Abstract. The production mechanism of atmospheric nitrous acid (HONO), an important precursor of hydroxyl radical (OH), was still controversial. Few studies have explored the effects of particulate nitrate photolysis on HONO sources in different environment conditions across China. In this work, the photolysis rate constants of particulate nitrate for HONO production ($J_{\text{NO}_3^--\text{HONO}}$) were determined through photochemical reaction system with PM_{2.5} samples collected from five representative sites in China. We developed a method to correct and quantify the “shadowing effect” — potential light extinction within aerosol layers at heavy PM_{2.5} loadings on the filters — for $J_{\text{NO}_3^--\text{HONO}}$ measurements, which showing that elemental carbon (EC), the dominant light-absorbing component in PM_{2.5}, played a dominant role in it. The corrected $J_{\text{NO}_3^--\text{HONO}}$ values varied with sampling period and location over a wide range, distributing from $1.6 \times 10^{-6} \text{ s}^{-1}$ to $1.96 \times 10^{-4} \text{ s}^{-1}$, with a mean ($\pm 1 \text{ SD}$) of $(1.71 \pm 2.36) \times 10^{-5} \text{ s}^{-1}$. Chemical compositions, specifically nitrate loading and organic component, affected the production of HONO through particulate nitrate photolysis: high $J_{\text{NO}_3^--\text{HONO}}$ values were generally associated with the PM_{2.5} samples with high OC/NO₃⁻ ratio ($R^2=0.86$). We suggested that the parameterization equation between $J_{\text{NO}_3^--\text{HONO}}$ and OC/NO₃⁻ established in this work can be used to estimate $J_{\text{NO}_3^--\text{HONO}}$ in different aerosol chemical conditions, thus reducing the uncertainty in exploring HONO daytime sources. This study confirms that the photolysis of particulate nitrate can be a potential HONO daytime source in rural or southern urban sites, which are characterized by high proportion of organic matter in PM_{2.5}.

29

30

31 **1 Introduction**

32 Gaseous nitrous acid (HONO) is an important nitrogen-containing trace gas in the troposphere,
33 which can produce hydroxyl radical (OH) through photolysis, thus stimulating the enhancement of
34 atmospheric oxidation and the formation of secondary aerosols (Fu et al., 2019; Slater et al., 2020; Ren
35 et al., 2003; Li et al., 2011; Su et al., 2011). In recent years, the contribution of HONO to atmospheric
36 oxidation in heavily polluted conditions has attracted great attention (Villena et al., 2011; Fu et al.,
37 2019; Slater et al., 2020). Even though observational research on HONO has been conducted for nearly
38 40 years, the understanding of HONO daytime source was still controversial (Fu et al., 2019; Wang et
39 al., 2017; Mora Garcia et al., 2021). Numerous mechanisms have been proposed to explain the
40 extremely high HONO concentrations at noon, including direct combustion emission (Kurtenbach et al.,
41 2001; Liang et al., 2017; Liao et al., 2021), gas-phase reaction of NO and OH radical (Li et al., 2011;
42 Zhang et al., 2016), heterogeneous reaction of NO₂ (Wang et al., 2017; Ammann et al., 1998; Monge et
43 al., 2010; Stemmler et al., 2006), soil emissions (Su et al., 2011; Oswald et al., 2013; Melissa A, 2014;
44 Kim and Or, 2019), and the photolysis of HNO₃/nitrate on aerosol or ground surface (Zhou et al., 2003;
45 Zhou et al., 2011; Ye et al., 2016b; Ye et al., 2016a; Ye et al., 2017).

46 Particulate nitrate, which was conventionally considered as the ultimate oxidation product of NO_x,
47 can rapidly photolyze and recycle NO_x or HONO back to the gas phase (Andersen et al., 2023; Handley
48 et al., 2007; Beine et al., 2006; Ye et al., 2016a; Ye et al., 2017; Ye et al., 2016b; Gu et al., 2022b), at a
49 rate 10 to 300 times faster than the photolysis rate of gaseous HNO₃ ($\sim 7 \times 10^{-7} \text{ s}^{-1}$) under typical
50 tropical noontime conditions (Finlayson-Pitts, 2000). Recently, some field, laboratory and modeling
51 works have proposed that photolysis of particulate nitrate can be an important in situ source of HONO
52 in rural, suburban and urban environments (Ye et al., 2016b; Mora Garcia et al., 2021; Liu et al., 2019;
53 Bao et al., 2018; Wang et al., 2017). Fu et al. (2019) found that the photolysis of HNO₃/nitrate in the
54 atmosphere and deposited on surfaces was the dominant HONO source during noon and afternoon,
55 contributing above 50 % of the simulated HONO. However, there are large discrepancies in estimating
56 the rate constants in the atmosphere (Gen et al., 2022). In New York, Ye et al. (2017) reported that the
57 photolysis rates of particulate nitrate in clean areas were two orders of magnitude higher than that in
58 polluted areas, ranging from 6.2×10^{-6} to $5.0 \times 10^{-4} \text{ s}^{-1}$, with a median of $8.3 \times 10^{-5} \text{ s}^{-1}$. The proposed rate
59 constants of nitrate photolysis based on the aircraft observations over South Korea ranged from 7×10^{-6}

60 to $2.1 \times 10^{-5} \text{ s}^{-1}$ (Romer et al., 2018). Shi et al. (2021) derived the rate constant ($< 2 \times 10^{-5} \text{ s}^{-1}$) based on
61 chamber experiments, but found a limited role of this mechanism to HONO production. The
62 uncertainty of HONO production rate from the photolysis of particulate nitrate can reach up to 1.4 ppbv
63 h^{-1} , and greatly affect the accuracy of HONO source analysis (Liu et al., 2019; Lee et al., 2016; Ye et
64 al., 2016a). The highly-varied photolysis rate constant of particulate nitrate was closely associated with
65 environmental conditions and the aerosol chemical or physical characteristics, such as relative humidity
66 (RH), aerosol acidity, light intensity, and coexisting components (organic components, halogen, etc.)
67 (Gelencsér et al., 2003; Ye et al., 2016a; Bao et al., 2020; Wang et al., 2021; Reeser et al., 2013).
68 Elucidating the mechanism and dominant factors controlling the photolysis of particulate nitrate is
69 important to accurately estimate the HONO production rates from nitrate photolysis, thus improving
70 estimations of HONO budgets.

