20 **Abstract:** Secondary organic aerosols (SOA) from highly volatile organic compounds
21 (VOCs) are currently not well represented in numerical models as their heterogeneous
22 formation mechanisms in the atmosphere remain unclear. Based on the smog chamber
23 experiments, here we investigated the yield and formation pathway of SOA from acetone
24 photochemical reactions under low NO_x condition in the presence of preexisting haze
25 particles ((NH₄)₂SO₄, and NH₄HSO₄) and saline mineral particles (Na₂SO₄) under ammonia-
26 rich conditions. Our results showed that the yield of acetone-derived SOA is remarkably
27 enhanced via multiphase reactions in the presence of these preexisting seeds especially for
28 the saline mineral particles. We found that aerosol acidity is a key factor controlling the
29 formation pathways of acetone-derived SOA, in which organic acids, alcohol and carbonyls
30 produced from acetone photochemical reactions dissolve into the aqueous phase of the
31 preexisting seeds and subsequently esterify and/or oligomerize into SOA that consist of
32 larger molecules on the acidic aerosols but smaller molecules on the neutral mineral
33 aerosols. Moreover, light absorption ability of the acetone-derived SOA formed on
34 (NH₄)₂SO₄ aerosols is stronger than that formed on Na₂SO₄ mineral particles especially in
35 the presence of ammonia due to a formation of N-containing organics. By comparing with
36 that from methylglyoxal (MGly), we found that the total SOA from acetone in the chamber
37 is 2.8–8.2 times that from the irreversible uptake of MGly, suggesting that only considering
38 MGly as the precursor of acetone-derived SOA will probably underestimate the role of
39 acetone in the global SOA production since acetone abundantly exists in the troposphere.

42

43 **1. Introduction**

44 Secondary organic aerosols (SOA) are the major component of fine particles in the
45 atmosphere and produced from the photochemical oxidation of volatile organic compounds
46 (VOCs) (Zhang et al., 2015a; Srivastava et al., 2022; Wang et al., 2016b), which
47 significantly affects human health and global climate change (Jo et al., 2023; Chowdhury et
48 al., 2022). However, current numeric models cannot predict the evolution of atmospheric
49 SOA accurately; one of reasons is that models often only consider the partitioning process of
50 condensable oxidation products of VOCs as the major formation pathway of SOA and
51 neglect the contribution of heterogeneous reactions of highly volatile VOCs to atmospheric
52 SOA (Heald et al., 2005; Li et al., 2023).

53 A number of researchers have reported that SOA formation can be promoted
54 significantly in the presence of hydrated seeds by heterogeneous reactions (Wong et al.,
55 2015; Nguyen et al., 2014; Liu et al., 2018; Ge et al., 2017). For instance, Wong et al. (2015)
56 reported that more isoprene SOA was formed on deliquescent ammonium sulfate seeds in
57 comparison with that on the efflorescent ones. Such an enhancing effect of multiphase
58 chemistry on SOA formation has also be found by Liu et al. (2018) and Wang et al. (2022) in
59 their laboratory experiments. Their results showed that SOA multiphase formation is
60 affected by the aerosol liquid phase properties such as acidity, ionic strength and mixing
61 state, which can alter the gas-to-particle phase partitioning of VOC and change the
62 formation process of SOA (Zhang et al., 2023; Riva et al., 2019; Riva et al., 2016; Bateman
63 et al., 2014; Kampf et al., 2013; Wei et al., 2022). Amorim et al. (2020) analyzed the OH
64 reactivities of organic acids in aqueous phases with different pH, and found that all the
65 organic acids exhibited larger OH reactivities under basic conditions than those under acidic
66 conditions, indicating that aerosol acidity can influence the gas-particle partitioning and the
67 multigeneration oxidation of volatile organics in liquid phase (Wei et al., 2022; Amorim et
68 al., 2021; Amorim et al., 2020; Zhao et al., 2006; Lv et al., 2022). Moreover, a few studies
69 reported that the uptake of VOC oxidation products by inorganic aerosols can be affected by
70 a salting-in/salting-out effect (Waxman et al., 2015; Wang et al., 2016a). These results
71 suggest that heterogeneous reactions of VOCs are important sources of atmospheric SOA,

72 which are complex and affected by many factors. Currently, only a limited number of
73 volatile organics, such as glyoxal, methylglyoxal (MGly), formaldehyde and epoxydiols,
74 have been investigated by chemical transport models for their contribution to the
75 atmospheric SOA through heterogeneous reactions (Heald et al., 2005; Li et al., 2023; Fu et
76 al., 2008; Moch et al., 2020). While the role of heterogeneous reactions in SOA formation
77 from many other more volatile organics in the atmosphere is still unclear and is ignored
78 generally by model work.

