Abstract. This article presents a simple method for determining greenhouse gases (CH₄, CO₂, N₂O) ~~at ambient atmospheric~~
15 ~~levels~~ using an alternative new set-up of the chromatographic system. The novelty of the presented method is the application
of a Carboxen 1010 PLOT capillary column for separation of trace gases – CH₄, CO₂ and N₂O – from air samples and their
detection using a barrier discharge ionisation detector (BID). Simultaneously, a parallel molecular sieve column RT-MSieve
5A connected to a thermal conductivity detector (TCD) allowed the determination of CH₄, N₂ and O₂ concentrations from 0.±
2 to 100 %. The system was equipped with an autosampler transferring the samples without air contamination thanks to a
20 vacuum pump-inert gas flushing option. Method validation was performed using commercial gas standards and undertaking a
comparison measurement with a reference method: optical methods applying Picarro isotope and concentration instruments
with cavity ring-down spectroscopy for CO₂, CH₄ and N₂O. A three-day continuous measurement series of ~~the lowest~~ GHG
concentrations in ambient air and tests of typical vial sample measurements with increased GHG concentrations were
performed.

25 The advantage of this method is that the system is easy to set up and allows for simultaneous detection and analysis of the
main GHGs ~~in their ambient concentrations~~ using one GC column and one detector, thereby omitting the need for an electron
capture detector (ECD) containing radiogenic components for N₂O analysis and a flame ionisation detector (FID) with a
methaniser for low-concentration CO₂ samples. The simplification of the system reduces analytical costs, facilitates instrument
maintenance and improves measurement robustness.

30

1 Introduction

The reduction of greenhouse gas (GHG) emissions caused by human activity presents a major challenge that needs to be
addressed in order to limit the effects of global warming. The main GHGs responsible for global warming are CO₂, CH₄ and

N₂O (Lamb et al., 2021). Besides natural sources (e.g. volcanic activity, peat bogs, paddy soils, fresh and saltwater sediments
35 etc.), human activity also contributes to increasing GHG emissions by having an impact on global carbon and nitrogen cycling.
Therefore, precise measurement of GHG concentrations from natural sources and the environment is crucial in order to
quantify and estimate the contribution of different anthropogenic sources to worldwide emissions. The development of
analytical equipment in recent years has allowed the application of user-friendly methods to determine trace gases and monitor
slight changes in their concentrations precisely, even at the lowest levels expressed in units ppm and/or ppb (Zaman et al.,
40 2021). In the very near future, it can be expected that analytical devices and their measurement precision will be enhanced
further. Therefore, in order to maintain reliable continuity of measurement data on GHG concentrations in the atmosphere and
in other elements of the ~~earth's~~Earth's ecosystem, measurements should be performed with the utmost care using the most
modern techniques and devices available. It is also important to maintain easy access to simple and relatively cheap analytical
devices and their ease of use in order to obtain more statistical data. Often the analytical devices providing very precise
45 measurements have limitations in the analytical range and do not allow for observations of GHGs in a wide range of
concentrations observed in nature.
~~There is also a lack of relatively simple to use devices that do not require complicated modifications, which are designed to
analyze GHGs in a wide range of concentrations observed in nature.~~ Therefore, the development of a new analytical method
that is characterized by relatively high sensitivity in the range from the lowest to the highest concentrations is a desirable
50 feature, but quite very difficult to achieve in a single device.
Several methods are available for monitoring GHG based on optical techniques such as non-dispersive infrared spectroscopy
(NDIR), Fourier-transform infrared spectroscopy (FTIR), photoacoustic spectroscopy (PAS), tunable laser absorption
spectroscopy (TLAS), cavity ring-down spectroscopy (CRDS), and off-axis integrated cavity-output spectroscopy (OA-ICOS)
(Zaman et al., 2021). Some of these laser instruments allow for simultaneous analyses of CH₄, CO₂, N₂O and NH₃ using the
55 laser absorption spectroscopy method (e.g. Picarro G2509 Gas Concentration Analyzer). Although these devices guarantee the
stability of continuous measurements, their measurement range is much lower than chromatographic systems equipped with
typical detectors. For example, the Picarro G2509 operation range for CO₂ is 380-6000 ppm, for CH₄ 1-800 ppm and for N₂O
0.3-200 ppm. Other versions of Picarro analysers have been developed to measure single GHG concentrations, e.g. of CH₄,
CO₂ or N₂O, in combination with analyses of stable isotope composition of carbon or nitrogen from atmospheric air or
60 headspace samples (SSIM module). These methods are recommended only for the measurement of a single gas compound at
very specific concentrations. ~~Thus, the most reliable methods for checking samples~~ GHGs measurements in a very wide range
of concentrations are chromatographic methods (Ekeberg et al., 2004). ~~Thus the most reliable methods for checking samples
in a very wide range of concentrations are chromatographic methods: gas chromatography and and/or gas chromatography
coupled with mass spectrometry (GC-MS) (Ekeberg et al., 2004)~~ Another important limitation of the laser-based system is the
65 sample matrix, which should be stable and most similar to standard ambient air composition. Hence, these methods are not
well suited for untypical gas samples, like e.g. mine gases, or samples originating from laboratory experiments, e.g. with He
atmosphere.-

