau coefficients, the p-values for testing the null hypothesis of no correlation against the alternative hypothesis of a non-zero correlation; moreover, we estimate the mean absolute percentage error (MAPE) between predicted/estimated data and the observed field data. A Kendall's tau value closer to 1 indicates a better correlation between the field data and the model/estimate data, whereas a low p-value ( $<1\%$ ) indicates a significant correlation.

This test confirms that the estimates of both XWR and Tephra2 exhibit a better correlated variation with the field measurements, as indicated by the respective higher tau and lower p-values. The MAPE calculation further supports this conclusion.

**Table 2. Etna eruption on February 28, 2021: tephra load ( $\text{kg/m}^2$ ) on 14 sites, each one identified by the latitude and longitude, as deduced by Pardini et al. (2021), and in the same points as derived by Tephra2 and Fall3D models (fixing  $\phi = 0.5$ ) and retrieved by XWR.**

Assuming the width of  $(6 \pm 0.5)$  m for each road, we convert the tephra load to tephra mass (kg) for the event of 28 February 2021, assuming  $\phi = 0.5$ . We selected a few roads, characterised by their larger extension, for each municipality: Via Bellini and Corso Italia in Milo; via Mazzini, via Galimberti and via Stabilimenti in Santa Venerina; via Libertà, via Zafferana Milo and via delle Rose in Zafferana Etnea. We summarise in Table 4 the total tephra mass for streets of Milo, Santa Venerina and Zafferana Etnea as derived from Tephra2 and Fall3D models. The total mass computed for the selected roads in Milo by Tephra2 and Fall3D shows a comparable order of magnitude ( $10^7$  kg), whereas for two selected roads in Zafferana Etnea reveals a disagreement of one order of magnitude. However, the values computed for all municipalities show a maximum variability between approximately five times the tephra deposit collected on the ground (Scollo et al., 2007). The Tephra2 outcomes are generally larger than those of Fall3D, with the ratio between Fall3D and Tephra2 ranging from 0.3 to 1.4 for the roads and from 0.3 to 1.1 for towns. The variability in road width corresponds to a variability in tephra mass of approximately  $\pm 9\%$ . The last three rows in Table 4 show the total mass computed on the whole road network of the three municipalities, highlighting the comparable results (same order of magnitude of about  $10^9$  kg). It is worth noting that the total mass derived from Tephra2 in Zafferana Etnea municipality is four times larger than the total mass derived from Fall3D. This variability can be observed in Figure 3. Not all roads are affected by tephra load, as shown in Figure 3b, and this can be attributed to dissimilarity in the dispersal laws implemented in each model (Scollo et al., 2008; Bonadonna et al., 2005; Folch et al., 2012, 2016). It is important to note that during a typical explosive event at Etna, only a few kilograms of tephra accumulate on a limited number of streets across the three municipalities. This aspect is closely related to the intensity of the explosive event, the amount of pyroclastic material erupted, and the wind dispersal pattern.

**Table 4. Total tephra mass (kg) computed on main roads selected of Milo, Santa Venerina and Zafferana Etnea for the Etna eruption on 28 February 2021 as derived from the results obtained using Tephra2 and Fall3D models (fixing  $\phi=0.5$  and assuming a road width of  $6 \pm 0.5$  m). The total mass on the road network of Milo, Santa Venerina and Zafferana, for three road widths (5.5 m, 6 m, and 6.5 m), is presented in the last three rows. On the right column the mass ratio between Fall3D and Tephra2 results.**