79 Compared to glyoxal, MGly and formaldehyde, acetone is much more volatile, which is
80 of a Henry's law constant (K_H) being 2–4 orders of magnitude lower than the three species
81 and abundantly exists in the atmosphere from the ground surface to the upper troposphere
82 (Seinfeld and Pandis, 2006). Acetone can be directly emitted from the natural and
83 anthropogenic sources and indirectly produced from oxidation of hydrocarbons (Jacob et al.,
84 2002; Wang et al., 2023). Photolysis and OH oxidation are main sinks of acetone in the
85 atmosphere, with photolysis contributing 45% of the sink, OH oxidation 30%, ocean uptake
86 and dry deposition to land 25% (Jacob et al., 2002). Numerous studies have reported the
87 reaction mechanisms of acetone's photolysis and OH oxidation, and have estimated their
88 contributions to hydroxyl radicals in the upper troposphere and lower stratosphere,
89 respectively (Stefan and Bolton, 1999; Arnold et al., 2004; Raff et al., 2005; Wang et al.,
90 2020). However, the role of acetone in SOA heterogeneous formation remains unclear. A
91 laboratory experiment showed that deliquesced inorganic aerosols may promote SOA
92 formation from the photochemical oxidation of acetone significantly (Ge et al., 2017), but
93 up to now the yield of SOA derived from acetone photochemical reactions and the impact of
94 inorganic aerosol physicochemical properties on SOA formation from acetone have not been
95 reported. Therefore, the formation mechanism and the importance of acetone-derived SOA
96 in the atmosphere remain unclear, where acetone ubiquitously co-exists with NH_3 and
97 preexisting aerosols. MGly is an important product of acetone photochemical reactions with
98 14% molar yield as calculated by GEOS-Chem, which can partition into aqueous phase
99 followed by oligomerization, oxidation by OH or/and reaction with NH_3 or organic amine to
100 form SOA (De Haan et al., 2019; Aiona et al., 2017; Li et al., 2021b; Yasmeen et al., 2010;

101 Zhang et al., 2022). Currently, the SOA module in chemical transport models primarily
102 encompasses the homogeneous reactions of various volatility VOCs and heterogeneous
103 reactions of isoprene epoxydiol, glyoxal, methylglyoxal, hydroxymethyl-methyl- α -lactone,
104 2-methylglyceric acid, and 2-methyltetrols on the aerosol surface. Notably, these models do
105 not account for SOA formation from the heterogeneous photochemical reactions of acetone
106 on aerosols (Fu et al., 2008; Huang et al., 2024a; Huang et al., 2024b; He et al., 2024; Zheng
107 et al., 2023). However, Ge et al. found that other products derived from acetone photo-
108 oxidation such as alcohols and organic acids also can dissolve into the aqueous phase and
109 transform into SOA by esterification (Ge et al., 2017), indicating that only considering the
110 uptake of MGly will probably underestimate the contribution of acetone to the global SOA
111 production. Thus, it is necessary to investigate the SOA formation from acetone and
112 compare it with MGly-SOA.

113 In this work, we quantitatively investigated the effects of deliquescent seeds and NH_3
114 on SOA formation from the photochemical reaction of acetone via chamber experiments,
115 and compared the difference of SOA formation processes in the presence of different seed
116 particles. We for the first time revealed a key role of seed acidity in controlling the yield and
117 formation pathways of SOA from acetone photochemical reactions, in which NH_3 and dust
118 particles can greatly enhance the production and light absorption of acetone-derived SOA.

119 **2. Experiments section**

120 **2.1 Materials and methods**

121 All batch mode experiments in this study were performed in a 4 m³ sealed Teflon smog
122 chamber (Figure S1). Firstly, zero air and seed particles were introduced into the chamber.
123 Then, acetone, H_2O_2 and NH_3 were introduced sequentially for the heterogeneous reactions.
124 The experiment details are reported by our previous studies (Ge et al., 2019; Zhang et al.,
125 2021; Liu et al., 2021a).

126 Briefly, zero air produced by the Zero Air Supply (Model 111 and Model 1150, Thermo
127 Scientific, USA) was used as the background gas in this study. Saturated water vapor flow
128 produced by bubbling zero air through ultrapure water (Milli Q, 18.2 M Ω , Millipore Ltd.,
129 USA) was introduced into the chamber for adjusting the relative humidity ($85 \pm 1.0\%$ RH).

130 Three types of water-solutions containing Na_2SO_4 , $(\text{NH}_4)_2\text{SO}_4$ and NH_4HSO_4 were nebulized
131 to produce seed particles. A polydisperse mode of wetted inorganic aerosols was generated
132 from the solutions by using a single jet atomizer (7388SJA, TSI) and directly introduced into
133 the chamber as droplets without any dessication. Reactant gases including acetone, H_2O_2 ,
134 NH_3 and SO_2 were added separately into the chamber along with a N_2 flow using a glass
135 syringe (Liu et al., 2022; Liu et al., 2021b).

136 **2.2 Smog chamber experiments and characterization**

137 **2.2.1. Smog chamber experiments**

138 In this study, the chamber experiments can be divided into two phases: Phase I, SOA
139 formation from the photochemical oxidation and photolysis of acetone on aerosols was
140 investigated, in which the OH radicals were produced from the photolysis of H_2O_2 under 254
141 nm UV irradiating conditions; Phase II, the effect of NH_3 on SOA formation was explored
142 under dark conditions. The H_2O_2 concentrations injected into the chamber were 2.95×10^{13}
143 molecules cm^{-3} in all experiments. The influence of different inorganic particles on the two
144 phases were studied. To compare the influence of different inorganic particles on the SOA
145 formation, SO_2 was added into the chamber after Phase II to produce $(\text{NH}_4)_2\text{SO}_4$ aerosols
146 during the Na_2SO_4 seed experiments. All the experiments were conducted under $85 \pm 1.0\%$ RH
147 conditions and thus all the seeds in the chamber were deliquescent. At the end of each
148 experiment, aerosol in the chamber were collected on 47 mm quartz filters and stored at
149 -20°C prior to analysis. The experimental conditions are shown in Table S1.