The GC systems can be developed for specific gases at ambient concentrations with precision similar or even better to those achieved by optical techniques. Van der Laan et al. (2009) developed the GC system which allows for simultaneous measurement of CH₄, CO₂, N₂O, CO and SF₆ using one gas chromatograph and single injection. This system allows the measurement of GHG from ambient air at remote stations. However, the system is very complex in individual parts as multiple gas valves, columns, methaniser, ECD and FID.

Gas chromatography with automated sampling injections is a very common, flexible and user friendly technique. The most common GHG measurement systems have been developed with: a thermal conductivity detector (TCD) (measurement of CH₄ and CO₂), flame ionisation detector - FID (measurement of CH₄ and CO₂ using a methaniser), electron capture detector - ECD (for N₂O measurement) (Hedley et al., 2006; Loftfield et al., 1997; Wang and Wang, 2003). Gas chromatography with automated sampling injections is very common and user friendly. The most common GHG measurement systems have been developed with two detectors: a flame ionisation detector - FID (measurement of CH₄ and CO₂ using a methaniser) and electron capture detector - ECD (for N₂O measurement) (Hedley et al., 2006; Loftfield et al., 1997; Wang and Wang, 2003). Other systems for CH₄ or CO₂ analyses are equipped with a thermal conductivity detector (TCD) connected to, for example, a Carboxen 1010 PLOT column or a FID system equipped with a methaniser (for reduction of CO₂ to CH₄ with H₂ supply). The GC systems can be dedicated for specific gases at ambient concentrations with precision similar or even better to those achieved by optical techniques. Van der Laan et al. (2009) developed the GC system which allows for simultaneous measurement of CH₄, CO₂, N₂O, CO and SF₆ using one gas chromatograph and single injection, that allows the measurement of GHGs from ambient air at remote stations. However, the system is characterised by a quite complex set-up with multiple gas valves, columns, methaniser, ECD and FID.

The most popular analytical technique for determining N₂O concentration is gas chromatography equipped with ECD using Porapak Q or Hayesep Q columns (Rapson and Dacres, 2014).

However, the use of an ECD is associated with additional difficulties. The main disadvantage of the ECD is its poor stability over a long period of time. During ongoing analyses, the cell interior may become contaminated and natural wear may occur. This can result in an increasing response to the tested concentrations. Consequently, within a week a significant increase in the measured area may be observed for the same analysed concentrations. This drift can be compensated for by the addition of an internal standard. Moreover, due to the presence of radioactive material in the ECD detector, special safety requirements have to be taken into account. According to current regulations, the purchase of a new unit, its possession and the disposal of a used detector cell involve a number of formal requirements.

In the case of the dielectric barrier discharge ionisation detector (BID), there are no such limitations and restrictions. The only requirement is to ensure a supply of helium of appropriate purity (99.9999 %). The detector is incredibly stable and maintenance-free for a very long period of time. Application of the BID for N₂O measurements has the advantages of avoiding radiogenic compounds present in the ECD and reducing the number of gases required. Combination of ECD+FID requires

installation of minimum 3 gas tanks (carrier gas He, Ar, or N₂; synthetic air; H₂ or H₂ generator; make-up gas for ECD N₂ of 6.0 purity, min. 99.9999%), whereas for BID only He tank is required.

