7 **Abstract.** Understanding phenolic pollutants interaction with soil colloids has been a focus of extensive research,
8 primarily under controlled conditions. This study addresses the need to explore these processes in a more natural,
9 complex soil environment. We aim to enlighten the underlying mechanisms of hydroquinone (a representative
10 phenolic pollutant) oxidation in ambient, MnO₂-rich sandy soil within soil columns designed for breakthrough
11 experiments. Our innovative approach combines noninvasive electrical measurements, crystallographic and
12 microscopic analyses, and chemical profiling to comprehensively understand soil-pollutant interactions. Our study
13 reveals that hydroquinone oxidation by MnO₂ initiates a cascade of reactions, altering local pH, calcite dissolution,
14 and precipitating amorphous Mn-oxides, showcasing a complex interplay of chemical processes. Our analysis,
15 combining insights from chemistry and electrical measurements, reveals the oxidation process led to a constant
16 decrease in polarizing surfaces, as indicated by quadrature conductivity monitoring. Furthermore, dynamic shifts in
17 the soil solution chemistry (changes in the calcium and manganese concentrations, pH, and EC) correlated with the
18 non-monotonous behavior of the in-phase conductivity. Our findings conclusively demonstrate that the noninvasive
19 electrical method allows real-time monitoring of calcite dissolution, serving as a direct cursor to the oxidation process
20 of hydroquinone, enabling the observation of chemical interactions in soil solution, and on soil particle surfaces.

21 1. Introduction

22 Phenolic pollutants may originate from various sources, including agricultural, industrial, municipal, and medical
23 wastes (Davi and Gnudi, 1999; Farhan Hanafi and Sapawe, 2020). Due to their chemical characteristics, phenolic
24 pollutants tend to persist in soil and water at relatively low concentrations for an extended period, posing a significant
25 environmental threat. The chemical fate of these pollutants in soil has been extensively studied, with particular
26 attention given to processes such as adsorption-desorption and oxidation (Ahmed et al., 2015; Delgado-Moreno et al.,
27 2021; Kang and Choi, 2008; Lambert, 2018; Loffredo and Senesi, 2006; Sun et al., 2022). Regarding oxidation,
28 various oxides, both natural and engineered, have been investigated for their potential to remove phenolic pollutants
29 (Gusain et al., 2019; Remucal and Ginder-Vogel, 2014). Among these, birnessite (MnO_2), a manganese oxide naturally
30 found in soils, is known for its effectiveness in oxidizing various phenolic compounds (Murray, 1974; Remucal and
31 Ginder-Vogel, 2014).

32 While manganese oxides' ability to oxidize phenols has been explored widely, most of these studies have been
33 conducted in buffered, controlled environments within batch experiments, which may not accurately reflect
34 manganese oxide behavior in more complex, heterogeneous soil (Chien et al., 2009; Fukuzumi et al., 1975; Liao et
35 al., 2021; Liu et al., 2011; McBride, 1987; McKenzie, 1971; Shindo and Huang, 1984; Stone and H, 1989; Trainer et
36 al., 2021). To the best of our knowledge, only a few works have investigated the oxidation of phenolic pollutants by
37 manganese oxides in situ in soils. For instance, studies have shown the oxidation of phenolic acids and dissolved
38 organic matter by manganese oxides in soils, but these works focused on naturally occurring, non-contaminating
39 compounds rather than phenolic pollutant fate in the soil (Ding et al., 2022; Lehmann et al., 1987). In a study by
40 Grebel et al. (Grebel et al., 2016), the oxidation of various phenolic contaminants was investigated using engineered
41 MnO_2 -coated sand columns, and their key conclusion underscores MnO_2 efficacy as an oxidizing agent for phenolic
42 contaminants. However, to determine whether MnO_2 can be equally effective in natural soil environments, further
43 investigation is required.

44 We aim to investigate the fate of phenolic pollutants, specifically in the context of oxidation processes in MnO_2 -
45 enriched soil. To achieve this, we will apply both classical methodologies and an advanced geoelectrical method
46 recently introduced to soil science: spectral induced polarization (SIP) (Gao et al., 2019; Johansson et al., 2019;
47 Kessouri et al., 2019; Mellage et al., 2022; Revil, 2012; Revil et al., 2021; Schwartz et al., 2012; Schwartz and Furman,
48 2012; Shefer et al., 2013; Vaudelet et al., 2011; Vinegar and Waxman, 1984; Zhang et al., 2012). This approach allows
49 us not only to track the transformation of phenolic pollutants through oxidation by MnO_2 but also to monitor the
50 broader impacts of this oxidation process on other elements within the soil environment.

51 SIP is a method where a low frequency, time dependent electrical field is applied, and the resultant potential is
52 recorded. This technique captures both the conductive and capacitive characteristics of the surface, characterized by
53 the in-phase (σ') and quadrature (σ'') conductivity, respectively, in a non-invasive way (Binley and Kemna, 2005;
54 Binley and Slater, 2020; Reynolds, 2011). Quadrature and in-phase conductivity are associated with the interfacial
55 chemistry of the grain surface and grain size, while in-phase conductivity is also related to pore-water electrolyte
56 conductivity (Ben Moshe and Furman, 2022). The σ'' is frequency dependent and related to polarization processes at

57 the electric double layer (EDL), and indeed Vinegar & Waxman (Vinegar and Waxman, 1984) proposed a linear
58 relationship between the soil cation exchange capacity (CEC) and the σ'' . Additionally, studies on the impact of
59 organic contaminants on the low-frequency complex conductivity of soils and porous materials demonstrated the
60 ability of the SIP method to detect and monitor organic contaminants within the subsurface (Kirmizakis et al., 2020;
61 Mellage et al., 2018, 2022; Revil, 2012; Schwartz et al., 2020; Schwartz and Furman, 2012, 2015; Vaudelet et al.,
62 2011).