150 **2.2.2. On-line monitoring**

151 RH and temperature inside the chamber were monitored online. The temperature in the
152 chamber was stabilized at $25 \pm 1^\circ\text{C}$ by using air conditioners. Concentrations of VOCs and
153 SO_2 in the chamber were monitored by a proton transfer reaction time-of-flight mass
154 spectrometer (PTR-TOF-MS, Ionicon Analytik, Innsbruck, Austria) and a SO_2 analyzer
155 (Model 43i, Thermo scientific), respectively. Size distribution and mass concentration of
156 aerosols during the reaction process were measured by a scanning mobility particle sizer
157 (SMPS, model 3082, USA). The real-time chemical composition evolution of aerosols in the
158 chamber was measured by a high-resolution time-of-flight aerosol mass spectrometer (HR-

159 ToF-AMS, Aerodyne Research Ltd, USA), which was operated on a high sensitivity V-mode
160 with a 30 s time resolution. Prior to the experiments, ionization efficiency of the AMS was
161 calibrated by using 300 nm NH₄NO₃ particles and the value was 5.01×10⁻⁸, and the relative
162 ionization efficiency (RIE) for ammonium was 4.6. The RIE for sulfate was calibrated using
163 (NH₄)₂SO₄ particles, and the value was 0.8.

164 Particle wall loss in the chamber was corrected using a total-mass-concentration-based
165 method and the detailed descriptions were shown in Text S1 (Liu and Abbatt, 2021; Zhang et
166 al., 2024). The wall loss of NH₃ and VOCs in the chamber was also corrected (see the details
167 in Text S2 and S3) (Li et al., 2021a; Huang et al., 2018; Zhang et al., 2015b). Aerosol liquid
168 water content (ALWC) was estimated using the E-AIM thermodynamic model IV, and the
169 pH values of aerosols were calculated by Eq.1.

$$\text{pH} = -\log_{10} (\gamma_{\text{H}^+} m_{\text{H}^+}) \quad (1)$$

170 Where γ_{H^+} and m_{H^+} were the activity coefficient and molality of H⁺ calculated by E-AIM
171 model, respectively.

172 **2.2.3. Off-line analysis of particles**

173 The collected samples were extracted with 15 mL of Milli-Q pure water in an ultrasonic
174 bath for 30 min, and filtered by a 0.45 μm PES syringe filter. The concentration of water-
175 soluble organic carbon (WSOC) and light absorption of the extracts were analyzed by a total
176 organic carbon analyzer (model TOC/TN-LCPH, Shimadzu Inc. Japan) and a liquid
177 waveguide capillary cell (model LWCC3000, Ocean Insight. USA) coupled with a UV/Vis
178 spectrophotometer (ocean insight) over a wavelength range of 200–900 nm, respectively.
179 Light absorption (Abs_λ) and mass absorption coefficient (MAC) of the water extracts were
180 calculated (see the details in Text S4). In addition, the collected particles were extracted with
181 pure methanol and analyzed for their chemical compositions using an ultrahigh-resolution
182 orbitrap mass spectrometer (Q-Exactive Orbitrap mass spectrometer, Thermo Scientific,
183 Germany) (Jia et al., 2023). Specifically, imidazole compounds (IMs) were determined using
184 the orbitrap-mass spectrometry, and the detailed analysis methods were reported in our
185 previous study (Liu et al., 2023).

186 **2.2.4. Observation-Based Chemical Box Model**

187 In this work, an observation-based model (OBM) incorporating the latest version 3.3.1
188 of MCM (MCM v3.3.1; available at <http://mcm.leeds.ac.uk/MCM/>) was utilized to simulate
189 the acetone photochemical reactions in the chamber. The observation levels of acetone,
190 acetaldehyde, formic acid and acetic acid throughout the photochemical reactions, along
191 with meteorological parameters (temperature and relative humidity) and the initial H₂O₂
192 concentration, were incorporated into the OBM-MCM model as constraints. The
193 comprehensive MCM mechanisms related to the photochemical reactions of acetone and
194 other VOCs observed in this work were also incorporated into the OBM-MCM. The
195 photolysis rate for H₂O₂ is $9.1 \times 10^{-6} \text{ s}^{-1}$. The average concentration of OH radicals during the
196 reactions is $5.89 \times 10^6 \text{ molecules cm}^{-3}$. The time series of OH and HO₂ radical concentrations
197 are shown in Figure S2.

198 **3. Results and discussion**

199 **3.1. Formation of acetone-derived SOA**

200 Figure 1 shows the time evolution of gas and particle phase species during the reaction
201 in the presence of (NH₄)₂SO₄ seeds. In this study the whole smog chamber reaction process
202 consists of two phases, of which Phase I is a photochemical reaction of acetone without
203 NH₃(g) and Phase II is a dark reaction with introduced NH₃. During the Phase I, once the
204 light was turned on the gas phase concentrations of MGly, acetaldehyde, formic acid and
205 acetic acid quickly increased with a decreasing acetone (Phase I, Figure 1a), while SOA
206 were instantly produced and sharply increased to over $90 \mu\text{g m}^{-3}$ (Phase I, Figure 1b). When
207 the concentration of SOA during the Phase I did not change and even started to decrease, the
208 light was turned off and NH₃(g) was introduced into the chamber (Phase II). According to
209 the formation time of these gas products, acetaldehyde and MGly are often taken as the first-
210 generation products, while formic and acetic acids are usually considered as the final-
211 generation products (Poulain et al., 2010). Oxidation state of compounds (OSc) and O/C
212 elemental ratio of SOA in the aerosol phase continuously increased during the reaction
213 process (Figure 1c), which is corresponding to a decreasing fraction of CHO⁺ plus C₂H₃O⁺
214 and an increasing fraction of CO₂⁺ (Figure 1d), indicating an efficient conversion of
215 carbonyl compounds to carboxylic acid compounds. In the Phase I, we observed an aerosol-