350

351 **4.2. Tephra mass on specific road-points**

352 We investigate how the tephra load, derived from both models, can be used to assess the accumulated tephra mass on the road  
353 network for the selected municipalities, assuming a cell size of (5×5) metres in the interpolated tephra load map. It is important  
354 to highlight that deposited tephra causes disruptions on main roads, specifically in terms of the kilometres of roadways that  
355 may face critical driving conditions. The location of the Etna volcano, along with the prevailing westerly and northwesterly  
356 winds at high altitude, favours the tephra fallout and dispersal primarily toward east (31%), southeast (35%) and north-west  
357 (29%) Etna flanks, and only (6%) directed towards south. These patterns are derived from the analysis of ERA5 reanalysis  
358 wind data during 39 eruptive events that occurred in 2021. These results are consistent with the historical statistical distribution  
359 of wind direction and relative velocity from the 1990-2007 period at altitudes between 5 and 10 km, as derived from  
360 meteorological forecast data (Barsotti et al., 2010; Scollo et al., 2013). The deposited tephra mass, derived from two models, is  
361 computed by selecting eight road-points (shown in Figure 1) across different roads in the municipalities of Milo, Santa  
362 Venerina (Sven), Zafferana Etnea (Zaff) and Giarre municipalities: provincial roads (SP41, SP92, SP8 and SP59); the highway  
363 (E45); and the state road (SS114). To increase the number of road-points on the southeast flank of Etna, we also include road-  
364 points from the E45 and SP114 in the municipality of Giarre. In Figure 5 we show the time cumulative tephra mass for different  
365 median  $\phi$  values at specific points in the selected roads, as computed by Tephra2 (Figure 5a) and Fall3D (Figure 5b).  
366 Generally, increasing the median  $\phi$  increases the deposited tephra mass and vice versa. Obviously, this estimate depends on the  
367 collection point, because for a given  $\phi$ , if the mass deposited in the proximal area increases, it decreases in the distal one, since  
368 the total mass deposited is conserved. The highest simulated tephra mass values from both models are found at SP59 in Milo,  
369 with Tephra2 recording between 2750 and 3375 kg and Fall3D showing between 3000 and 4250 kg at the end of the paroxysm  
370 sequence. This location is approximately 12 km from the summit of Etna, making it the closest among the analysed points. In  
371 contrast, SP92 in Zafferana Etnea shows lower ash loads, with Tephra2 reporting about 725 to 800 kg and Fall3D indicating  
372 between 250 and 450 kg at the end of the paroxysm sequence. While Zafferana Etnea is also near Etna (12.2 km away), it is  
373 situated further south than Milo. We can evaluate these results taking into account the tolerance boundaries, usually considered  
374 as more/less five times the estimated values (Scollo et al., 2007). Indeed, the variability of tephra mass for all the road-points  
375 computed with Tephra2 ranges between limit values of 750-3375 kg, whereas the variability derived from Fall3D is between  
376 250-4250 kg. The time-cumulative function derived from Tephra2 presents larger steps in concomitance with events of 14  
377 March, 22 and 28 May, 1 July 2021 for SP59 in Milo, E45, SP49 and SS114 in Santa Venerina and SP8 in Zafferana Etnea

378 whereas E45 and SS114 in Milo show a larger step during the event on 24 May 2021. During the other events, the tephra mass  
379 is not large enough to generate major steps in the time-cumulative function. For most road-points, the total accumulated tephra  
380 mass stabilises at values between 500 kg and 1250 kg after the paroxysm of 20 July 2021, with the exception of SP59 in Milo.  
381 The time-cumulative function obtained with Fall3D shows larger steps during the events of 28 May, 2 and 27 June, 31 July  
382 2021 for SP59 in Milo. E45 and SS114 in Milo show a larger step on 27 June 2021, whereas SP41, E45 and SS114 in Santa  
383 Venerina exhibit a large step on 29 August 2021, and SP92 in 17 June 2021. In Zafferana Etnea, SP8 shows a time increase of  
384 tephra mass, whereas in Zafferana Etnea the tephra mass stabilises at values between 250 kg and 500 kg by the end of June. The  
385 time-cumulative tephra mass on SP41, E45 and SS114 in Santa Venerina and SS114 on Milo stabilises between 1325 kg and  
386 2075 kg starting from the beginning of August. Also in the case of Fall3D, SP59 in Milo is confirmed as the most impacted  
387 road-point due to accumulation of tephra in time where the time-cumulated tephra increases more than at the other target  
388 points, with larger steps, and then stabilises starting from August. These results suggest that, following the 2021 cluster of  
389 Etna lava fountains, the roads of Milo and Santa Venerina municipalities have been the most impacted from tephra deposition  
390 in time.