105 Separation of CH₄, CO₂, and N₂O from one sample can be done using, for example, a system of two columns with 10-port valves (Scion Instruments, 2023) ~~and/or a single column e.g. Micropacked ST Shin Carbon (Shimbo and Uchiyama, 2022) or RT Q-Bond column (Shimbo and Uchiyama, 2022).~~ Methods using a single-column Micropacked ST Shin Carbon or RT Q-Bond are typically applied by Shimadzu using a GC Nexis 2030 gas chromatograph equipped with a dielectric barrier discharge ionisation detector (BID) dedicated to trace compounds (Shimbo and Uchiyama, 2022). ~~This set-up using single column and single BID detector is commonly used for determination of CH₄ and CO₂ at very low atmospheric concentrations (Gruca-Rokosz et al., 2020).~~ ~~This set up is commonly used for determination of CH₄ and CO₂ at very low atmospheric concentrations (Gruca-Rokosz et al., 2020), as well as CH₄, CO₂, and N₂O in the system, using FID-BID detectors (Shimbo and Uchiyama, 2022)~~ Unfortunately, the retention times for CO₂ and N₂O are often insufficient for correct measurement, especially by high CO₂ concentrations, when CO₂ tailing can even cover the N₂O peak. This separation can be enhanced by application of cryogenic methods for decreasing oven temperature. However, these methods are time-consuming and expensive. The present study tested an alternative solution that involved the application of Carboxen 1010 PLOT for CH₄, CO₂ and N₂O separation.

115 A simple chromatographic system is presented here for quick and accurate analysis of GHG using TCD and BID ~~detectors~~ of the GC Nexis 2030 gas chromatograph combined with an ~~AS-210 Greenhouse Gas Autosampler (SRI Instruments Europe GmbH, Bad Honnef, Germany) SRI autosampler at wide range of concentrations–ambient concentrations– from ambient~~ observed in the ~~earth's–Earth's~~ atmosphere ~~to the higher fluxes observed typically for the measured emission sources.~~

120 ~~The GC separation columns used in this study were performed with a porous layer open tubular column (Carboxen 1010 PLOT) and a molecular sieve column (RT-MSieve 5A), which assured the full separation of the analysed gases.~~ ~~The GC separation columns used in this study were a Carboxen 1010 PLOT and a RT-MSieve 5A, which assured the best separation of the analysed gases.~~ The results of the experimental data were compared with the concentrations obtained for CH₄, CO₂ and N₂O using the CRDS technique by Picarro analysers (~~G2201-i for CO₂ and CH₄; G5131-i for N₂O).~~

2 Materials and methods

2.1 Gas chromatography system

This chromatographic system was built based on the Shimadzu GC Nexis 2030 equipped with two parallel detectors: BID and TCD (~~Fig. 1~~). The carrier gas was controlled by an advanced flow controller (AFC) connected to a split/splitless injector.

130 Between the AFC and the injector, a two-position six-port valve with a 1 mL (or 2 mL) sample loop was placed on the carrier line.

– sformatowano: Indeks dolny

– sformatowano: Indeks dolny

– sformatowano: Indeks dolny

– sformatowano: Indeks dolny

– sformatowano: Indeks dolny

The gas chromatograph oven was equipped with an additional cryogenic option (CRG) where liquid nitrogen (LN₂) was used as a cooling agent, which allowed for separation at below-ambient temperatures. The samples from AS-210 Greenhouse Gas Autosampler~~the headspace sampler SRI AS 210 autosampler~~ (SRI Instruments GmbH) were transferred to the sampling valve through a stainless steel transfer line continuously warmed to 110°C with heating tape to prevent moisture contamination. The presence of moisture in the samples results in loss of sorption capacity of carbon molecular sieves which are used commonly for separation of gases (Fastyn et al., 2003). The injection was performed by valve rotation. The sample was transferred from the loop (1 mL or 2 mL) through the injector at a total flow of 10 mL/min, and was then split 1:7 just before the column inlet. This was sufficient to achieve a good peak shape with sufficient area.