216 phase decreasing trend of molar ratio of NH_4^+ to SO_4^{2-} , which was accompanied by an
217 increasing trend of N/C ratio of SOA (Figures 1b and 1c), indicating a transformation of
218 inorganic NH_4^+ to N-containing organic compounds. Such a phenomenon can be ascribed to
219 the uptake of organic acid products and a reaction of carbonyl compounds with the
220 $(\text{NH}_4)_2\text{SO}_4$ seeds during the Phase I (Liu et al., 2023; Li et al., 2021b). The pH value of
221 particles reduced rapidly from the initial 4.89 to 1.77 after a 30 min reaction due to the
222 formation of NH_4HSO_4 . The increased acidity can hinder the gas-particle partitioning of gas-
223 phase reaction products such as formic, acetic acids and methylglyoxal (Lv et al., 2022;
224 Zhao et al., 2006), as most weak acids are unable to dissociate at $\text{pH} < 2$ (Tilgner et al., 2021).
225 Therefore, SOA formation by the partitioning process sharply decreased after the 30 min
226 reaction time, resulting a slow increase of the SOA concentration. Subsequently, the SOA is
227 primarily formed through aqueous reactions on aerosols, leading to a persistent increase in
228 the O/C, N/C ratios and oxidation state of SOA.

229 As shown in Figures 1a and 1b, after NH_3 was introduced (Phase II) the formic and
230 acetic acids decreased dramatically while SOA did not change obviously, suggesting that the
231 decreases of the gas acids were mainly resulted from the enhanced wall loss due to the
232 neutralization of NH_3 on the chamber wall. Interestingly, we found that during the dark
233 reaction OSc and O/C ratio of SOA decreased slightly but their N/C ratio increased
234 significantly by a factor of approximately two (Figure 1c), implying that chemical
235 composition of SOA changed remarkably after NH_3 was introduced, although the SOA mass
236 did not change evidently (Figure 1c, Phase II). Moreover, such a slight decrement of O/C
237 and a significant increment of N/C in the elemental compositions of SOA (Figure 1c) were
238 also accompanied by a sharp increase of CHN family fragment fractions (Figure 1d, Phase
239 II), which can be explained by a carbonyl-ammonium condensation under the dark
240 conditions that forms a C-N bond and loses a H_2O molecule (Aiona et al., 2017; Li et al.,
241 2021b; Liu et al., 2023). Such an aqueous-phase dark reaction after NH_3 was introduced can
242 be further revealed by a change in SOA composition during the Phase II, which is
243 characterized by higher fractions of $\text{C}_x\text{H}_y\text{N}_1$ fragments in the Phase II than those in the
244 Phase I (Figure 2). Organic ammonium salt would contribute NH_x fragments instead of

245 fragments containing N, C, and O elements. Therefore, the CHN species should generated
246 from the reactions of carbonyls with NH₃ rather than the acid-base neutralization of organic
247 acid with NH₃ (Liu et al., 2015). As seen in Figure S3, the CHN family species mainly
248 include CHN, CH₄N, C₂H₆N, C₂H₇N, C₂H₄N, CH₅N and C₃H₆N ions, which are similar to
249 the fragments of N-containing organics produced from the reaction of carbonyls with
250 (NH₄)₂SO₄ (De Haan et al., 2010), and increased significantly during the Phase II, resulting
251 in an enhancing role of NH₃ on the SOA formation from acetone photochemical reaction.

252 **3.2. Enhancing effect of seeds on the SOA formation**

253 As shown in Figure S4, the concentration of SOA derived from acetone photochemical
254 reactions in the presence of (NH₄)₂SO₄ seeds is twenty times higher than that in the absence
255 of the seeds, suggesting that the occurrence of (NH₄)₂SO₄ seeds remarkably promoted the
256 SOA formation. Such an enhancing role was also found for Na₂SO₄ and NH₄HSO₄ seeds
257 (Figure S5). Because of the significant influence of surface area of aerosols on the
258 multiphase reactions (Huang et al., 2016), the SOA formation amounts were normalized by
259 the aerosol surface area (SA) to eliminate the interference of the difference in seed
260 concentrations. As seen in Figure 3a, the normalized concentration of SOA on Na₂SO₄ seeds
261 is two times larger than that on (NH₄)₂SO₄ and NH₄HSO₄ seeds, respectively, indicating that
262 the difference in physicochemical properties of seeds are of different promoting effects on
263 the SOA formation. MGly is one of the first-generation oxidation products of the acetone
264 photochemical reactions and also one of the critical precursor of SOA (Li et al., 2021b).
265 Therefore, we choose it as the target compound to explore the effect of the seeds on the SOA
266 formation. The multiphase reactions of acetone-derived MGly in the chamber can be divided
267 into two processes: the gas-particle partitioning and the subsequent aqueous phase reactions
268 (Srivastava et al., 2022; Waxman et al., 2015), which are further discussed as follows:

269 **3.2.1. The effects on the gas-to-particle phase partitioning**

270 It has been reported that the presence of salts in aerosol aqueous phase can significantly
271 influence the gas-particle phase partitioning of MGly, which can decrease the solubility of
272 MGly, i.e., salting out effect (Waxman et al., 2015). In this study, the effective Henry's law
273 constants ($K_{H, \text{salt}}$) of MGly in the aqueous phase of various seeds were further estimated by

274 Eq.2 (Waxman et al., 2015; Cui et al., 2021).

$$\log \left(\frac{K_{H,w}}{K_{H,salt}} \right) = K_S c_{salt} \quad (2)$$

275 Where $K_{H,w}$ and $K_{H,salt}$ are the Henry's law constants of MGly in pure water ($3.71 \times 10^3 \text{ M}$
276 atm^{-1}) (Curry et al., 2018) and in a salt solution, respectively; K_S is the salting constant or
277 Setschenow constant, which is 0.16 M^{-1} used in this work (Waxman et al., 2015), supposing
278 that the K_S values are similar in the three types of inorganic aerosols (Gen et al., 2018); c_{salt}
279 is the salt concentration in molality.

280 As shown in Figure 3b, $K_{H,salt}$ of MGly on Na_2SO_4 seeds in this study is more than two
281 times that on $(\text{NH}_4)_2\text{SO}_4$ and NH_4HSO_4 seeds, respectively, because of its lower salt
282 concentration and weaker salting out effect. The acidity of aerosol aqueous phase also can
283 affect the uptake of MGly. For instance, Zhao et al. (2006) found that the effective Henry's
284 law constant of MGly decreased with an increase of aqueous acidity in their laboratory
285 experiments. As shown in Figure 3b, the pH values of Na_2SO_4 , $(\text{NH}_4)_2\text{SO}_4$ and NH_4HSO_4
286 seeds in our chamber study are 7.0, 4.9 and -0.2, respectively, indicating that the neutral
287 nature of Na_2SO_4 seeds is more favorable for the uptake of MGly compared to the two other
288 acidic seeds. The SOA formation with NH_4HSO_4 seeds is similar to that with $(\text{NH}_4)_2\text{SO}_4$
289 seeds, which is possibly caused by the promotion of residual trace NH_3 in the chamber on
290 the uptake of acidic organics (Figure 3a).

291 In addition, the higher OSc and larger fraction of $\text{C}_x\text{H}_y\text{O}_z$ signals of SOA on Na_2SO_4
292 seeds (Figure 3a and Figure S6) may also be caused by enhanced uptake of carboxylic acids
293 (e.g., formic and acetic acids) in comparison with those by other two kinds of acidic seeds
294 (Huang et al., 2016), which also resulted in the less abundant formic and acetic acids in the
295 gas phase at the end of Phase I during the Na_2SO_4 seed experiment (Figure S7).

296 **3.2.2. The effects on the aqueous reaction**

297 The aqueous formation of SOA could be affected by the phase state and acidity of
298 aerosols (Amorim et al., 2020; Amorim et al., 2021; Shen et al., 2022). Since particles in all
299 the experiments of this work are deliquesced under 85% RH conditions (Wong et al., 2015;
300 Bateman et al., 2015), the influence of phase state can be neglected. Here, we focus on the

301 impact of aerosol acidity on the SOA formation pathway by characterizing the chemical
302 composition of SOA in the chamber using ESI-Q-MS technique. The mass spectra of SOA
303 formed on different seeds are shown in Figures 3c and 3d, and the detail peak assignments
304 are presented in Table S2, respectively. As shown by Figures 3c and 3d, the main peaks of
305 SOA formed on Na₂SO₄ seeds locate in the mass range lower than m/z=200, whereas the
306 main peaks of SOA formed on (NH₄)₂SO₄ seeds locate in the mass range larger than
307 m/z=200, clearly showing that SOA formed on neutral aerosols are dominated smaller
308 molecules while those formed on acidic aerosols are dominated larger molecules. The
309 phenomenon can be attributed to the promotion of the acid-catalyzed reactions in the
310 formation of high-order oligomers on the acidic seeds (Jang et al., 2002; Zhang et al.,
311 2015a). On the other hand, such different formation pathways of SOA also can be explained
312 by the difference of reactive oxygen species formed in the aqueous phase of the different
313 aerosols. On neutral aerosols, organic hydroperoxides produced from the reaction of
314 peroxides radicals and HO₂ radicals decompose and generate OH radicals through the
315 cleavage of the weaker O-O bond (Wei et al., 2022). Then, the OH radicals oxidize the
316 oligomers to low molecular weight (LMW) compounds (Zhao et al., 2017). In contrast, on
317 acidic aerosols the acid-catalyzed thermal decomposition of the organic hydroperoxides
318 leads to the formation of alcohol and ketone as the end products, which does not involve
319 radical formation (Wei et al., 2022; Yaremenko et al., 2016). Then, the carbonyls in the
320 aqueous phase will undergo hydration, oligomerization and acid-catalyzed aldol
321 condensation to form high molecular weight (HMW) compounds (Zhang et al., 2015a;
322 Kenseth et al., 2023; Li et al., 2021b). Such an explanation can be supported by the higher
323 OSc of SOA formed on the neutral aerosols (Figure 3a). On the other hand, the lower SOA
324 mass formed on acidic aerosols can also in part be attributed to the different reactivity of OH
325 radical to carboxylic group; OH radical does not react with the carboxyl group (COOH)
326 rapidly through H-abstraction from an O-H bond, but OH radical is more reactive to the
327 carboxylate group (ROO⁻) by abstracting an electron, which can result in a high SOA yield
328 on neutral aerosols (Amorim et al., 2021; Herrmann et al., 2015).