Figure 5: The time series of cumulative tephra mass simulated by the Tephra2 (a) and Fall3D (b) models for all analysed explosive events at Etna in 2021, which shows plumes dispersing to the east and southeast. Each road-point is represented by a unique colour and symbol. We display the cumulative tephra mass corresponding to each road-point and varying the median value of  $\phi$ . The larger the mean grain size, the higher the accumulated load for that road-point, as indicated on the right side of each figure.

#### 4.3 Total mass accumulated on selected roads

In this section we quantify the total tephra mass deposited on selected main roads previously listed in Table 3 for each municipality. Three panels in Figure 6a, 6b and 6c are related, respectively, to the time-cumulative mass on Milo (a), Santa Venerina (b) and Zafferana Etnea (c) computed on selected roads of known area. Analysing the panels in Figure 6 we observe some rapid increases in the cumulative trend of tephra mass mainly for the Fall3D simulations (grey dashed line) with respect to Tephra2 (dark continuous line) simulations. These rapidly increasing trends are found in Milo on 12 March, 28 May (18:10-21:10 UTC), 27 June 2021, in Santa Venerina on 30 May, 17 June 2021 and in Zafferana Etnea. Generally, all the selected roads show a large step in the estimated cumulative tephra mass on 19 February, regardless of the model used. The largest step of total mass is found around June and July, as confirmed by the plots shown in Figure 6a.

410 **Figure 6: Cumulative tephra mass on selected roads for Milo (a), Santa Venerina (b) and Zafferana Etnea (c), respectively, for all**  
411 **Etna explosive events here analysed and simulated using the Tephra2 (dark continuous line) and Fall3D (grey dashed line) models.**  
412 **Each road is plotted with different symbols and identified by the relative area (m<sup>2</sup>, assuming a road width of 6 m), as listed in the**  
413 **legend.**

414 In Table 5 we summarise the total tephra mass deposited during the 39 Etna events in 2021 for the selected roads in each  
415 municipality. The last three rows show the total tephra mass computed for the complete road network of each town. The Fall3D  
416 estimates are generally larger than those from Tephra2, with the ratio ranging from 1.5 to 3.8 for the roads and from 2.0 to 5.0  
417 for the towns, though the variability can be as much as a factor of five in either direction. We observe that during about one year  
418 of Etna’s paroxysms, in the nearest municipalities under examination, the estimated value of total tephra mass accumulated in  
419 the main streets ranges between 10<sup>6</sup>-10<sup>9</sup> kg. A difference of at most one order of magnitude in the total accumulated mass  
420 according to the two models is found. It is worth noting that these values are computed under the worst condition, i.e. without  
421 considering the tephra mobilisation due to external factors, such as rain or wind, during the complete time range, as well as  
422 assuming not road cleaning after each event. Therefore, this tephra mass represents a computed estimate of the total amount of  
423 tephra mass that theoretically had to be removed to the roads and disposed of during and after the 2021 crisis.

424 **Table 5. Total mass accumulated over 39 Etna events on the selected roads for Milo, Santa Venerina and Zafferana Etnea**  
425 **municipalities, as simulated by Tephra2 and Fall3D models (fixing  $\phi=0.5$  and assuming a road width of  $(6 \pm 0.5)$  m). The total mass**

41

426 on the whole road network of Milo, Santa Venerina and Zafferana, for three road widths (5.5 m, 6 m, 6.5 m), is in the last three rows.