Additionally, using a T-joint, the injection sample was then divided between two porous layer open tubular capillary columns filled molecular sieve 5A (RT-Msieve 5A 30 m x 0.32 mm x 30 µm; Restek, USA, Cat. No. #19722) and fused silica (Carboxen 1010 PLOT 30 m x 0.53 mm x 30 µm; Supelco, USA, Cat. No. #25467). ~~Additionally, using a t-joint, the injection sample was then divided between two columns: a Molecular Sieve 5A 30 m x 0.32 mm and a Carboxen 1010 PLOT 30 m x 0.53 mm.~~ The dimensions of the columns were selected to achieve a splitting ratio of 1:5, directing most of the sample to the Carboxen 1010 PLOT and BID. Corresponding calculations were performed in Shimadzu AFT (Advanced Flow Technology) software (Fig. 2).

Extremely low baseline noise (signal/noise ratio (S/N) always above 10) was achieved by a combination of two factors: a high purity carrier gas helium grade 5.0 connected to the Valco Helium Purifier HP2 (VICI Valco Instruments Co. Inc.) and particle traps (2.5 m x OD 0.32 mm) mounted on the columns' outlets. The presence of the traps protected the detectors from particles dislodging from the porous layer open tubular (PLOT) capillary column~~the PLOT column~~, which can cause spikes.

Both the detectors used are concentration dependent; therefore to obtain the highest sensitivity on the BID channel, the discharge gas flow rate was decreased from a default of 50 mL/min to 30 mL/min, which is the lowest possible flow (Barrier Discharge Ionization Detector for GC-2010 Plus BID-2010 Plus Instruction Manual. Shimadzu Corporation 2013). Below this value the plasma flame is not stable and tends to flicker or extinguish. Detection levels did not need to taken into consideration with the TCD:

The linearity of the both detectors response was controlled and maintained during all the measurements with minimal R_t²=0.99 applying at least 2two standard gases and 0 point.

2.2 Parameters of the separation and detection methods

The temperature programme for gas chromatography analyses started at 100 °C for 13 minutes, and later increased to 200 °C at a rate of 25 °C/min with the oven set at 200 °C for one minute. The temperature of the split/splitless injector was 120 °C.

The TCD and BID detectors were at an equal temperature of 220 °C. The carrier gas pressure was 70 kPa and the column flow was 5.25-3 mL/min. Linear velocity was 41.2 cm/s and purge flow was 1 mL/min. The total flow for split ratios 1, 2, 3, 4 and 5 was 11.5, 16.8, 22.0, 27.3 and 32.5 mL/min, respectively.

2.3 Standard gas mixtures

170 Standard gas mixtures used for testing and final determination of the measurements precision were atmospheric air from Wrocław (Poland) (analyses of N₂, O₂, CH₄, CO₂ and N₂O at ambient atmospheric concentrations) and a special gas mixture from Messer (CH₄ 10 ppm, CO₂, 1000 ppm, N₂O 50 ppm, diluted in pure N₂). The in-house standard of compressed air from Wrocław (Poland), which contained natural moisture (water vapour), was stored in the 10 literslitres gas cylinder. It was prepared by oil-free compressor for diving cylinders. The second standard was ordered in Messer Polska Sp. z o.o. and is the
175 commercially product prepared in Switzerland according to the norm ISO6141:2015. The linearity of calibration was maintained for each of the gases (R²=0.99). This standard was prepared in pure N₂, without moisture, in volume of 8 literslitres. Based on information from Messer each of the standard and contains filter-F10 filter, which protects outer valve from thete possible water vapour or solid particles. The standards were directly connected by 1/8²² capillary to the AS-210 Greenhouse Gas AutosamplerSRI instrument. The sample loops used for tests of standard gases were 1 mL and 2 mL. The atmospheric air
180 was tested for splits 1, 2, 3, 4 and 5. The special gas mixture from Messer was tested for splits 3, 4 and 5.