329 **3.3 The different effect of NH₃ on SOA formation on different seeds**

330 As shown in Figure 4a, when NH_3 was introduced into the reaction system (Phase II),
331 the ratio of N/C of SOA increased significantly because of the reaction of $\text{NH}_4^+/\text{NH}_3$ with
332 carbonyls on acidic $(\text{NH}_4)_2\text{SO}_4$ and NH_4HSO_4 seeds, but such an evident change was not
333 observed in the presence of NH_3 for neutral Na_2SO_4 seeds. One of the reasons is that NH_3
334 dissolve more readily on acidic aerosols. The gas-to-particle phase partition coefficients of
335 NH_3 ($\epsilon(\text{NH}_4^+)$) on different seeds were calculated (Text S5) (Guo et al., 2017; Lv et al.,
336 2023). As shown in Figure 4b, $\epsilon(\text{NH}_4^+)$ is zero and 1.0 for Na_2SO_4 and NH_4HSO_4 seeds,
337 respectively, suggesting that NH_3 was almost not absorbed by Na_2SO_4 seeds but efficiently
338 absorbed by NH_4HSO_4 seeds. The phenomenon can be confirmed by the Figure S8, more N
339 mass partitioned on more acidic aerosols. Liu et al. (2015) analyzed the uptake of NH_3 onto
340 SOA and also found that the uptake coefficient positively correlated with particle acidity.
341 Several studies put forward that the reaction of NH_3 with carbonyl are likely acid-catalyzed
342 (Zhang et al., 2015a; Liu et al., 2015). However, such a conclusion was inconsistent with the
343 phenomenon observed by Yang et al. (2024); they found that the light absorption ability of
344 brown carbon produced from the aqueous reactions of α -dicarbonyls with ammonium or
345 amine increased exponentially with the increase of pH. To resolve such a disagreement. We
346 analyzed the chemical composition of SOA detected by HR-ToF-AMS at different reaction
347 phases. As shown in Figure S6a-d, no change was observed on Na_2SO_4 particles at Phase II
348 after NH_3 was introduced, but the fraction of the CHN family species increased dramatically
349 on $(\text{NH}_4)_2\text{SO}_4$ and NH_4HSO_4 particles at phase II. Hence, we supposed that NH_3 can
350 promote the formation of N-containing SOA on acidic aerosols significantly via reacting
351 with carbonyl compounds. To verify such an assumption, we performed additional
352 experiments by introducing 500 ppb SO_2 into the chamber in the presence of Na_2SO_4 seeds
353 after Phase II (Phase III, Figure S9). The addition of SO_2 resulted in $(\text{NH}_4)_2\text{SO}_4$ produced
354 immediately in the chamber (Phase III, Figure S9a), and then the fraction of CHN species
355 increased sharply (Phase III, Figure S9b). Such results again demonstrate the pivotal role of
356 acidic particles in the formation of N-containing SOA.

357 The optical properties of the acetone-derived SOA on different particles were measured
358 by LWCC. Compared with the light absorption spectra of SOA formed on Na_2SO_4 seeds in

359 the absence of SO₂, an enhanced MAC peak at ~270 nm was observed for SOA formed on
360 (NH₄)₂SO₄ seeds and on Na₂SO₄ seeds with SO₂, respectively (Figure 4c). Such enhanced
361 absorptions are in agreement with that of the products from MGly and (NH₄)₂SO₄ reaction,
362 which displays prominent peaks at <240 and ~270 nm with a tail extending to >350 nm
363 (Kasthuriarachchi et al., 2020). The increased absorption peak at 270 nm can be ascribed to
364 a formation of imidazoles through the reaction of MGly with NH₄⁺ (You et al., 2020). In this
365 work, 1H-imidazole-4-carboxylic acid was observed for the SOA formed on (NH₄)₂SO₄
366 seeds (Figure 4d). However, the absorption peak at ~270 nm for the products of the Na₂SO₄
367 particles in the absence of SO₂ was weaker than that with (NH₄)₂SO₄ seeds significantly
368 (Figure 4c), further confirming the enhancement effect of acidic particles on the formation
369 of light-absorbing SOA, which is often termed as brown carbon.

370 **3.4. Formation mechanisms of acetone-derived SOA on different seeds**

371 Figure 5 shows the mass yield and MAC of acetone-derived SOA at the end of Phase II.
372 Clearly, SOA is formed more readily on neutral Na₂SO₄ seeds than on acidic (NH₄)₂SO₄
373 seeds. However, in the presence of NH₃, SOA formed on (NH₄)₂SO₄ seeds are more light-
374 absorbing than those formed on Na₂SO₄ aerosols, suggesting that a stronger acidity of
375 aerosol phase is favorable for the formation of light-absorbing organics, because NH₃ cannot
376 be taken up by neutral aerosols and thus carbonyl-ammonium condensation is only active
377 under acidic conditions and produce light-absorbing N-containing organics.