71 In general, the photolysis rate constant of particulate nitrate was derived through photochemical
72 experiments using bulk particle samples collected on filters (Ye et al., 2017; Bao et al., 2018).
73 Comparing with the suspended particles in the ambient atmosphere, the collected $\text{PM}_{2.5}$ particles in the
74 aerosol filters may present a multiple-layer structure, especially in heavy air pollution conditions (Bao
75 et al., 2018). The light-absorbing species within $\text{PM}_{2.5}$ particles would hinder the light absorption of
76 particulate nitrate in the lower layers of the filter sample, thus inhibiting the photolysis of particulate
77 nitrate, which was called the “shadowing effect” (Ye et al., 2017). The shadowing effect may be
78 negligible in clean air conditions but should be evaluated and quantified in heavy haze conditions.
79 However, previous works generally ignored this shadowing effect.

80 According to previous field observations, the $\text{PM}_{2.5}$ chemical composition, especially particulate
81 nitrate (NO_3^-), showed obvious spatial differences across China (Wang et al., 2022a, b; Wang et al.,
82 2022c; Wang et al., 2016; Cheng et al., 2024). As one of the key industrial development areas in China,
83 the Pearl River Delta Region (PRD) has a great number of large-scale industrial parks dominated by the
84 chemical industry, resulting in significant VOC emissions and a large proportion of organic matter (OM)
85 in $\text{PM}_{2.5}$. In the North China Plain (NCP), the particulate nitrate (NO_3^-) has surpassed sulfate (SO_4^{2-})
86 and OM to become the dominant $\text{PM}_{2.5}$ component in recent years (Wang et al., 2022b). For now, the
87 investigation of particulate nitrate photolysis in different atmospheric environments was limited in
88 China, and the influence of aerosol chemical or physical characteristics on HONO production was still
89 unclear. In this work, to shed light on the contribution of particulate nitrate photolysis to the HONO

90 daytime source, we examined the photolysis rate constant for HONO based on photochemical
91 experiments with PM_{2.5} samples collected from five typical sites in China. In addition, the shadowing
92 effect due to increasing aerosol particle loading on the filters was quantified. After correcting this effect,
93 the influence of various environmental conditions, including particulate nitrate, organic matter, and
94 aerosol acidity, on the formation of HONO was investigated and the possible role of this photolytic
95 process as HONO sources was also examined.