3 Results and Discussion

3.1 Basic testing of the SH-Q-BOND and Carboxen 1010 PLOT columns and BID detector

The chromatographic system for GHG analyses using a single BID was initially tested for application of the SH-Q-BOND column (30 m ~~x~~, 0.53 mm ID, ~~x~~ 20 um df, Cat. No. #221-75765-30) from Shimadzu, which allows for ~~detection~~ separation of CH₄, CO₂ and N₂O, and is resistant to water vapour contamination. The scheme showing GC configuration for testing of SH-Q-BOND and RT-Msieve 5A is presented in Appendix 1. In this configuration most of the parameters were exactly the same (length of the column, diameter, film thickness, flow parameters, split ratio) as in configuration using Carboxen 1010 PLOT column. The only differences were usage of SH-Q-BOND column for separation of CH₄, CO₂, N₂O and different column oven
190 temperature programme.

Separation of these gases was tested at different low temperatures of the column oven (30 °C, 35 °C and 40 °C). The lowest temperature (30 °C) was difficult to achieve quickly by the oven without using a cryogenic trap. At the laboratory's normal temperature (22 °C), it was possible to decrease the oven temperature rapidly to 35 °C and 40 °C, but unfortunately both ~~these~~ temperatures were insufficient to separate CO₂ from N₂O at a retention time interval longer than 30 seconds, which appeared
195 very problematic while analysing real samples of elevated CO₂ concentration. When the CO₂ concentration was high (e.g. 700 ppm), the tail of the CO₂ peak partially covered the N₂O peak, as shown below in Figures ~~43A and 3B~~, and ultimately the N₂O peak area was understated. Moreover, this set-up did not allow detection of CH₄ in atmospheric concentrations.

Figure 1: Chromatogram of ambient air gases separated using the SH-Q-BOND column and detected using BID

3A

— sformatowano: Czcionka: Pogrubienie

3B

Figure 3: A - Chromatograms of ambient air gases separated using the SH-O-BOND column and detected using BID; B – Zoomed chromatogram from Figure 3A

Therefore, after basic tests of the SH-Q-BOND column at different temperatures, it was decided to check the retention times of individual CH₄, CO₂ and N₂O gases on the Carboxen 1010 PLOT column. The Carboxen 1010 PLOT column offered very good separation of CO₂ from N₂O, even at a very high concentration (CO₂ 1000 ppm), as shown in Figure 24 (peaks of CH₄ and N₂O are visible only when zoomed). Moreover, the ambient CH₄ was very well separated from the N₂+O₂ peak (Fig. 24).

The longer programme of separation guaranteed the ideal separation of CH₄, CO₂ and N₂O (more than two minutes between each gas). The time of one single analysis is 18 minutes, but this is necessary because a low flow of the carrier gas is recommended for the Carboxen column by its manufacturer. A carrier gas flow that is too high (e.g. above 20 mL/min) causes faster destruction of the column and contamination of the particle trap, and subsequently of the detector, with fragments of the column filling. However, the disadvantage of the application of the Carboxen column is also its low resistance to water vapour. Therefore, before starting the analyses, all lines of the AS-210 Greenhouse Gas Autosampler SRI autosampler as well as the sample loop were carefully heated using heating tape and a gun heater to remove water from the stainless steel capillaries and metal parts of the valves. The parallelly connected column Rt-Msieve 5A and TCD allow for determination of N₂ and O₂ (and if necessary CH₄) concentrations in range from 0.2 to 100% (example showed in Fig. 5).

3.2 Compressed air standard measurements

The analyses of the compressed air standard with split ratios 1, 2, 3, 4 or 5 and using 1 and 2 mL sample loops showed a different precision, expressed as a coefficient of variation (CV: calculated as the standard deviation divided by the mean value, expressed in %). The CV of the CH₄ measurement (~~mean =~~ 1.895 ppm) was in the range of 3.31 to 8.57 % for the 1 mL sample loop and 1.51 to 2.76 % for the 2 mL sample loop. In the case of CO₂ (~~mean =~~ 411 ppm), the CV ranged from 0.91 to 2.83 % for the 1 mL sample loop and from ~~1.420.57~~ to 1.87 % for the 2 mL sample loop. The CV of the N₂O measurement was ~~significantly~~ lower for the 2 mL sample loop, and ranged from ~~7.092.76~~ to 12.67 %, compared with the 1 mL sample loop where the CV of the N₂O measurement ranged from 9.15 to 20.19 %. Generally, it was observed that gases at low detection limits (CH₄, CO₂) were measured more precisely using the 2 mL sample loop.