378 By combining the gas and aerosol phase chemistry evolution in the chamber, chemical
379 mechanism for SOA formation from acetone multiphase photochemical reactions on
380 different aerosols in the presence of NH₃ was proposed (Figure 6). The photochemical
381 reactions of acetone in this work include photolysis and oxidation by OH radicals.
382 According to the results of OBM-MCM, the reaction rates of photolysis and OH oxidation
383 are 3.66×10⁶ and 1.32×10⁷ molecules cm⁻³ s⁻¹, respectively. These two photochemical
384 reactions produce various peroxy radical (RO₂) and undergo two RO₂ fates, RO₂+HO₂ and
385 RO₂+RO₂ reactions. The concentrations of three main RO₂ concentrations and loss rates of
386 two RO₂ pathways during the experiments are shown in Figure S11 and S12, respectively.
387 Initially, CH₃O₂ and CH₃CO₃ are predominantly formed from the photolysis of acetone, and

388 $\text{CH}_3\text{COCH}_2\text{O}_2$ is generated from oxidation by OH radicals (Ge et al., 2017). Meantime, both
389 CH_3O_2 and CH_3CO_2 can be produced within the $\text{CH}_3\text{COCH}_2\text{O}_2$ chemistry, resulting in their
390 higher concentrations compared to $\text{CH}_3\text{COCH}_2\text{O}_2$ and a consistent increase in concentrations
391 throughout the experiments. Obviously, RO_2+HO_2 was the main pathway in RO_2 chemistry,
392 the loss rate of which was 3.19 times that of RO_2+RO_2 pathway. Concentrations of main
393 gaseous products from RO_2 chemistry are shown in Table S3. $\text{C}_2\text{H}_4\text{O}_3$ and $\text{C}_3\text{H}_6\text{O}_3$ are
394 intermediate volatility organic compounds (IVOCs) and can undergo gas-particle
395 partitioning readily to form SOA. Moreover, there are abundant gas-phase intermediate
396 products containing hydrophilic functional groups such as alcohol, ketone and organic acids
397 formed from acetone photochemical reactions, which can dissolve into aqueous phase and
398 undergo further oxidation reaction, esterification reaction and radical-radical reaction to
399 form SOA on particles (Poulain et al., 2010; Ge et al., 2017). For example, the dissolved
400 MGly can be hydrolyzed and then oxidized into organic acids such as pyruvic and oxalic
401 acids or proceeds to a series of oligomerizations to produce many oligomers, giving rise to
402 SOA formation. The acetone alcohol can react with acetic acid to form esters $\text{C}_5\text{H}_8\text{O}_3$ in
403 aqueous phase. The organic hydroperoxide $\text{C}_3\text{H}_6\text{O}_3$ produced from acetone- RO_2+HO_2
404 pathway also can react with acetic acid and pyruvic acid to form $\text{C}_5\text{H}_8\text{O}_4$ and $\text{C}_6\text{H}_8\text{O}_5$ in
405 particle phase, respectively. These esterification reactions can also contribute to SOA
406 formation effectively.

407 In the presence of NH_4^+ , carbonyl compounds in the aerosol phase can react with free
408 NH_3 molecules and produce N-containing SOA including imine, imidazole and other
409 oligomers (Liu et al., 2023). LMW SOA are formed readily in neutral aerosol phase, while
410 HMW SOA and N-containing brown carbon are formed favorably in acidic aerosol phase,
411 because the acidic condition is favorable for the uptake of NH_3 . The carbenium cations,
412 which are produced from protonation and dehydration of the hydration products of MGly
413 under acidic conditions, are the key intermediates for formation and propagation of
414 oligomerization (Ji et al., 2020). The oligomers and N-heterocycles are produced from the
415 nucleophilic addition of the negative hydroxyl O-atom of hydration products and the
416 negative N-atom of NH_3 to the carbenium cations, respectively (Li et al., 2021b; Li et al.,

417 2021a).

418 **3.5. Comparison of SOA from acetone with that from MGly in the chamber**

419 Currently, estimations of acetone-derived SOA by models only consider its product
420 MGly as the precursor (Fu et al., 2008). The uptake coefficient (γ) of MGly used in their
421 work is 2.9×10^{-3} without taking into account the influence of salting effects. Curry et al.
422 (2018) revised the γ to 10^{-10} - 10^{-6} after considering salting effects, aerosol thermodynamics,
423 mass transfer, and irreversible reactions of organic species with OH in aqueous phase. In
424 addition, previous laboratory studies showed a large difference among the uptake
425 coefficients of MGly, ranging from 4.0×10^{-7} to 2.4×10^{-2} (Li et al., 2023; Li et al., 2021b).
426 Salting effects and other VOCs such as formaldehyde and acetaldehyde also can influence
427 the SOA formation from aqueous reaction of MGly (Rodriguez et al., 2017; Waxman et al.,
428 2015). These documented values suggest a big uncertainty for SOA model work on MGly.
429 Currently, the uptake coefficient (γ) of MGly is set as 2.6×10^{-4} in CMAQ v5.3 (Chen et al.,
430 2021). Hence, the concentration of SOA formed in the chamber only from the irreversible
431 uptake of MGly can be calculated by Eq.3 (Chen et al., 2021; Li et al., 2023).

$$\frac{\partial aqSOA}{\partial t} = \left(\frac{\alpha}{D_g} + \frac{4}{v_{MGly}\gamma_{MGly}} \right)^{-1} A[MGLY] \quad (3)$$

432 Where $\frac{\partial aqSOA}{\partial t}$ is the formation rate of SOA in experiments; α is the effective radius of
433 aerosols; D_g is the gas-phase molecular diffusion coefficient; v_{MGly} is the gas-phase mean
434 molecular speed of MGly; A is the aerosol surface area per unit air volume; $[MGly]$ is the
435 vapor-wall loss corrected concentration of MGly (see the details in Text S3).