63 This study aims to thoroughly explore the behavior of hydroquinone, a model phenolic molecule with a well-known
64 oxidation mechanism by Mn-oxides, in MnO₂-enriched sandy soil (Mn-sandy soil). To achieve this, we employed an
65 array of methods including; electric measurements of the soil profile, crystallographic and microscopic examination
66 of the soil minerals, and chemical analysis of the soil solution. We hypothesized that integrating electrical
67 measurements, soil solution analysis, and soil surface examinations would enable us to reach a unique understanding
68 of the oxidation process in the soil and provide insights into the resulting chemical mechanisms in the soil
69 environment.

70 **2. Materials and Methods**

71 In this study, we investigated the oxidation of hydroquinone by MnO₂ in sandy soil column experiments. The
72 experiments were conducted using sandy soil and MnO₂-enriched sandy soil (Mn-sandy soil) to observe the behavior
73 of hydroquinone and its oxidation product, benzoquinone. During the experiments, we employed SIP measurements
74 to study the electrical characteristics of the soil as the oxidation process occurred. We analyzed the samples for
75 hydroquinone and benzoquinone concentrations using High-Performance Liquid Chromatography (HPLC), and
76 measured ion concentrations and composition by Coupled Plasma Atomic Emission Spectrometer (ICP-AES), pH,
77 and Electrical Conductivity (EC). Additionally, we conducted Scanning Electron Microscopy (SEM), Energy-
78 Dispersive X-ray Spectroscopy (EDS), and X-ray Diffraction (XRD) analyses to observe any changes in soil
79 morphology and mineralogy before and after the introduction of hydroquinone to the soil.

80 Hydroquinone (99% purity), benzoquinone (99% purity), acetonitrile (HPLC grade), and calcium chloride were
81 purchased from Sigma-Aldrich. Potassium permanganate, and hydrochloric acid 32% were purchased from Mercury
82 LTD. Sandy soil with 97% sand and 3% silt (measured using PRIO, Meter group, Germany), contains 4% CaCO₃, and
83 2.5% organic matter.

84 **2.1. MnO₂ preparation**

85 MnO₂ was synthesized following the procedure of McKenzie (McKenzie, 1971). In brief, concentrated HCl was added
86 dropwise to a boiling solution of potassium permanganate to form a dark purple precipitate of δ -MnO₂. After synthesis,
87 the suspension was centrifuged (15,200 g, 15 min), and the supernatant was decanted and replaced with double-
88 deionized water. The procedure was repeated until the supernatant was colorless; then the slurry was oven-dried
89 overnight at 35 °C and freeze-dried.

90 **2.2. Spectral induced polarization measurements**

91 In the SIP method, a low frequency (typically 0.01 Hz to 10 kHz) oscillating current I (A) is applied through two
92 electrodes on a porous medium, and electrical potential U (V) is measured by two other electrodes. Using Ohm's law,

93 the complex admittance of the medium, $Y^* = I/U$ (S) is obtained. The complex conductivity is related to the
94 admittance through the geometric factor G (m^{-1}) such that $\sigma^* = G \cdot Y^*$. The complex conductivity signal can be
95 expressed as $\sigma^* = \sigma' + i\sigma'' = |\sigma^*|e^{i\varphi}$, where σ' ($S m^{-1}$) is the in-phase conductivity (also referred to as the real
96 conductivity), associated with energy dissipation processes, σ'' ($S m^{-1}$) is the quadrature conductivity (also referred
97 to as the imaginary conductivity), related to energy storage processes (Vinegar and Waxman, 1984), and φ (rad) is
98 the phase shift.

99 The SIP signal was measured using the PSIP impedance spectrometer (Ontash & Ermac Inc, NJ, USA), in polyvinyl
100 chloride (3 cm diameter, 30 cm long) columns equipped with 4 brass electrodes, 6 mm in diameter, for both current
101 injection and potential measurement (Fig.1). The current electrodes were 8 cm long and they crossed the entire sample,
102 while the potential electrodes were 5 cm long, and they were retraced in their respective holes to prevent electrode
103 polarization (as suggested by Cassiani et.al (Cassiani et al., 2009), and Schwartz and Furman (Schwartz and Furman,
104 2012). Electrical contact between the potential electrodes and the sample was ensured through the electrolyte. The
105 geometric factor (G) was determined by measuring the admittance of a series of electrolytes with different electrical
106 conductivities.