427 On the right column the mass ratio between Fall3D and Tephra2 results.

428

| Location  | Mass (10 <sup>7</sup> kg)             |                                      |            |
|---|---------------------------------------|--------------------------------------|------------|
|   | Tephra2<br>(5.5, 6, 6.5 m-width road) | Fall3D<br>(5.5, 6, 6.5 m-width road) | Mass Ratio |
| Milo-Via V. Bellini                                       | 66.2, 72.2, 78.2                      | 216.3, 235.9, 255.6                  | 3.3        |

| Zafferana E.-Via Zafferana Milo                           | 18.7, 20.4, 22.1                      | 43.7, 47.7, 51.7                     | 2.4        |
| Zafferana E.-Via delle Rose                               | 4.6, 5.0, 5.4                         | 6.8, 7.4, 8.1                        | 1.5        |
| Total mass on the whole road network of each municipality |                                       |                                      |            |
| Milo  | 7310.7, 7975.3, 8639.9                | 14937.5, 16295.5, 17653.5            | 2.0        |
| Santa Venerina  | 488.4, 805.5, 952.0                   | 1510.4, 2641.9, 3122.3               | 3.3        |
| Zafferana Etnea   | 5162.3, 5631.5, 6100.9                | 26632.4, 29053.5, 31474.6            | 5.0        |

429

430 **4.4 Total mass accumulated on the full road network**

431 Similarly to Figure 3, Figure 7 shows the cumulative tephra load (kg/m<sup>2</sup>) on the geo-referenced road map within the Milo (light

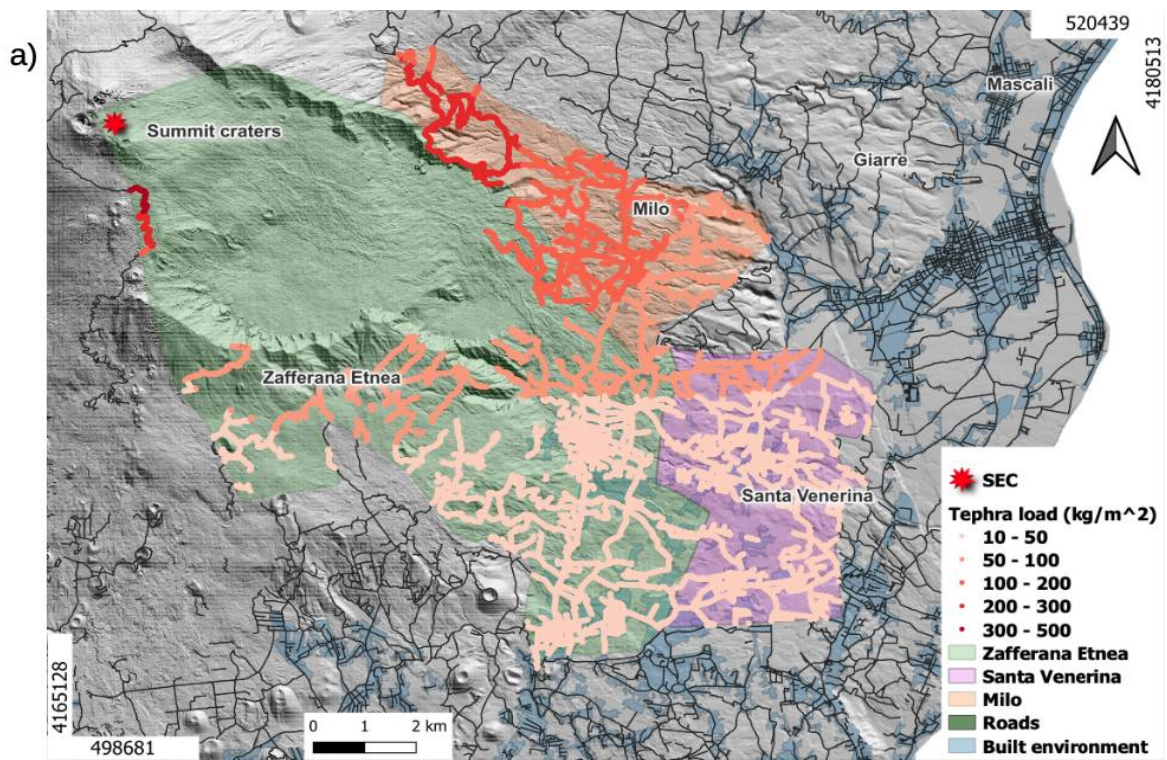

432 orange area), Santa Venerina (light pink area) and Zafferana Etnea (light green area) municipalities for all 39 Etna lava

433 fountains, computed using Tephra2 (Figure 7.a)) and Fall3D (Figure 7.b)) models.