436 As shown in Table 1, the concentrations of the total SOA-derived from acetone
437 photochemical reaction in the chamber is 2.8-8.2 times that only from the irreversible uptake
438 of MGly, suggesting that only considering the role of MGly will inevitably underestimate
439 the contribution of acetone to SOA production in continental atmosphere, which is often
440 characteristic of high loadings of acetone and aerosols.

441 **4. Conclusions**

442 In this study we investigated the mass yield and formation mechanism of SOA from

443 acetone photochemical reaction in the presence of preexisting haze particles ((NH₄)₂SO₄ and
444 NH₄HSO₄) and saline mineral particles (Na₂SO₄) under ammonia-rich conditions. We found
445 that the presence of seeds can significantly promote the formation of acetone-derived SOA,
446 and the SOA yield on Na₂SO₄ seeds is larger than that on acidic (NH₄)₂SO₄ and NH₄HSO₄
447 seeds, indicating that the differences in physicochemical properties of pre-existing aerosols
448 are of different promoting effects on the acetone-derived SOA formation. In comparison
449 with those of (NH₄)₂SO₄, and NH₄HSO₄ seeds, the weaker salting-out effect and lower
450 acidity of Na₂SO₄ seeds are in favor of the gas-to-particle partitioning of the SOA
451 precursors. Moreover, SOA formed on the neutral seeds are dominated by smaller molecules
452 with a higher OSc, while those formed on the acidic seeds are dominated by larger
453 molecules with a lower OSc.

454 Because NH₃ cannot be taken up by neutral aerosols, heterogeneous reaction of
455 carbonyl with ammonium is only active under acidic conditions, which produces light-
456 absorbing N-containing compounds such as imidazoles, resulting in the acetone-derived
457 SOA formed on (NH₄)₂SO₄ seeds more light absorbing than those formed on Na₂SO₄ seeds.
458 In the chamber the total SOA-derived from acetone photochemical reaction is 2.8-8.2 times
459 that only from the irreversible uptake of MGly, suggesting that only considering the
460 irreversible uptake of MGly will inevitably underestimate the contribution of acetone
461 photochemical reactions to SOA in the atmosphere.

725

726

727

728

729

730 **Table 1.** Concentrations of total SOA formed in the chamber and that formed only from the
 731 uptake of methylglyoxal (MGly) in the chamber

Seed	SOA ^a ($\mu\text{g m}^{-3}$)	Surface area of seeds ($\text{m}^2 \text{m}^{-3}$)	MGly ($\mu\text{g m}^{-3}$)	γ^b	SOA _{MGly} ^c ($\mu\text{g m}^{-3}$)	SOA/SOA _{MGly}
Na ₂ SO ₄	140	9.30×10^{-3}	26.74	2.6×10^{-4}	17.17	8.2
(NH ₄) ₂ SO ₄	101	1.95×10^{-2}	42.95	2.6×10^{-4}	28.88	3.5
NH ₄ HSO ₄	57	1.14×10^{-2}	38.43	2.6×10^{-4}	20.17	2.8

732 ^aSOA values are the concentrations of SOA on different seeds observed in the experiments. ^bThe values of
 733 γ are consistent with the parameters of the irreversible uptake of MGly used in CMAQ v5.3. ^cSOA_{MGly} is
 734 estimated concentration of SOA formed from the irreversible uptake of MGly on different aerosols.

779 **Figure 1.** Time evolution of gas-phase and aerosol-phase species in the presence of
 780 $(\text{NH}_4)_2\text{SO}_4$ seeds during acetone oxidation process (Phase I: Photochemical reactions of
 781 acetone by OH radicals without NH_3 ; Phase II: Reaction of acetone oxidation products with
 782 NH_3 under dark conditions) (a) Gas-phase compounds; (b) SOA and molar ratio of NH_4^+ to
 783 SO_4^{2-} in the aerosol-phase; (c) N/C and O/C elemental ratios and oxidation state of
 784 compounds (OSc, $2 \times \text{O}/\text{C} - \text{H}/\text{C}$) of SOA; (d) Relative abundances of CO_2^+ , the sum of CHO^+
 785 plus $\text{C}_2\text{H}_3\text{O}^+$, and CHN family fragments of SOA.

Figure 3. Effect of seed acidity on SOA formation. (a) The amount SOA normalized by the surface area (SA) of aerosols and OSc of SOA in the presence of different seeds at Phase I; (b) Effective Henry's law constants ($K_{H, \text{salt}}$) of MGly and acidity (pH) of inorganic aerosols during the reaction; (c) and (d) Mass spectra of SOA from acetone oxidations by OH radicals with no NH₃ in the presence of Na₂SO₄ and (NH₄)₂SO₄ seeds, respectively.

806

807 **Figure 4.** Effect of ammonia on SOA formation. (a) The Difference in N/C ratio of Phase II
 808 relative to Phase I on different seeds; (b) Partitioning coefficients of NH₃ ($\epsilon(\text{NH}_4^+)$) on
 809 different seeds in the chamber; (c) MAC of acetone-derived SOA in the presence of different
 810 seeds; (d) Mass spectrum of 1H-imidazole-4-carboxylic acid formed during the
 811 heterogeneous oxidation of acetone in the presence of (NH₄)₂SO₄ seed.