107

Figure 1. Scheme of experimental SIP column: inlet solution is injected in through the bottom and the outlet is collected in fractions. The current (I) is injected between the top and the bottom electrodes, and the SIP signal is measured between the potential electrodes (U)

108 **2.3. Column experiments**

109 Breakthrough experiments were conducted to study the behavior of hydroquinone, and benzoquinone in sandy soil
110 and Mn-sandy soil in an unbuffered environment. Two sets of experiments were performed using triplicate columns
111 for each treatment: untreated sandy soil and Mn-sandy soil, which was prepared by mixing sandy soil with 5% w/w
112 MnO₂. Air-dried soil was mixed with 10% w/w of CaCl₂ 5mM solution as the saturating liquid. This soil was then
113 packed in the columns in approximately 100 mL increments and gently compressed after each addition. Based on an
114 assumed particle density of 2.65 g cm⁻³ (Warrick, 2002), the average porosity of the sandy soil and Mn-sandy soil
115 samples was 0.4 and 0.44±0.02, respectively.

116 After packing, the columns were placed vertically and a 5mM CaCl₂ solution was introduced from the bottom to wash
117 away excess salt, ensuring saturated flow at a constant flow rate of 1 mL/min using a peristaltic pump (Masterflex L/S
118 series, Cole-Parmer Inc., IL, USA). The soil was washed with CaCl₂ until equilibrium was reached between the inlet
119 and outlet solutions (EC=900 μS cm⁻¹). Upon reaching equilibrium, the inlet solution was replaced either by a mixed
120 solution of hydroquinone and benzoquinone (0.1M each in CaCl₂ 5mM solution) for the sand-only columns or by a
121 hydroquinone-only solution (0.1M in CaCl₂ 5mM solution) for the Mn-sandy soil columns. The mixed solution was
122 used for the sand-only columns to ensure no interactions occurred with benzoquinone, while the primary purpose was
123 to follow the hydroquinone oxidation. Both solutions passed through their respective columns for 4 or 8 pore volumes
124 (PV), respectively, until mass balance was achieved. Both solutions were left unbuffered and unpurged to better
125 represent natural conditions.

126 Throughout the experiments, continuous SIP measurements were taken, and at 20-minute intervals, 2 mL samples of
127 the outlet solution were collected and immediately filtered using a 0.22 μm reverse cellulose membrane filter syringe
128 for further analysis. The collected outflow was analyzed to determine (1) hydroquinone and benzoquinone
129 concentrations using HPLC (Waters 600, Waters, Milford, MA), equipped with a diode-array detector. The HPLC
130 column was an XBridge Phenyl 3.5 μm 4.6X150 mm, with a flow rate of 1 mL/min, and the column temperature was
131 set to 25 °C. Hydroquinone and benzoquinone were monitored at wavelengths of 222 nm and 246 nm, respectively.
132 The mobile phase consisted of acetonitrile and double distilled water (DDW). The phase gradient started at 5%
133 acetonitrile for 0-3 min, linearly increased to 40% for 3-10 min, and then increased again to 95% over 10-11 min.
134 Acetonitrile maintained at 95% over 11-12 min, then decreased back to 5% over 12-13 min, and maintained at 5% for
135 13-16 min. (2) Ca²⁺ and soluble Mn concentration in the effluent by ICP-AES (Arcos Spectro Ltd., Germany), and
136 (3) pH and EC values.

137 **2.4. Colloid surface analysis by SEM-EDS and XRD**

138 Sandy soil, MnO₂, and Mn-sandy soil morphology was observed, before and after the introduction of hydroquinone
139 by SEM (JEOL IT 100 Low vacuum). All samples were oven-dried at 40°C and thinly ground before analysis,
140 mounted on 30 mm round SEM aluminum stubs using adhesive carbon tape. Secondary electron images were taken
141 using the following operating conditions: 20 keV, 9 mm WD, and x350 magnification for all samples. For each soil,
142 10 images were obtained and scanned for calcium, manganese, and silica semi-quantitative percentages, using EDS.
143 The concentration of the elements in the Mn-sandy soil samples was corrected to the relative addition of Mn to the
144 system. The effect of hydroquinone oxidation on Ca and Mn content in the soil was conducted using a non-parametric

145 comparison for each pair, using the Wilcoxon method. The statistical analysis was carried out by JMP®, Version 16.
146 SAS Institute Inc.

147 The mineralogy of the soil and the change in MnO₂ mineralogy, pre- and post-oxidation were also evaluated by XRD.
148 Soil samples were ground and loaded into an XRD sample holder by front loading followed by razor blade leveling.
149 XRD patterns were acquired in Bragg-Brentano geometry using a PANalytical X'Pert diffractometer with CuK α
150 radiation operated at 45 kV and 40 mA. The samples were scanned from 5 to 70° 2 θ at a step size of 0.013° 2 θ , using
151 a PIXcel detector in continuous scanning line (1D) mode with an active length of 3.35°. Mineral phase identification
152 was performed using HighScore Plus® software based on the ICSD database.