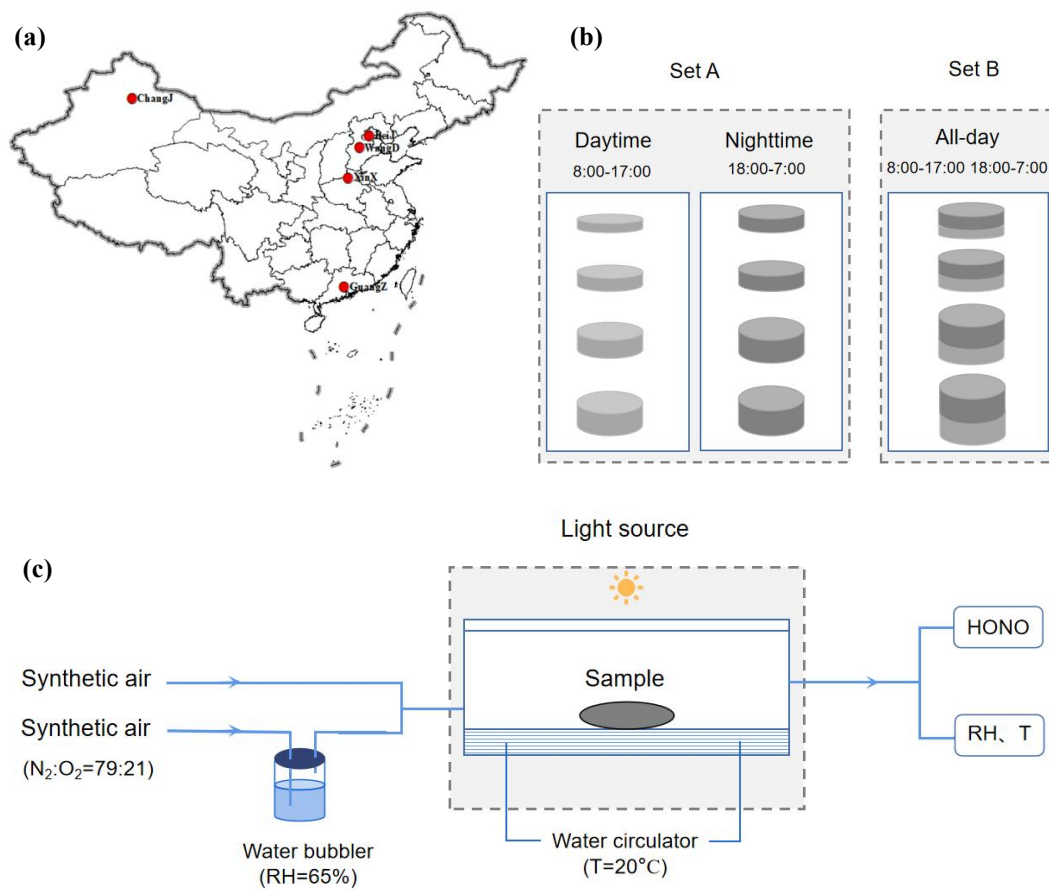

96 **2 Method**

97 **2.1 Sampling and filter treatment**

98 The ambient PM_{2.5} was collected on Teflon or quartz filters in autumn-winter seasons in five
99 representative sites, i.e., Beijing, Wangdu, Xinxiang, Guangzhou, and Changji, which were shown in
100 Figure 1a and described in detail in the Supporting Information. These cities were located in the North
101 China Plain (NCP, urban: Beijing, rural: Wangdu), Central China, Pearl River Delta Region (PRD), and
102 Northwestern China, respectively. The sampling flow rates ranged from 16.7 to 1050 L min⁻¹, the
103 sampling times from 9 h to 23 h, and the overall sampling volumes of air from 8 m³ to 1450 m³, to
104 collect a very wide range of particulate nitrate loadings. The comparison experiments between Teflon
105 and quartz filters have been conducted, and no significant differences in HONO production rates from
106 particulate nitrate photolysis have been found ($T < 0.01$). The sampling settings employed in Wangdu
107 were designed to quantify the shadowing effect (Figure 1b). In Wangdu, PM_{2.5} was collected at a flow
108 rate of 16.7 L min⁻¹ with four channels (A, B, C, and D). A and B channels were set for
109 daytime(8:00–17:00) and nighttime (18:00–7:00) PM_{2.5} samples, respectively, and the other two
110 channels were for the “all-day” (including 8:00–17:00 and 18:00–7:00) PM_{2.5} samples. A total of 158
111 effective PM_{2.5} samples were obtained in this study. These aerosol filter samples were labeled and
112 stored at -20°C in the freezer.

113 Fractions with given surface area from each filter sample were used to perform photochemical
114 reaction experiments and analysis of aerosol chemical components. For each PM_{2.5} sample, the fraction
115 with given surface area was rinsed by deionized water and then sonicated for 15 min. The amounts of
116 water-soluble ions including Na⁺, NH₄⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, NO₃⁻, and SO₄²⁻ were measured by ion
117 chromatography (IC, Thermo ICS-2100). To measure the values of carbon components, including

118 organic carbon (OC) and elemental carbon (EC), a part (0.5024 cm^2) of each filter was detected using a
 119 thermal optical carbon analyzer (DRI model 2015). The concentration of OM was obtained by
 120 multiplying the OC concentration by a factor of 1.6 (Li et al., 2021). $\text{PM}_{2.5}$ concentration was estimated
 121 by the sum of all the water-soluble ions and carbon components. The surface concentration of $\text{PM}_{2.5}$
 122 and its components on aerosol filters were calculated through dividing the absorbed loading with the
 123 geometric area of the aerosol filter sample ($\mu\text{g cm}^{-2}$).

124

125

126 **Figure 1.** (a) Location map of five representative sampling sites in China, (b) the sampling settings to
 127 quantify the shadowing effect in Wangdu, and (c) a schematic diagram of the photochemical
 128 experimental setup.

129 **2.2 Photochemical reaction system**

130 A custom-made cylindrical quartz vessel was used as the photochemical flow reactor (Figure 1c).
 131 The diameter was 10 cm and the depth was 2.5 cm, with a cell volume of ~ 200 ml. A xenon lamp (300
 132 W) was placed 20 cm above the reactor as the light source. The light was filtered by a Pyrex sleeve to
 133 remove heat-generating infrared light. The effective light intensity in the center of the flow reactor,

134 where aerosol samples were placed, was measured to be about 0.5 times higher (1.5 kW m^{-2} , measured
 135 by a calibrated optical power meter) than that at tropical noon on the ground (solar elevation angle
 136 $\theta=0^\circ$). Synthetic air, composed of ultrahigh-purity nitrogen and ultrahigh-purity oxygen mixed at a
 137 ratio of 79:21, was used as the carrier gas. The relative humidity (RH) in the air flow was adjusted
 138 through a water bubbler and monitored with an online RH sensor (Vaisala, HMT130). The aerosol filter
 139 sample was exposed to the solar simulator radiation for 20 min. The photochemical reaction
 140 experiment for each sample was repeated 2–3 times with different fractions from the same sample. The
 141 gaseous product (i.e., HONO) released during the experiment was flushed out of the reactor by the
 142 carrier gas and was detected online by a custom-built HONO analyzer, which had been applied in
 143 several measurements previously (Zhang et al., 2020b; Li et al., 2021).

144 **2.3 HONO Production from the photolysis of particulate nitrate**

145 The production rates (nmol h^{-1}) of HONO from particulate nitrate photolysis (P_{HONO}) were
 146 calculated from their time-integrated signals above the baselines over the period of light exposure:

$$147 \quad P_{\text{HONO}} = \frac{F_g \times 60}{V_m(t_2 - t_1)} \int_{t_1}^{t_2} C_{\text{HONO}} dt \quad (1)$$

148 Where F_g (L min^{-1}) is the flow rate of the carrier gas, V_m (24.5 L mol^{-1}) is the molar volume of gas at
 149 25°C and 1 atm of pressure; t_1 and t_2 (min) are the starting and ending time of the irradiation,
 150 respectively; C_{HONO} (ppb) is the online measured concentration of HONO. With the flow rate of 2.5 L
 151 min^{-1} , the residence time in the reaction system was around $\sim 5 \text{ s}$. The photolytic loss of HONO was
 152 less than 5 %, thus no correction was made in the calculation of HONO production.