Measurement of N₂O in split ratio 3 resulted in a significantly higher CV when compared with the results obtained in split ratios 4 and 5 (Table 1). This is because the injection of a higher amount of water vapour contained in the sample partially covered the peak area of the N₂O (by increasing the baseline level), similarly to the measurement in split ratio 2 (CV 20.19 %). In this case the lower CV at split ratio 1 was only calculated for three measurements to avoid unnecessary contamination of the column.

The gases analysed using the TCD-detector, O₂ and N₂, were characterised by a narrow CV ranging from 0.10 to 0.39 %. The highest CV (0.39 %) was observed for the N₂ measurement with the sample loop 2 mL, where the peak area was very large. The results of the measurement (peak area, SD, CV) are presented in Table 1.

240

Tabela sformatowana

245 The main atmospheric gases had the lowest SD for split ratio 5—more than three times better precision than for split ratio 3. It was observed that in split ratios 1-3, the baseline was noised by vapour from the gas samples, and therefore the standard deviation was higher. The increasing dilution of the sample reduces the amount of water vapour entering the chromatography

column, and hence the measurement is more accurate. However, if the sample is diluted too much, the amount of N₂O will not be sufficient for precise measurement or N₂O will be below the detection limit. The present results showed that with split ratio 4, the amount of gas in the column was sufficient to detect CH₄, CO₂ and N₂O at atmospheric levels and obtain satisfactory measurement precision.

3.23 Standard gas mixture measurements

The CH₄, CO₂ and N₂O measurements of the special gas mixture standard at split ratios 3, 4 and 5 were characterised by a repeatable-repeatable CV within a narrow range from 0.11 to 3.22 %. The CV of the CH₄ measurement (10 ppm) using the 1 mL sample loop ranged from 0.11 to 0.55 %, while for the 2 mL sample loop the CV was in the range of 0.34 to 1.79 %. The CV of CO₂ (1000 ppm) for the 1 mL sample loop was between 2.05 and 3.08 % and for the 2 mL sample loop between 1.57 and 3.22 %. The N₂O measurement (50 ppm), which is a very high concentration (rare in the natural environment), was characterised by a CV in the range of between 0.18 and 0.44 % for the 1 mL sample loop and 0.85 to 2.14 % for the 2 mL sample loop. These values clearly show that measurements of the gas mixtures with relatively high concentrations of N₂O using BID were repeatable for all splits 3, 4 and 5, and were slightly better using the 1 mL sample loop. However, the application of the sample loops (1 and 2 mL) at split ratios 3, 4 and 5 guaranteed the achievement of reportable-repeatable results. Table 2 shows all the data of the standard gas mixture testing measurements.

Table 2: Peak area, SD (standard deviation) and CV (coefficient of variation) of special gas mixture measurements at split ratios 3, 4, and 5 with sample loops 1 mL and 2 mL

| Gas | Conc. | | Sample loop 1 mL | | | Sample loop 2 mL | | |

3.4 Direct measurement of ambient laboratory air using the ~~SRI autosampler~~AS-210 Greenhouse Gas Autosampler

270 Another testing of the GC system was carried out with the application of splits 3, 4 and 5 and sample loop 2 ml (Table 3). The ambient air from the laboratory on one day was analysed directly from the ~~AS-210 Greenhouse Gas Autosampler~~SRI autosampler (empty plate for vials, which enabled direct sampling of the ambient air from the needle to the line connected with the GC's sample loop). The tests were performed with splits 3, 4 and 5 (splits 1 and 2 were omitted to avoid excessive introduction of air containing natural moisture into the Carboxen column).

275 The CV of CH₄ was in the range of 3.40 to ~~7.444.10~~ % (the highest value for split ~~5~~4). The CV of CO₂ was in range of 1.31 to 2.29 %, whereas for N₂O it was between 3.11 and ~~7.704.04~~ %. These CV values are close to the results obtained during measurements of the compressed air standard (Section 3.3, Table 1). The difference between the two experiments is that compressed air always had the same composition and gas concentrations, whereas the CH₄ and CO₂ concentrations in ambient air could change slightly over time (daily variability).