153 3. Results and Discussion

154 3.1. Hydroquinone and benzoquinone fate in sandy soils - breakthrough curves

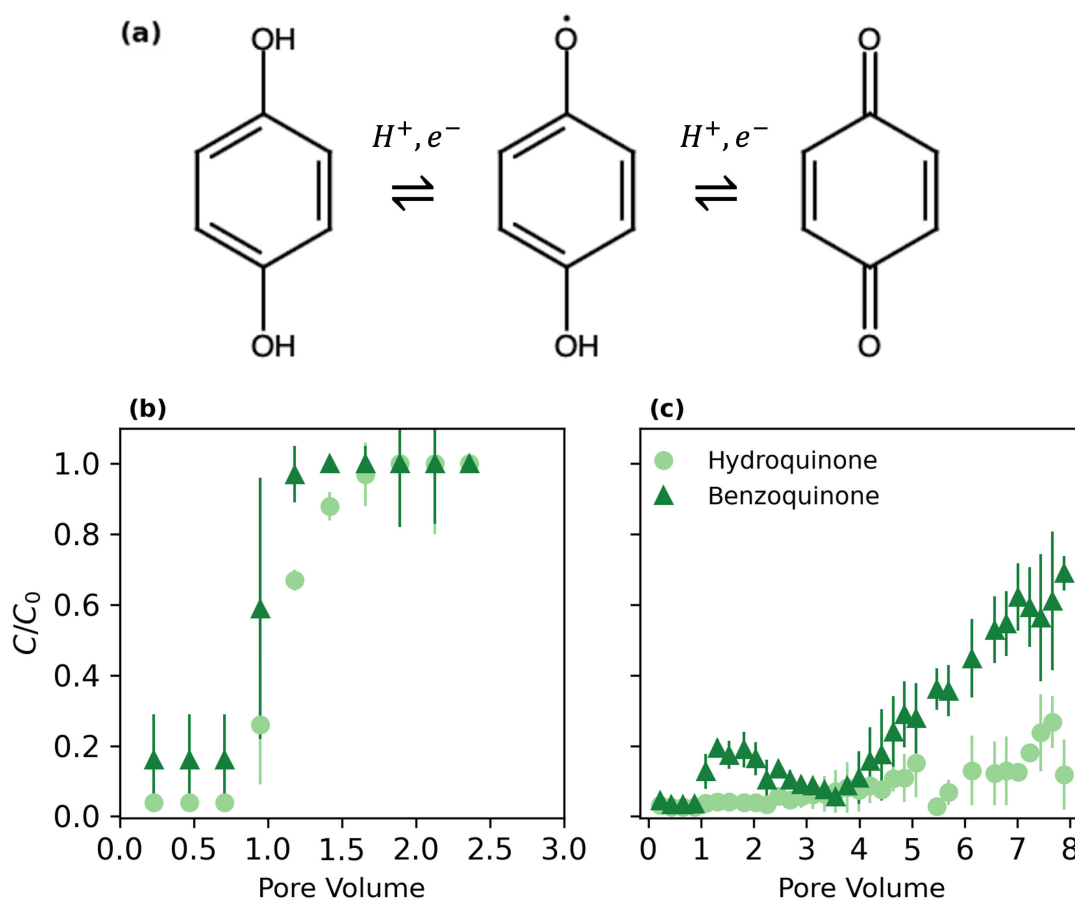

Figure 2. (a) Oxidation-reduction reactions of hydroquinone and benzoquinone. Relative concentrations of hydroquinone (0.1 M initial) and benzoquinone (0.1 M) in (b) sandy soil and (c) Mn-sandy soil columns.

155 Figure 2 illustrates the oxidation-reduction process (Fig 2a) and breakthrough curves of hydroquinone and
156 benzoquinone in sandy soil (Fig. 2b) and Mn-sandy soil (Fig. 2c) columns. Hydroquinone undergoes oxidation,
157 involving the transfer of protons and electrons, to form benzoquinone (Fig 2a). In the control sandy soil columns (Fig.
158 2b), both hydroquinone and benzoquinone displayed characteristic symmetric sigmoidal breakthrough curves, typical

159 of inert substances that do not undergo adsorption or oxidation in the soil, with breakthrough occurring at
160 approximately 1 pore volume (PV). This suggests that there was negligible adsorption or chemical transformation of
161 these compounds in the sandy soil, allowing them to pass through the column relatively unimpeded.

162 Benzoquinone deviations likely occur due to measurement errors and may also be influenced by the reduction of
163 benzoquinone under the natural, unbuffered conditions of the system used for these experiments.

164 In contrast, the breakthrough curves in the Mn-sandy soil columns (Fig. 2c) demonstrate different behavior.
165 Benzoquinone showed an initial breakthrough at around 4 PVs, reaching a relative concentration (C/C_0) of about 0.2,
166 and continued to increase gradually. Hydroquinone, however, exhibited a significantly delayed breakthrough,
167 occurring at approximately 7 PVs with a relative concentration of 0.7. The moderate slopes of these breakthrough
168 curves compared to the steep slopes observed in the sandy soil columns indicate that hydroquinone undergoes
169 oxidation in the presence of MnO_2 , forming benzoquinone. This oxidation process is responsible for the delayed and
170 more gradual breakthrough of hydroquinone, highlighting the reactive nature of the Mn-sandy soil in altering the
171 transport and fate of these pollutants (Buamah et al., 2009).

172 3.2. SIP and soil solution chemistry monitoring

173

Figure 3. In-phase (σ') (a) and quadrature (σ'') (b) conductivity of sandy and Mn-sandy soils (5 % w/w).