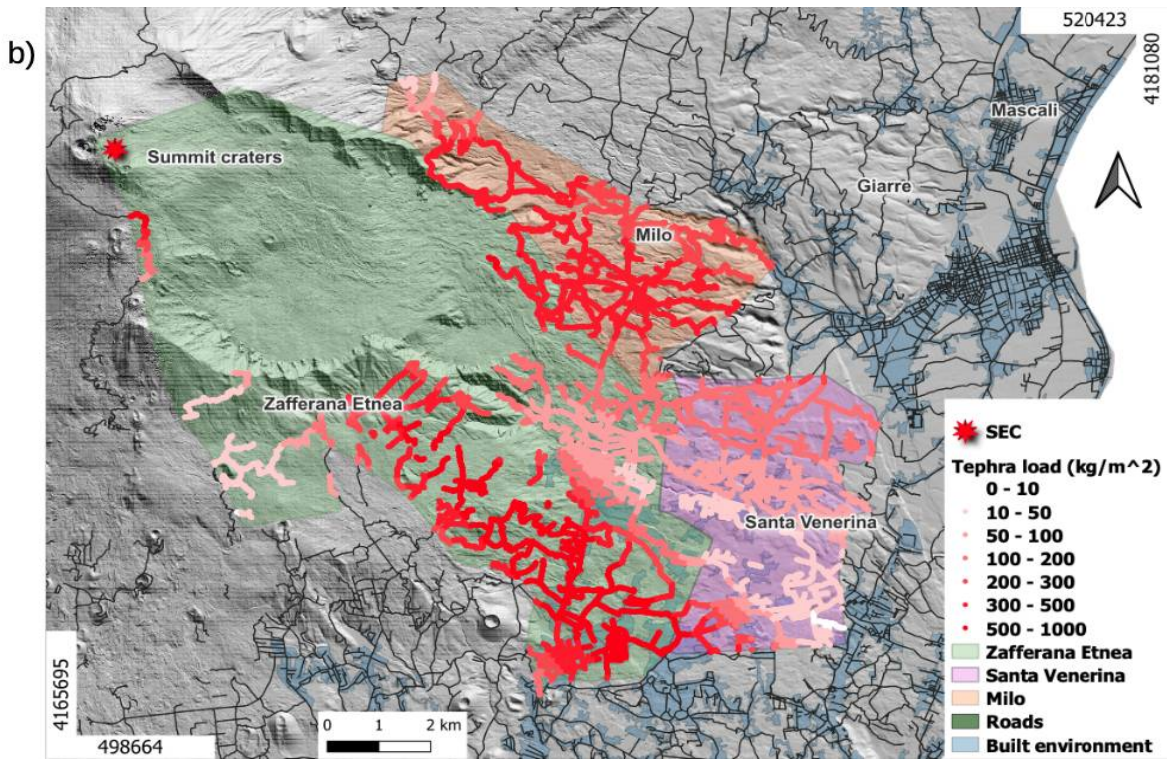

434

435

436

437

438 **Figure 7: Cumulative tephra load (kg/m2) for all 39 Etna lava fountains analysed in this work, computed on the whole road network**  
439 **of Milo, Santa Venerina and Zafferana Etnea using (a) Tephra2 and (b) Fall3D models, assuming  $\phi=0.5$ . The road graph is bold**  
440 **highlighted and in red scale coloured in function of deposited tephra values.**

441 Considering the area of each road, we compute the time-cumulative tephra mass (kg) relative to Milo, Santa Venerina and  
442 Zafferana, over the whole road network, as computed by both numerical models (Figure 8). Normally, the cumulative tephra  
443 mass derived from Tephra2 (dark continuous line) after an initial rapid growth tends to stabilise, in contrast with the trends  
444 obtained using Fall3D (grey dashed line), which present rapid increases in estimates throughout the sequence. These leaps in  
445 Milo are for the events on 28 May, 23 June (17:40-19:00 UTC) and 27 June 2021, in Santa Venerina on 28 February, 23 and 27  
446 June 2021, and in Zafferana Etnea on 28 February and 17 June 2021. The maximum value of tephra mass deposited on the  
447 whole road network in the three municipalities ranges between  $10^{10}$  to  $10^{12}$  kg.