153 The photolysis rate constant of particulate nitrate leading to HONO production ($J_{\text{NO}_3^- - \text{HONO}}$, s^{-1})
 154 was calculated by the following equation:

$$155 \quad J_{\text{NO}_3^- - \text{HONO}} = \frac{P_{\text{HONO}}}{N_{\text{NO}_3^-} \times 3600} \quad (2)$$

156 Where $N_{\text{NO}_3^-}$ (mol) is the amount of NO_3^- in the tested $\text{PM}_{2.5}$ sample. In principle, the photolysis rate
 157 constant should be calculated on the amount of NO_3^- that is reachable to the irradiation. However, the
 158 amount of the light-reachable NO_3^- in the $\text{PM}_{2.5}$ sample was hard to quantify. In this work, the
 159 deviation of $J_{\text{NO}_3^- - \text{HONO}}$ due to the overestimate of the amount of NO_3^- under light irradiation, which
 160 was called the shadowing effect, would be corrected in Sect. 3.1.

161 3 Results

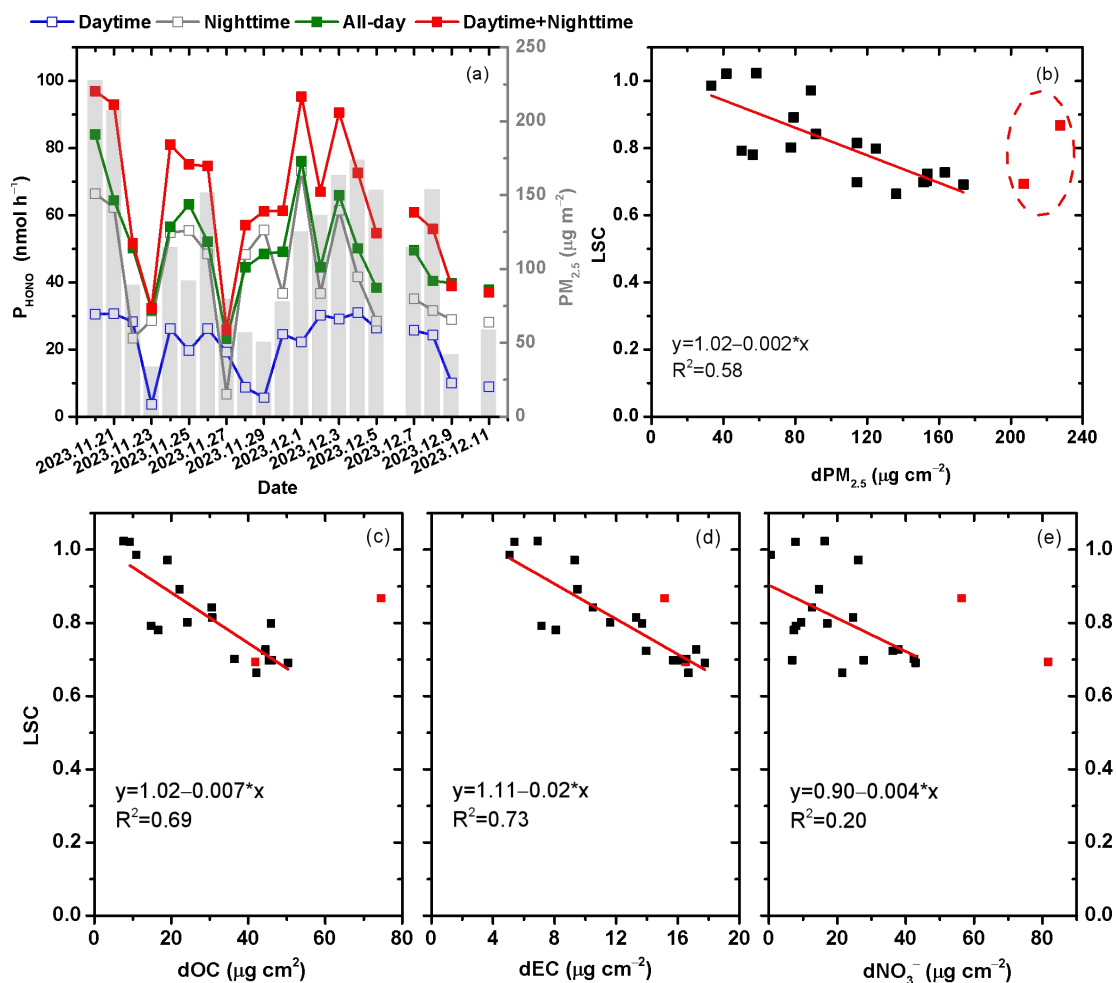

162 3.1 Quantify the influence of the shadowing effect

163

164 **Figure 2.** (a) Online measured concentrations of HONO during the light-exposure of an aerosol sample
165 collected on June 12, 2023 in Beijing, P_{HONO} as a function of (b) light intensity (kW m⁻²) and (c) RH
166 (%).

167 HONO production within the first 20 min of irradiation during the photochemical experiment was
168 investigated on the PM_{2.5} samples collected from five typical sites in China. Figure 2a showed a typical
169 profile of the changes in HONO concentration in the reaction system. When the light was turned on,
170 HONO concentration in the reactor increased immediately, then leveled off and slightly decayed
171 afterwards. After the light was turned off, the HONO generation stopped immediately and the signal
172 nearly returned to the baseline level. Previous works have revealed that the decay of HONO generation
173 during light exposure period was not resulted from the evaporation loss of particulate nitrate (Ye et al.,
174 2017), but mainly related to the inhomogeneity of particulate nitrate photochemical reactivity or the
175 consumption of reactive electron donors (Bao et al., 2018). HONO production from the photochemical
176 reactions of particulate nitrate were significantly influenced by ambient environmental conditions (i.e.,
177 light intensity and RH). As shown in Figure 2b, with the increase of light intensity, P_{HONO} gradually
178 increased, with P_{HONO} in 3.85 kW m⁻² approximately twice than that in 1.50 kW m⁻². Previous works
179 found that the formation of HONO was negligible at low RH (<5%), and increased at intermediate RH
180 (15%–75%), then turned to decrease at RH > 90% (Bao et al., 2018). Here, we found that P_{HONO}
181 climbed to its highest when RH was around 65 % (Figure 2c). In this work, the photochemical
182 reactions on different aerosol samples were all conducted under the same environmental condition
183 (RH=65 %, temperature=20 °C, and light intensity=1.50 kW m⁻²).