174 Sandy soil (control) and Mn-sandy soil columns were saturated with background solution (5 mM $CaCl_2$) and their SIP
175 signatures were recorded upon reaching equilibrium, before the introduction of the pollutant (Fig. 3). The quadrature
176 conductivity (σ'') (associated with surface polarization) of the sandy soil, exhibited classical spectra for frequency-
177 dependent polarization of porous media, with a peak at around 0.5 Hz (Fig. 3Error! Reference source not found.b).
178 Compared to the sandy soil, σ'' of Mn- sandy soil increased by $\sim 40\%$, most likely due to the contribution of the high
179 CEC of MnO_2 (Händel et al., 2013; McKenzie, 1971; Post, 1999). Similarly, the in-phase conductivity σ' was also
180 higher ($\sim 40\%$) than that of the sandy soil (Fig. 3a), most probably due to the contribution of MnO_2 to the surface
181 conductivity of the media (recall, that the EC of the soil solution was kept constant between the treatments).

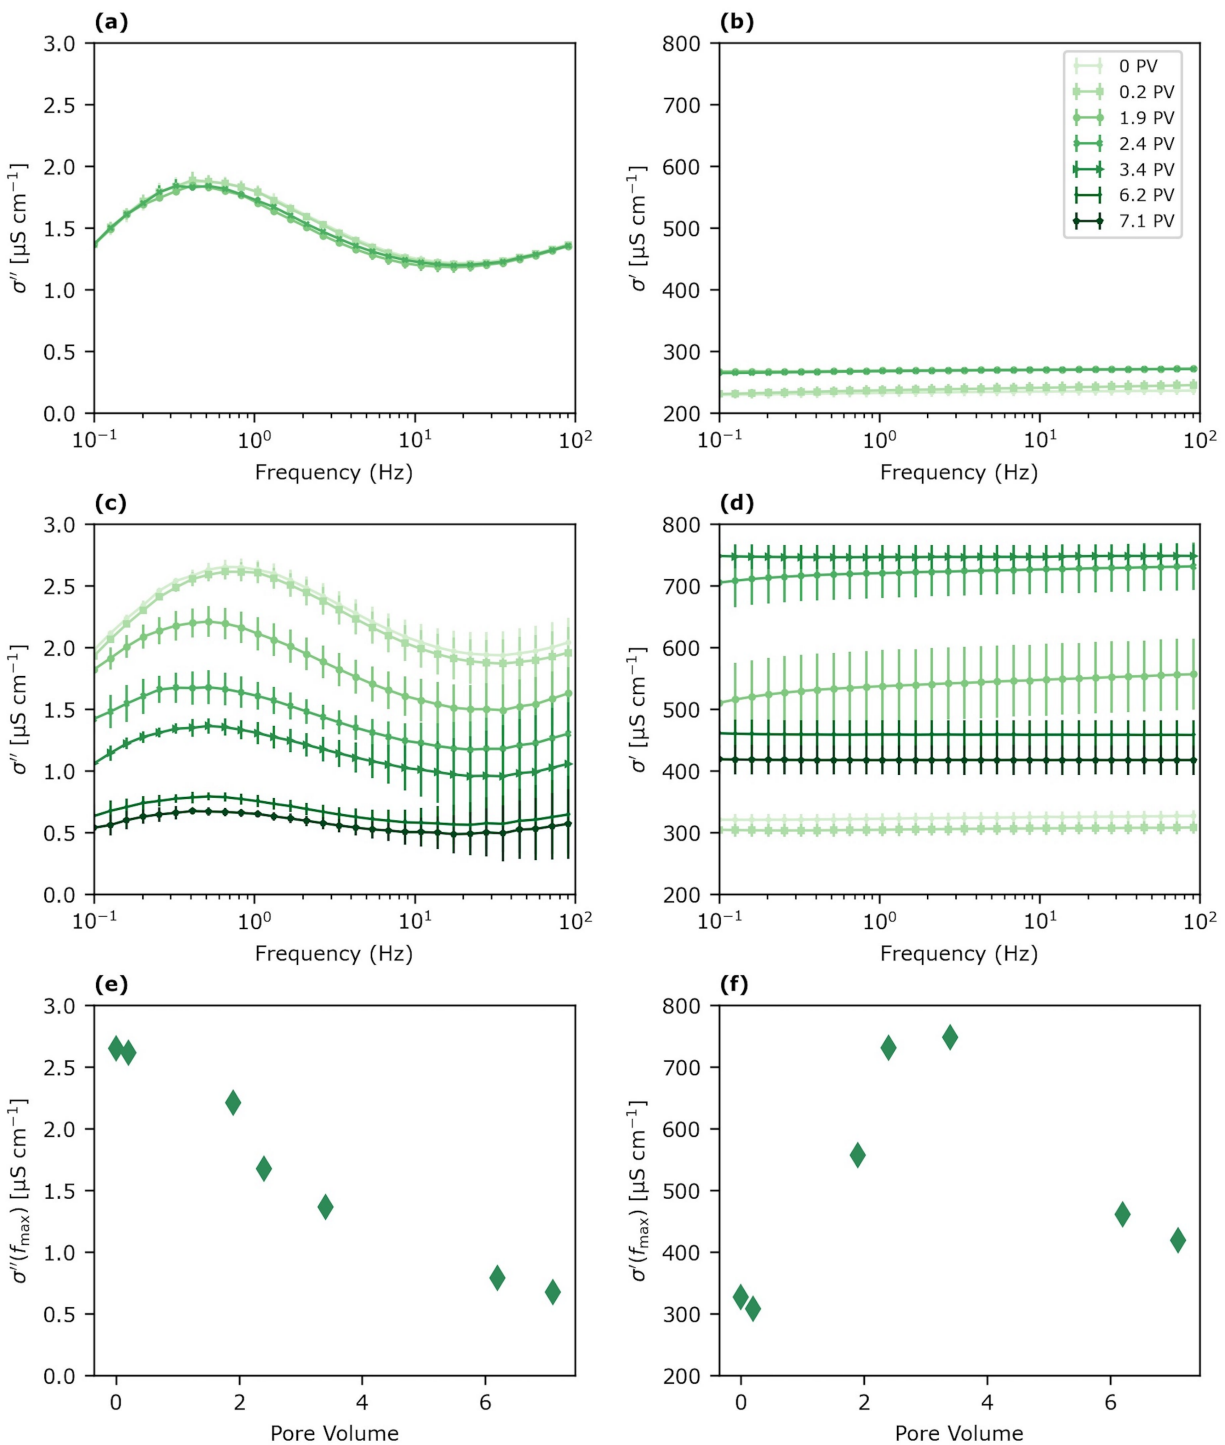

Figure 4. Quadrature (σ'') and in-phase (σ') conductivity of sandy (a,b) and Mn-sandy soils (c,d) during hydroquinone oxidation. σ'' (e) and σ' (f) at the peak frequency of Mn-sandy soil

184 Upon the addition of hydroquinone, the control columns demonstrated no change in both σ'' and σ' throughout the