448

449 **Figure 8: Cumulative tephra mass for all the 2021 Etna lava fountains analysed in this work, simulated using Tephra2 (dark**  
450 **continuous line) and Fall3D (grey dashed line) models, for the whole road network in Milo, Santa Venerina and Zafferana Etnea.**  
451

#### 452 **4.5. Analysis of variability in tephra mass results**

453 The estimates of tephra mass, as a function of uncertainty variation related to ESPs used as input to train both numerical  
 454 models and the specific limitations of the two dispersal models, are already well-documented in the literature (Scollo et al.,  
 455 2008b). In the present work, we evaluated the potential mass load and total mass accumulated on the road networks of several  
 456 target towns. Due to the complexity of the Fall3D model, requiring significant computational resources compared to Tephra2,  
 457 the number of simulations considered for each analysed eruption was limited to the GSD variability. However, the comparison  
 458 between the results provided by the two models allows a first analysis of the variability in tephra mass estimates. The  
 459 evaluation of the results for the case study on 28 February 2021, observed by the XWR and analysed by Pardini et al. (2021),  
 460 allowed us to confirm Tephra2 as a useful numerical model for rapid assessment of tephra dispersal and deposition on road  
 461 points, and for quickly evaluating the relative tephra fallout hazard. These results are consistent with the distribution of field  
 462 data in relation to XWR measurements and model outcomes shown in Figure 4a, 4b, and 4c. The Kendall's tau correlation  
 463 coefficient and the MAPE presented in Table 4 further support our findings. We also highlight the high performance of XWR  
 464 in measuring these quantities, although these observations are not always available in real-time. By shifting focus from  
 465 individual road points to selected roads for the same Etna eruption event on 28 February 2021, we observe that the Fall3D  
 466 estimates are approximately comparable with those of Tephra2, as confirmed by a ratio ranging from 0.3 to 2. When  
 467 considering the entire sequence of 39 Etna eruptive events, Fall3D estimates are higher than Tephra2 for the main roads in the  
 468 three municipalities and for the entire road network selected in this work. Furthermore, assuming a variability of road width  
 469 ( $\pm 0.5$  m) in our computations, we estimate a variability in tephra mass of approximately  $\pm 9\%$ . All of this information allows us  
 470 to outline a more comprehensive framework for estimating the mass of tephra accumulated on roads, which is essential for  
 471 managing the impact of volcanic eruptions.

#### 472 **5. Discussion and conclusions**

473 Considering the question about the quantification of the total tephra mass deposited in a given infrastructure of interest  
 474 following an (or a series of) explosive volcanic eruption(s), in this work we assessed, for the first time, the cumulated tephra  
 475 mass on the road networks in three selected towns on Etna's eastern flank during several paroxysms that occurred in 2021. This  
 476 accumulated mass is a theoretical estimate of the amount of material that had to be removed from the roads and disposed of  
 477 during the 2021 volcanic activity. We have focussed on three target municipalities located on the east flank, i.e. Milo, Santa  
 478 Venerina and Zafferana Etnea. According to the law at the time of the eruption, such material had to be handled and disposed  
 479 of as special waste (Art. 35 decreto legge 77/2021). At the time of writing this paper a new law allows the use of this material  
 480 for other purposes (DA n.8/Gab. 22/04/2024, <https://www.regione.sicilia.it>) as, for example, building construction. Processing  
 481 measurements derived from visible and thermal cameras of INGV-OE, and, when available, from SEVIRI images and the  
 482 XWR data, we can retrieve the main ESPs, useful inputs to run numerical models. In this way we can simulate and evaluate the

483 cumulated tephra load on roads in time. Processing these results with the QGIS tool, we are able to identify the roads more  
484 exposed to tephra deposition. We consider that the results of this analysis can be a valuable source of information to support the  
485 management of volcanic crises and for planning the reinstatement of road networks after a crisis.