280

Table 3: Peak area, SD (standard deviation) and CV (coefficient of variation) of direct measurements of laboratory air at split ratios 3, 4, and 5 with sample loop 2 mL

| Gas | Conc. | | Sample loop 2 mL | | |

3.5 Experimental measurement series comparing the GC results with the reference method (Picarro analyser)

285 To verify the long-term stability of the measurements and the system performance for real samples, a 55-hour-long measurement series of ambient laboratory air was performed. The subsequent air samples were measured in parallel with the GC setup and with the optical instruments dedicated to analyses of GHG concentrations and isotopic signatures (Picarro G5131-i for isotopic N₂O and Picarro G2201-i for CO₂ and CH₄) (Picarro, Santa Clara, USA). The reference methods were applied to check whether slight changes in GHG concentrations over the day/night period can be monitored well with this GC system. The reference instruments – isotopic Picarro – showed a quite narrow range of possible concentration measurements (Picarro G5131-i isotopic N₂O up to 2000 ppb, Picarro G2201-i up to 2000 ppm CO₂ and up to 12 ppm CH₄) but a very high precision for ambient concentrations, without the need for calibration. Therefore they served here as an ideal reference method. During this 55-hour time series, the Picarro measurement was performed every three minutes and the GC measurement every 19 minutes. For GC measurements, split 4 was applied. The concentration trends for CO₂ and CH₄ were observed to be generally in good agreement and the N₂O concentration was very stable (Fig. 36). Importantly, it was observed for CO₂ that after 24 hours the measurements were slightly recalibrated and shifted in relation to the reference method. This indicates the need for repeated calibration at least every 24 hours, especially for CO₂. However, even without recalibration, the maximum difference between the GC measurement and the reference value was below 3 % for both CO₂ and CH₄. The largest variations in the GC results were observed for N₂O, especially when comparing them to the very stable Picarro measurements. This is the most challenging analysis, since N₂O ambient concentrations are lowest and hardest to measure correctly. The maximum difference between the GC measurement and the reference value for N₂O was around 8 % and the standard deviation of GC measurements was 15 ppb, which represents a 4.4 % error. This is quite high when compared with Picarro statistics where the standard deviation over 55 hours of measurement was 0.24 ppb, which represents less than 0.1 % error. However, for typical N₂O measurements [of unknown sample](#) with GC techniques, a 5 % error is a satisfactory result, typically given as an accepted GC measurement error in research studies (Arnold et al., 2001; Harvey et al., 2020). The precision obtained for ambient air measurements is similar for CO₂ and CH₄ compared with classical FID measurements, with an error of around 2 % (Lofffield et al., 1997), but is lower when compared with ECD measurements, for which a 1.2 % error has been reported (Lofffield et al., 1997). Usually systems that enable the simultaneous measurement of CH₄ and CO₂ are very accurate, but the main limitation is the upper detection limit. For example, Wang and Wang (2003) achieved a CH₄ precision error in a range from 3.37 % (ambient concentration) to 0.05 % (60 ppm), or for CO₂ from 0.66 % (ambient concentration) to 0.04 % (4000 ppm). In the present system, higher concentrations of CH₄ can be measured by the TCD ~~detector~~ simply using a [RT-Molecular-Sieve-sieve](#) 5A column. The chromatographic system can be improved by the addition of a second gas valve aimed at transferring CO₂ to the TCD ~~detector~~ after separation using the Carboxen column. This would allow further improvement of this chromatographic system for the maximum range of measured GHG concentrations.