 185 experiment (Fig. 4a, b). This was accompanied by negligible concentrations of benzoquinone and manganese, while
 186 the Ca^{2+} concentration remained constant at 5 mM in the effluent. Additionally, the EC remained constant at 1 mS m^{-1}
 187 ± 0.3 and the pH values were steady at 9 ± 0.2 (Fig 5. a, b). These results indicate that there was neither adsorption nor
 188 oxidation of hydroquinone in the control columns, as also demonstrated by the breakthrough curves (**Error!**
 189 **Reference source not found.**2a).

190 Hydroquinone flows through Mn-sandy soil columns induced a constant decrease in σ'' , as expected, due to oxidation
 191 processes in the system, resulting in a reduction in oxidizing and polarizing surfaces (Fig. 4 c, e). On the other hand,
 192 the σ' increased up to ~ 4 PVs and then decreased (Fig. 4 d, f). The maximum σ' value reached post ~ 4 PVs
 193 corresponded with peaks in EC and pH values, as well as Ca^{2+} concentration in the effluents (Fig 5. c, d). The pH
 194 value and EC dramatically increased from $8.82 (\pm 0.25)$ and $1.7 \text{ mS m}^{-1} (\pm 0.4)$ to $10.8 (\pm 0.1)$ and $4.53 \text{ mS m}^{-1} (\pm 0.03)$,
 195 respectively (Fig. 5 c). Simultaneously, the Ca^{2+} concentrations increased noticeably (from 0.1 to 25 mM) while the
 196 manganese concentrations increased only slightly (from below the detection limit to 0.1 mM) (Fig 5. d). Indeed, σ' is