486 It is known that effective and realistic transport management strategies are essential into volcanic contingency planning in  
487 sectors where key infrastructure are at risk, such as the road networks. Evaluating tephra mass using two (or more) different  
488 models allows assessing epistemic uncertainty, to estimate the different sensitivity of each model to same input ESPs and the  
489 variability of the median  $\phi$ . It is worth highlighting that in this work, we have neglected the uncertainties in the ESP values  
490 (such as  $Q_M$ , TEM and  $H_{TP}$ ), but this analysis is already available in literature (see e.g., Scollo et al., 2008b). However, these  
491 values are affected by various sources of uncertainty, including pre- and post-processing of data, as well as instrument  
492 sensitivity and accuracy, all of which can significantly impact the model outputs (see e.g., Mereu et al., 2023). This can lead to  
493 larger uncertainties in the simulated tephra load in addition to those related to the different model settings and the physical  
494 assumptions implemented in each numerical model.

495 In this work we are not considering the effect of rain which can remain trapped in the tephra deposit. Furthermore, depending  
496 on the rain's intensity, the road traffic safety can worsen (e.g., by making the transport network particularly slippery) or can be  
497 improved (e.g., by washing the road surface from the ash deposit). Specific thresholds of tephra load that can damage the main  
498 roads system, and the necessary actions to mitigate the tephra effects are defined and known in the literature (e.g. Jenkins et al.  
499 2015; Bonadonna et al. 2021b; Table 8 in Bonadonna et al., 2021a).

500 As a final consideration, we point out the importance of the validation of the results of tephra load simulation obtained with  
501 two different numerical models by comparing their output with ground sampling data (in our case available from Pardini et al.,  
502 2023) as well as with the XWR retrievals for the Etna explosive activity on February 28, 2021. The tephra deposit estimations,  
503 as listed in Tables 2 and 3, highlight the good agreement among the ground sampling, XWR retrievals and the output of  
504 numerical models. This observation makes us confident to use the two different models in evaluating not only qualitatively but  
505 also quantitatively the tephra deposited during recent Etna paroxysms. In this way it is possible to provide plausible values of  
506 ground cumulated tephra mass on roads, and identify which routes in the road network of the target towns may be most  
507 impacted in next eruptions.

508 We consider that the analyses and the results proposed in this paper provide interesting inputs for supporting decision making  
509 and crisis management. Indeed, such analyses may support planning for clean-up following volcanic eruptions, which is  
510 essential for effective volcanic risk management (Hayes et al., 2019). Post-eruption clean-up of tephra deposits on roads is a  
511 widespread and costly activity, both in terms of time and resources, and frequently it is an unplanned activity (Hayes et al.,  
512 2019). Combining different cleaning methods, such as sweeping, suction, spraying and air blasting, could help speed up tephra  
513 fallout removal from high-priority roads used in the management of these events, especially before markings are fully covered  
514 (with thickness ranging from 1 to 10 mm), in order to ensure safety during cleaning operations. Understanding the economic  
515 impact on affected areas (Hayes et al., 2015; Magill et al., 2006) also contributes to better risk management. Geospatial

analysis methods are well-documented in the literature for estimating the duration of roads cleaning-up (Hayes et al., 2017), although these operations are influenced by complex interactions between physical factors (e.g. erupted volume, column height, grain-size, wind speed and direction, and rainfall) and social factors (e.g. social priorities, prior planning, previous experience, and infrastructure interdependencies) (Hayes et al., 2015). Moreover, the presented results may support decision makers in different ways e.g. for planning and consequently for better management of a future volcanic crisis due to explosive activity of Etna volcano, as well as for getting valuable information about the order of magnitude of the total mass of tephra available for preparing the subsequent disposal and/or reuse.