184

185

186 **Figure 3.** (a) Temporal variation of P_{HONO} for aerosol filters collected in Wangdu during daytime,
 187 nighttime and all-day from November 20, 2023 to December 11, 2023, (b)-(e) relationships between
 188 light screening coefficient (LSC) and the surface concentrations of $PM_{2.5}$ ($dPM_{2.5}$), OC (dOC), EC (dEC)
 189 and NO_3^- (dNO_3^-), respectively. The red squares represent the aerosol samples with $PM_{2.5}$ surface
 190 concentration higher than $200 \mu\text{g cm}^{-2}$.

191 As expected, P_{HONO} increased with particulate nitrate loadings in different sampling locations
 192 (Figure S1), however, it's interesting to note that, P_{HONO} did not increase or somewhat decreased at very
 193 high NO_3^- loading condition. Previous works considered this may be attributed to the shadowing effect,
 194 wherein the particulate nitrate underneath the aerosol filters may receive less UV light at heavy aerosol
 195 particle loading on the filters, inhibiting the photolysis of particulate nitrate (Ye et al., 2017). Thus, the
 196 reported P_{HONO} values for the aerosol filters collected under polluted ambient conditions would be
 197 underestimated with heavy aerosol particle loading. To verify and quantify the underestimation of
 198 P_{HONO} due to the shadowing effect, we collected two sets of filters in Wangdu (set A: daytime and
 199 nighttime, set B: all-day, Figure 1b). Theoretically, the all-day one should share the same NO_3^- loading

200 and chemical composition as the sum of the daytime and nighttime filters, thus the sum of P_{HONO} during
 201 daytime ($P_{\text{daytime}}^{\text{HONO}}$) and nighttime ($P_{\text{nighttime}}^{\text{HONO}}$) should be equal to that during all-day ($P_{\text{all-day}}^{\text{HONO}}$) without
 202 considering the shadowing effect. A total of 20 pairs of comparative photochemical experiments were
 203 conducted, and the comparison of P_{HONO} between these two sets of filters was shown in Figure 3a. We
 204 found that the discrepancy between $P_{\text{all-day}}^{\text{HONO}}$ and $P_{\text{daytime}}^{\text{HONO}} + P_{\text{nighttime}}^{\text{HONO}}$ was widening along with the
 205 increase of surface $\text{PM}_{2.5}$ concentration. To quantify the shadowing effect, we introduced a parameter
 206 called “light screening coefficient” (LSC) to describe the decreasing efficiency of light penetrating into
 207 the particle with increasing $\text{PM}_{2.5}$ loadings:

$$208 \quad P_{\text{theory}}^{\text{HONO}} = P_{\text{daytime}}^{\text{HONO}} + P_{\text{nighttime}}^{\text{HONO}} \quad (3)$$

$$209 \quad \text{LSC} = P_{\text{observed}}^{\text{HONO}} / P_{\text{corrected}}^{\text{HONO}} = P_{\text{all-day}}^{\text{HONO}} / P_{\text{theory}}^{\text{HONO}} \quad (4)$$

210 where $P_{\text{observed}}^{\text{HONO}}$ represented the observed production rate of HONO from particulate nitrate photolysis
 211 through photochemical experiment, and $P_{\text{corrected}}^{\text{HONO}}$ represented the corrected value of P_{HONO} after
 212 quantifying the shadowing effect. As shown in Figure 3b, when $\text{PM}_{2.5}$ surface concentration ($d\text{PM}_{2.5}$)
 213 was low, LSC was almost equal to 1, indicating that the shadowing effect was negligible. With the
 214 increase of $\text{PM}_{2.5}$ loading, the value of LSC declined to lower than 65 %. In general, significant
 215 negative correlation existed between LSC and $d\text{PM}_{2.5}$, except when $d\text{PM}_{2.5}$ was higher than $200 \mu\text{g cm}^{-2}$
 216 (Figure 3b). In this experiment, we assumed that the daytime and nighttime $\text{PM}_{2.5}$ samples were both
 217 single-layered. However, with the increase of air pollution, these filters in each pair of comparative
 218 experiments may already have exhibited the shadowing effect, thus the sum of $P_{\text{daytime}}^{\text{HONO}}$ and $P_{\text{nighttime}}^{\text{HONO}}$
 219 would be underestimated. Therefore, when quantifying the shadowing effect, the LSC data with $\text{PM}_{2.5}$
 220 loading higher than $200 \mu\text{g cm}^{-2}$ was excluded. Correlations between LSC and the surface
 221 concentrations of $\text{PM}_{2.5}$ major chemical components, such as EC (dEC), OC (dOC), and NO_3^- ($d\text{NO}_3^-$),
 222 were conducted (Figure 3c-e). Significant correlation was found between LSC and carbonaceous
 223 component, especially EC ($R^2=0.73$), which was one of the most important light absorbing species in
 224 $\text{PM}_{2.5}$, indicating that the shadowing effect was mainly related to the light absorption components in
 225 $\text{PM}_{2.5}$. The relationship between LSC and dEC was established as following:

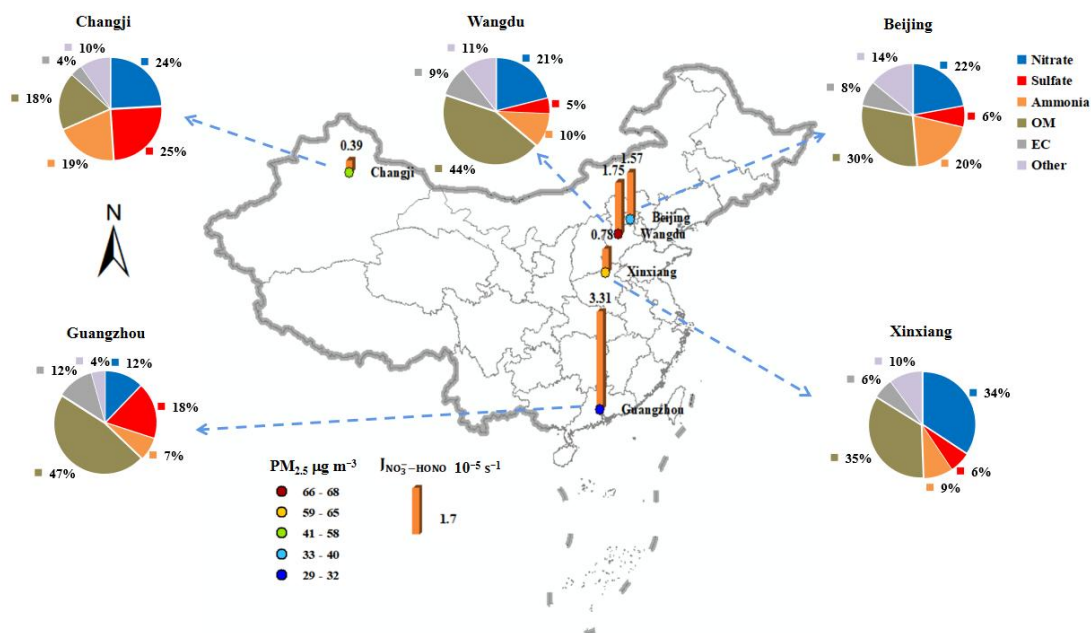

$$226 \quad d\text{EC} > 5.5 \mu\text{g m}^{-2}: \text{LSC} = 1.11 - 0.02 \times d\text{EC}$$

$$227 \quad d\text{EC} \leq 5.5 \mu\text{g m}^{-2}: \text{LSC} = 1 \quad (5)$$

228 when $d\text{EC} \leq 5.5 \mu\text{g m}^{-2}$, the shadowing effect can be ignored; when $d\text{EC} > 5.5 \mu\text{g m}^{-2}$, P_{HONO} can be
 229 corrected by the observed P_{HONO} and LSC, which was estimated using this fitting equation with dEC.

230 Previous works found that the heavy loads of carbonaceous particles can turn these filters into dark
 231 brown colors. The UV light was unlikely to transmit efficiently through the dark layer to the particulate
 232 nitrate underneath, thus inhibiting the generation of HONO from the photolysis of particulate nitrate
 233 (Ye et al., 2017). In consideration of the potential shadowing effect for the daytime and nighttime filters
 234 in each pair of comparative experiments, the $P_{\text{daytime}}^{\text{HONO}}$ and $P_{\text{nighttime}}^{\text{HONO}}$ observed would be
 235 underestimated, and the uncertainty of LSC should be considered at high $\text{PM}_{2.5}$ loadings. To evaluate
 236 this uncertainty, the observed $P_{\text{daytime}}^{\text{HONO}}$ and $P_{\text{nighttime}}^{\text{HONO}}$ values were recalculated and corrected to the
 237 theoretical single-layered condition based on Eq. (4) and (5). As shown in Figure S2, with the increase
 238 of $\text{PM}_{2.5}$ surface concentration, the deviations between LSC and the corrected one have enlarged.
 239 However, it's noted that the deviation was still lower than 20 % when $\text{PM}_{2.5}$ surface concentration was
 240 around $200 \mu\text{g cm}^{-2}$. For example, for the aerosol sample collected in December 4, 2023, in Wangdu,
 241 the $\text{PM}_{2.5}$ surface concentration was $173.57 \mu\text{g cm}^{-2}$, and the deviation was 15.74 %, which was
 242 acceptable in this work.

243 3.2 Spatial distribution and temporal variation of HONO production from particulate nitrate 244 photolysis

245
 246 **Figure 4.** Spatial distribution of the average ($J_{\text{NO}_3\text{-HONO}}$, $\text{PM}_{2.5}$ loading, and chemical composition of
 247 the aerosol filters collected from five representative cities in China during the observation period.

248 There were 158 filter samples collected from five representative cities in China, and the averaged
 249 concentrations of $\text{PM}_{2.5}$ and its chemical composition of these filters showed significant spatial