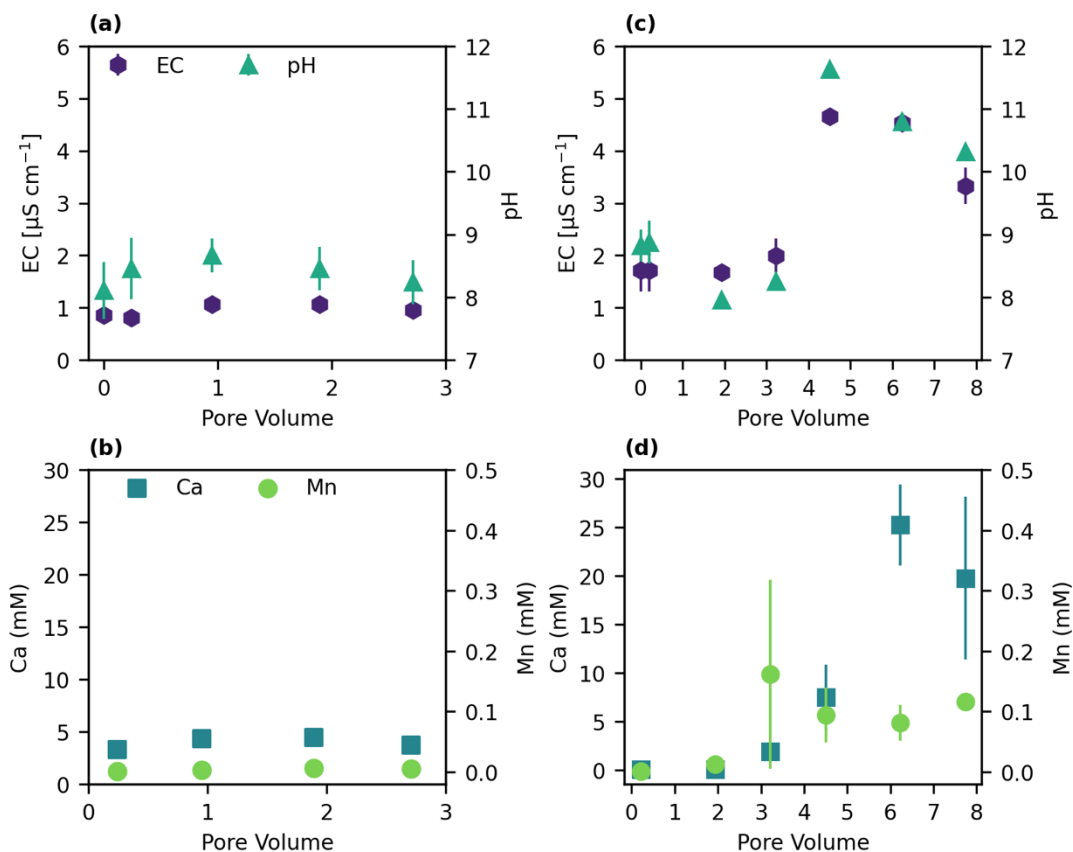

Figure 5. Effluent measurements of EC, pH, Ca^{2+} and Mn concentrations in (a), (b) sandy and (c), (d) Mn-sandy soil

197 related to the bulk solution properties, i.e., an increase in ion concentration, mainly Ca^{2+} , will result in an increase in
 198 σ' . Notably, all maxima for Ca^{2+} , EC, σ' , and pH corresponded with hydroquinone oxidation, as shown by
 199 benzoquinone breakthrough (Fig. 2b).

200 Since these trends are not observed in the control sandy soil columns (with hydroquinone flow, but without MnO_2)
 201 we suggest that hydroquinone oxidation by MnO_2 surfaces initiated a cascade of reactions: (i) a local increase in proton
 202 concentration due to hydroquinone deprotonation decreasing the local pH (Rudolph et al., 2013). At this stage two
 203 reactions, which require protons, may take place simultaneously but at different rates: (ia) calcite dissolution (evident
 204 by the Ca^{2+} , EC, σ' , and pH measurements), and (iib) MnO_2 reduction and dissolution to $\text{Mn}^{2+/3+}$ (Fukuzumi et al.,
 205 1975; McBride, 1987; Remucal and Ginder-Vogel, 2014; Stone and H, 1989), evident by benzoquinone breakthrough.
 206 The kinetics of calcite acid dissolution is at least 8 orders of magnitude higher than oxide acid dissolution (Anon,
 207 2004) i.e., the protons are consumed faster by the calcite than by the oxidation reaction. (iii) The oxidation processes
 208 diminish, due to adsorption or precipitation of $\text{Mn}^{2+/3+}$ as amorphous Mn-oxides on the birnessite (MnO_2) surface
 209 (Ding et al., 2022; Remucal and Ginder-Vogel, 2014; Stone and H, 1989), also supported by the very low manganese
 210 concentrations eluting (0.1 mM). (iv) Calcite dissolution is suppressed, resulting in a decrease in Ca^{2+} , EC, σ' , and
 211 pH. Indeed, the decrease in σ'' reflects the reduction in CaCO_3 content in the soil (Izumoto et al., 2020; Wu et al.,
 212 2010) and may also correlate to a reduction in active MnO_2 surfaces. To further support this suggested cascade of
 213 reactions, we tested the precipitation of $\text{Mn}^{2+/3+}$ as amorphous Mn-oxides.