315

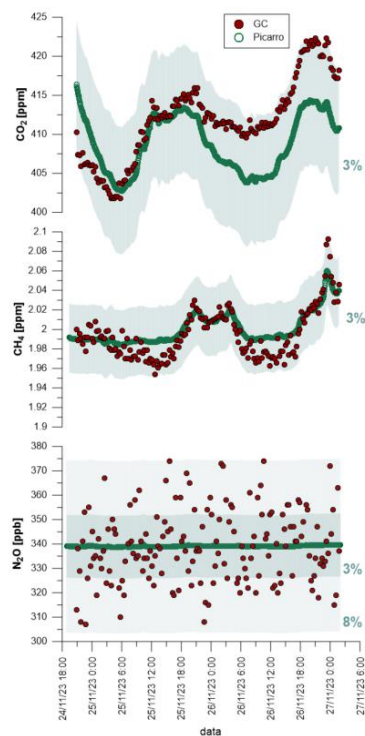

Figure 36: Comparison of CH₄, CO₂ and N₂O variations in ambient air measured using a Picarro analyser and the GC system

3.4. Conclusions

This article outlined a simple method for determination of CH₄, CO₂ and N₂O concentrations from ambient air. The main advantage is that the use of at least two ~~three~~ separate detectors can be avoided, including the ECD ~~deteetor~~ that contains radioactive materials, and FID which needs with methaniser to measure CO₂. A single column Carboxen 1010 PLOT can be successfully used for very good separation of ambient GHG (CH₄, CO₂, N₂O) in time interval enabling measurement of each gas separately without the effect of peak overlapping, and in parallel a connected Rt-MS sieve 5A column allows for determination of higher CH₄ concentrations as well control of the O₂ and N₂ concentrations in the sample. The main disadvantage of the method is the lack of direct measurement of samples with high CO₂ concentrations (above 4000 ppm) in the set-up presented here, which is the upper detection limit for the BID. In summary the detection limits of simplified GC

— sformatowano: Indeks dolny

— sformatowano: Indeks dolny

— sformatowano: Indeks dolny

— sformatowano: Indeks dolny

system are: CH₄ 1.8 ppm-100%, CO₂ 411-4000 ppm, N₂O 339-4000 ppm, O₂ 0.2-100%, N₂ 0.2-100%. Further reconstruction with an additional valve directing the separated CO₂ to the TCD ~~as well~~ would allow additional analyses of higher CO₂ concentrations.

330 Based on ~~these performed~~ tests, it is recommended that atmospheric GHGs are analysed using a BID at split ratio 4 or 5 and with a sample loop of 2 mL volume. This would help avoid unnecessary contamination of the Carboxen column with water vapour, therefore splits 1-3 should not be considered for the measurement of environmental gas samples. In this chromatography system, the CV of N₂O measurement at atmospheric level was ~~near 10-11-15~~ % (sample loop 1 mL), ~~or even~~ around ~~3-7-9~~ % (when using the 2 mL sample loop), CV of CH₄ measurement at atmospheric level was near 7 % (sample loop 1 mL), ~~or even~~ below 3 % (when using the 2 mL sample loop), CV of CO₂ measurement at atmospheric level was near 2 % (sample loop 1 mL), ~~and or even~~ around 1.5 % (when using the 2 mL sample loop). The diurnal variations for CO₂ and CH₄ can be monitored well with the precision below 3% error, whereas for N₂O measurements 8% error ~~must should~~ be taken into account.

340 ~~The presented results for the measurement precision are satisfactory for the most analytical needs for determining GHG fluxes in field studies or laboratory incubation experiments. However, we would like to emphasize that our this GC system is not designed for the most precise testing gases analyses at ambient concentration and monitoring daily changes or long-term periods. Its measurement accuracy is not sufficient for such purposes when compared with instruments using optical techniques or automated GC systems dedicated developed for GHG at ambient air concentration. The greatest advantage of proposed GC system is the ability to measurement GHGs at the widest possible concentration, almost from the near-ambient concentrations to 100%, and in any sample matrix, without the risk of damaging or decalibration of the equipment. It is easy to use and relatively cheap. Therefore, it can be successfully used for analyses of the gas samples with unknown GHG concentrations e.g. from soil chamber measurements, laboratory incubation studies, biogas plants, waste dumps, burning coal heaps, mines, or monitoring of environmental GHGs fluxes.~~

350 Authors contributions:

~~MB and PW constructed the analytical set-up. MB and DLS planned the measurement campaign; MB, DLS and PW performed the measurements; MB and DLS analyzed the data; MB, DLS, and PW wrote the manuscript draft; MB, DLS and PW reviewed and edited the manuscript.~~