250 characteristics as shown in Figure 4. During the sampling period, OM was the most abundant species in
 251 PM_{2.5} over most regions, except in the northwestern city (Changji), and NO₃⁻ was the dominant
 252 inorganic component in the NCP (Beijing and Wangdu) and Central China (Xinxiang), while SO₄²⁻
 253 showed the highest contribution in the PRD (Guangzhou) and Northwestern China (Changji). The
 254 values of J_{NO₃⁻-HONO} on these PM_{2.5} samples were calculated by Eq. (2) with the P_{HONO} corrected by
 255 Eq. (4) and (5), and summarized in Figure 4 and Table 1. The corrected J_{NO₃⁻-HONO}, median and mean
 256 (\pm one standard deviation), were $1.55 \times 10^{-5} \text{ s}^{-1}$ and $1.57 (\pm 2.14) \times 10^{-5} \text{ s}^{-1}$ in Beijing, $1.68 \times 10^{-5} \text{ s}^{-1}$ and
 257 $1.75 (\pm 2.83) \times 10^{-5} \text{ s}^{-1}$ in Wangdu, $0.69 \times 10^{-5} \text{ s}^{-1}$ and $0.78 (\pm 0.48) \times 10^{-5} \text{ s}^{-1}$ in Xinxiang, $3.04 \times 10^{-5} \text{ s}^{-1}$
 258 and $3.31 (\pm 1.15) \times 10^{-5} \text{ s}^{-1}$ in Guangzhou, and $0.38 \times 10^{-5} \text{ s}^{-1}$ and $0.39 (\pm 0.25) \times 10^{-5} \text{ s}^{-1}$ in Changji,
 259 respectively. The maximum J_{NO₃⁻-HONO} in these cities ranged from $0.91 \times 10^{-5} \text{ s}^{-1}$ in Changji to
 260 $1.96 \times 10^{-4} \text{ s}^{-1}$ in Wangdu. These values were in the comparable range to those previously reported for
 261 aerosol samples, such as $1.22 \times 10^{-5} \text{ s}^{-1} \sim 4.84 \times 10^{-4} \text{ s}^{-1}$ in China by Bao et al. (2018) (RH = 60%,
 262 temperature = 25°C, irradiation time=15 min) and 6.2×10^{-6} to $5.0 \times 10^{-4} \text{ s}^{-1}$ (the sum of HONO and
 263 NO_x production, with an average HONO/NO_x production ratio of ~ 2) in US by Ye et al. (2017) (RH =
 264 50%, temperature = 20(± 1)°C, irradiation time=10 min). It's interesting to note that the average
 265 J_{NO₃⁻-HONO} was the highest in Guangzhou, which was characterized with the lowest PM_{2.5} and NO₃⁻
 266 concentration among these cities. As for other cities with high PM_{2.5} concentrations, such as Changji
 267 and Xinxiang, the corrected J_{NO₃⁻-HONO} was comparatively lower. According to the National Ambient
 268 Air Quality Standard of China (GB3095-2012), the daily PM_{2.5} averages in Guangzhou can meet the
 269 Level II standard of $75 \mu\text{g m}^{-3}$, while exceeding the level I standard ($35 \mu\text{g m}^{-3}$). Here, we defined
 270 PM_{2.5} polluted days with daily mean PM_{2.5} exceeding $35 \mu\text{g m}^{-3}$. As shown in Figure 5, the distribution
 271 of the corrected J_{NO₃⁻-HONO} values in clean days were generally more dispersed and higher than those
 272 in polluted days, except in Guangzhou. The average value of J_{NO₃⁻-HONO} in Guangzhou during air
 273 polluted conditions was slightly higher than that in clean conditions, besides much higher than the
 274 values in other cities. Because the influence of the shadowing effect has been corrected to some degree,
 275 these spatial and temporal change characteristics of J_{NO₃⁻-HONO} in this work should be mainly related to
 276 the varied chemical and physical properties of PM_{2.5} samples collected from different atmospheric
 277 environments.

278 **Table 1.** The concentrations of PM_{2.5}, NO₃⁻, and OC, OC/NO₃⁻, corrected J_{NO₃⁻-HONO}, and S_{HONO} in
 279 five representative cities in China under different air conditions during the sampling period.

280 ^a represented the photolysis rate constant of particulate nitrate leading to HONO production after considering the
281 influence of the shadowing effect. ^{b, c} represented the noontime source strength of HONO through the photolysis of
282 particulate nitrate with the units of 10⁻⁵ mol h⁻¹ m⁻² and ppbv h⁻¹, respectively. ^{d, e} represented the minimum and
283 maximum values of S_{HONO} during the observation period.

284

285

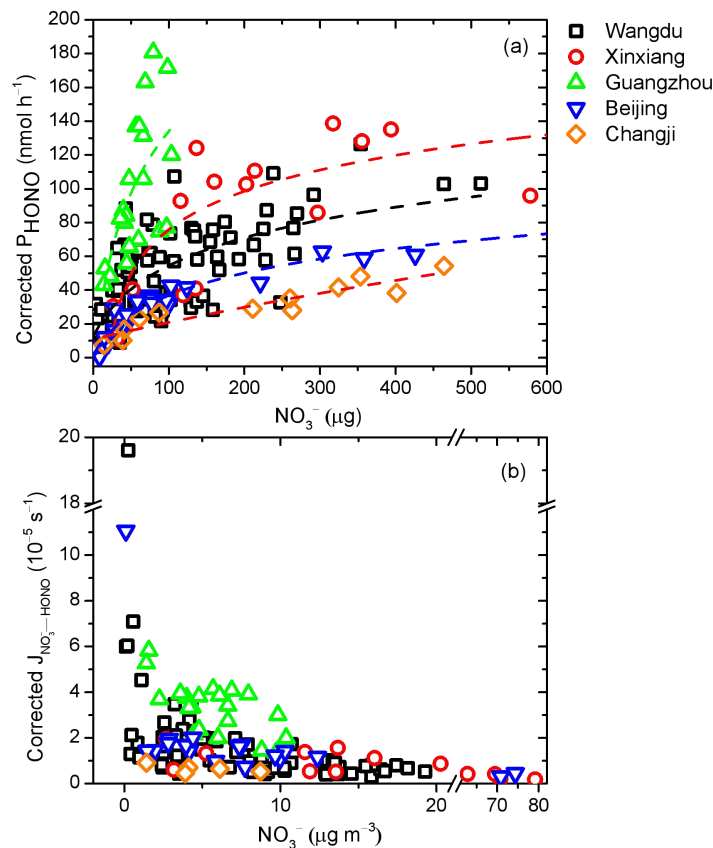

286

287 **Figure 5.** (a) Average corrected $J_{\text{NO}_3\text{-HONO}}$, and (b) the ratio of OC to NO_3^- under different air
288 conditions in five representative cities. The box represents the 25th to 75th percentiles, the horizon line
289 represents the median, the hollow square represents the mean, and the 10th and the 90th percentiles are
290 the bottom and top whiskers, respectively.