214 3.3. Soil mineral characterization

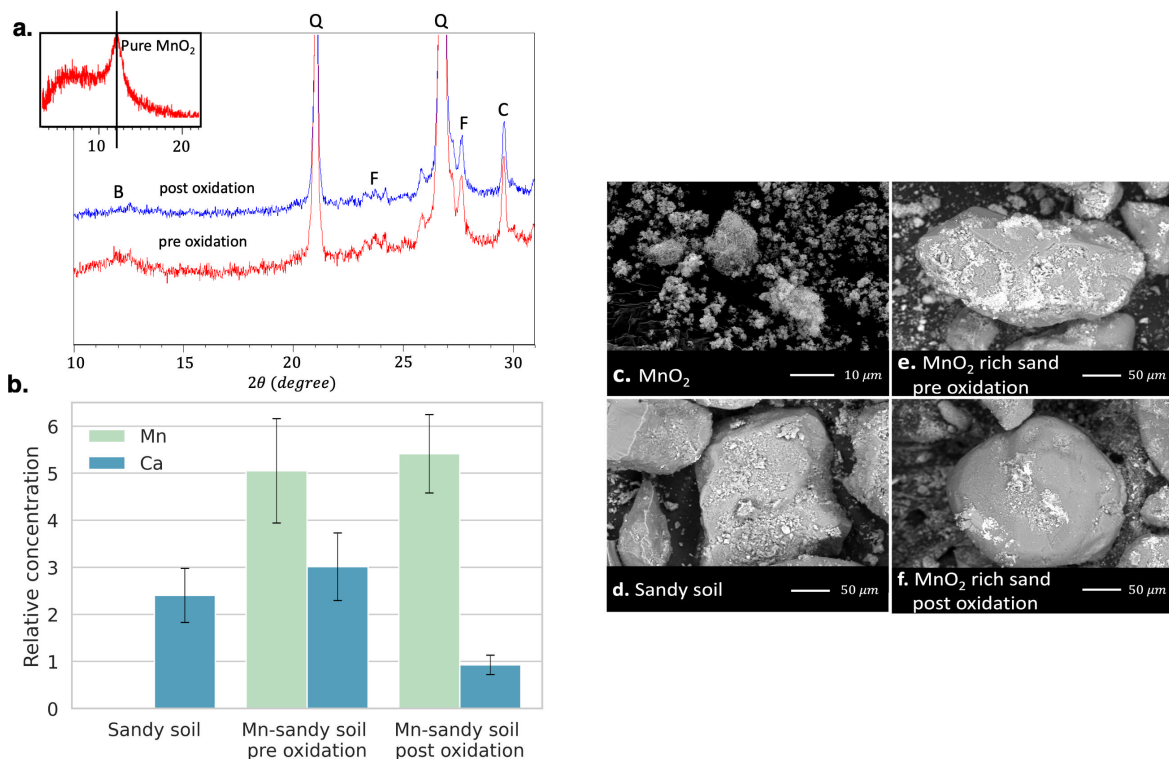

Figure 6. (a) X-ray diffraction full characterization curve of Mn-sandy soil, pre and post oxidation, and MnO_2 inset. B, Q, F, and C represent the peaks of birnessite, quartz, feldspar, and calcite (b) Ca and Mn relative concentration by EDS analysis, and scanning electron micrographs of (c) MnO_2 , (d) sandy soil, (e) MnO_2 rich sandy soil, and (f) MnO_2 rich sandy soil post oxidation.

215 To further test MnO_2 dissolution and $\text{Mn}^{2+/3+}$ precipitation, we characterized the soil samples before and after
216 hydroquinone oxidation using XRD (Fig. 6a). The sandy soil was found to be composed mainly of quartz, feldspar,
217 and calcite. X-ray diffractogram analysis confirmed that the Mn-sandy soil initially contained approximately 5% of
218 MnO_2 . After hydroquinone oxidation, the MnO_2 content was reduced to $\sim 1\%$, indicating that Mn^{4+} was most likely
219 reduced to $\text{Mn}^{2+/3+}$. These reduced manganese ions likely precipitated as amorphous Mn-oxides or were adsorbed onto
220 the MnO_2 surface, which would not be detected by XRD. This conclusion is further supported by the very low
221 concentration of $\text{Mn}^{2+/3+}$ eluting from the columns (Fig. 5b, d).

222 Finally, SEM images coupled with EDS analysis of the samples (2 replicates, 10 images per sample) confirm the
223 reduction in Ca content post oxidation, while the Mn content remains constant in both samples (Fig. 6 b). SEM images
224 vividly depict the morphology of pure MnO_2 (Fig. 6c), quartz, and CaCO_3 deposits in the sandy soil samples (Fig.
225 6d). In the Mn-sandy soil samples, MnO_2 is also notably present (Fig. 6e). Comparisons of post-oxidation samples to
226 pre-oxidation samples showed no significant visual changes (Fig 6. e, f).

227 **Conclusions**

228 We explored the oxidation mechanism of hydroquinone in Mn-sandy soil by applying a combination of methods,
229 including electrical measurements (SIP), crystallographic analysis (XRD), microscopic examination (SEM-EDS) of
230 soil minerals, and chemical assessments of the soil solution (HPLC, ICP, pH, EC, etc.). Integrating results from these
231 different methods provided insights into subsequent reactions such as mineral dissolution, chemical precipitation, and
232 leaching.

233 Our findings suggest that hydroquinone oxidation by MnO_2 surfaces to benzoquinone initiated a cascade of reactions
234 starting with local alterations in pH levels. These triggers increased CaCO_3 dissolution, while simultaneously, MnO_2
235 reduction results in its dissolution to $\text{Mn}^{2+/3+}$ and adsorption or precipitation as amorphous Mn-oxides on the MnO_2
236 surface. These results were supported by both chemical and electrical measurements. CaCO_3 dissolution was identified
237 by a reduction in Ca by SEM-EDS analysis and by the SIP signature, showing a consistent decline in σ'' due to a
238 reduction in polarized surfaces. The changes in Ca^{2+} concentrations in the effluent were monitored by ICP and
239 reflected by the alternating σ' signature. The effluent contained only minimal Mn concentration. XRD and SEM-EDS
240 analysis results demonstrated a reduction in MnO_2 content and constant Mn content, respectively.

241 These combined findings support the precipitation of $\text{Mn}^{2+/3+}$ as amorphous Mn-oxides and MnO_2 surface passivation,
242 most likely also contributing to the consistent decrease in σ'' . This study has provided valuable insights into the
243 sensitivity of SIP signatures to changes in soil properties, due to oxidation processes within the soil. Future research
244 should include the dynamic role of microbial activity in altering soil redox conditions, leading to MnO_2 reduction or
245 CaCO_3 dissolution. Furthermore, deeper exploration into the implications of soil structure changes resulting from
246 CaCO_3 dissolution and precipitation on the fate of pollutants in the subsurface is necessary, considering diverse
247 pollutant groups, organic matter, etc. In natural environments and at field scale, the complexities will require further
248 investigation, potentially formulating effective environmental remediation strategies.