291 3.3 Dominant factors controlling $J_{\text{NO}_3\text{-HONO}}$

292 3.3.1 Particulate nitrate

293 As shown in Table 1, the corrected $J_{\text{NO}_3\text{-HONO}}$ values varied with sampling periods and locations
294 over a wide range, distributing from $0.16 \times 10^{-5} \text{ s}^{-1}$ for the aerosol sample collected in Changji with
295 $\text{PM}_{2.5}$ higher than $90 \mu\text{g m}^{-3}$, to $19.60 \times 10^{-5} \text{ s}^{-1}$ for the aerosol sample collected in Wangdu with $\text{PM}_{2.5}$
296 lower than $25 \mu\text{g m}^{-3}$. Several factors may contribute to the discrepancy of $J_{\text{NO}_3\text{-HONO}}$ in these
297 different aerosol samples, such as particulate nitrate, organic matter, and aerosol acidity.

298

299 **Figure 6.** Relationships between (a) corrected P_{HONO} and particulate nitrate loading, and (b) corrected
 300 $J_{\text{NO}_3^- - \text{HONO}}$ and particulate nitrate concentration in different sampling locations. The dash lines in (a)
 301 were the best fits to the data for the fitting equation: the aerosol samples in Guangzhou ($a=4.30$, $b=0.06$,
 302 $c=1 \times 10^{-6}$, $R^2=0.42$), Wangdu ($a=2.54$, $b=0.11$, $c=1 \times 10^{-6}$, $R^2=0.50$), Beijing ($a=1.51$, $b=0.06$,
 303 $c=1 \times 10^{-6}$, $R^2=0.91$), Xinxiang ($a=2.28$, $b=0.06$, $c=1 \times 10^{-6}$, $R^2=0.47$), and Changji ($a=0.58$, $b=0.04$,
 304 $c=1 \times 10^{-6}$, $R^2=0.86$).

305 As shown in Figure 6, after considering the shadowing effect, the corrected P_{HONO} generally
 306 increased along with the increased amount of particulate nitrate ($p\text{NO}_3^-$, μg), but still gradually slowed
 307 down at high particulate nitrate loading, resulting in a rapid decrease in $J_{\text{NO}_3^- - \text{HONO}}$. For example, when
 308 NO_3^- concentration was at low level (around $0.5 \mu\text{g m}^{-3}$) in Wangdu, the value of corrected $J_{\text{NO}_3^- - \text{HONO}}$
 309 was about 30 times higher than that at high NO_3^- concentration (around $20 \mu\text{g m}^{-3}$). Previous works
 310 found that the particulate nitrate was associated with matrix components in aerosol samples, and the
 311 photolysis reactivity of particulate nitrate was closely associated with the surface catalysis effect (Ye et
 312 al., 2017). In such a mechanism, the interaction between particulate nitrate and the substrate can distort
 313 the molecular structure of nitrate and increase the absorption cross-section. The increases of P_{HONO} with
 314 $p\text{NO}_3^-$ exposed to the light radiation can be fitted by a logarithm curve under different

315 environment: $P_{\text{HONO}} = \frac{a}{b} \ln(1 + b(p\text{NO}_3^-)) + c(p\text{NO}_3^-)$ (Ye et al., 2017; Ye et al., 2019). Based on this
316 fitting equation, the corrected P_{HONO} as a function of $p\text{NO}_3^-$ was showed in Figure 6a. Interestingly,
317 these relationships under different sampling locations showed distinct upward trends. Ye et al. (2019)
318 found that this ratio of a to b was related to the catalysis power of surface reactive sites and the organic
319 matters in the matrix. The much higher ratio of a (4.30) to b (0.06) values fitted for Guangzhou than
320 those for other cities, especially Changji (a=0.58, b=0.04), suggested extra catalytic power of organic
321 components in addition to the surface reactive site on particulate nitrate. The large deviation of the ratio
322 of a to b among these cities indicated the limitation of predicting P_{HONO} only based on the relationship
323 with particulate nitrate in different atmospheric environments, and other varied aerosol chemical and
324 physical conditions should be considered as well.

325 3.3.2 Organic matter

326 Organic matter was ubiquitous in the atmosphere and contributed significantly to the total aerosol
327 mass. The selectivity of organic matter that coexisted in the aerosols was very important for the
328 production of HONO from the photolysis of particulate nitrate (Bao et al., 2018; Ye et al., 2016a;
329 Svoboda et al., 2013; Reeser et al., 2013; Stemmler et al., 2006; Yang et al., 2018; Beine et al., 2006;
330 Wang et al., 2021). As shown in Figure 7a, corrected P_{HONO} generally increased as the amount of OC in
331 aerosol samples ($p\text{OC}$, μg) went up, while these positive correlations between P_{HONO} and $p\text{OC}$ shown
332 may be due to the moderate correlation between $p\text{NO}_3^-$ and $p\text{OC}$ ($R^2=0.39$, Figure S3). To eliminate
333 the contribution from particulate nitrate, the dependence of $J_{\text{NO}_3^--\text{HONO}}$ on the ratio of OC to NO_3^-
334 (OC/NO_3^-) was examined:

$$335 \text{ Corrected } J_{\text{NO}_3^--\text{HONO}} = 0.74 \times (\text{OC}/\text{NO}_3^-) + 0.08 \quad (6)$$

336

337

338 **Figure 7.** Relationship between (a) corrected P_{HONO} and OC loadings, (b) corrected $J_{\text{NO}_3-\text{HONO}}$ and
 339 OC/NO_3^- , and (c) average corrected $J_{\text{NO}_3-\text{HONO}}$, $\text{PM}_{2.5}$, and OC/NO_3^- during the sampling period in
 340 five representative cities.

341 As shown in Figure 7b, significant linear correlation between corrected $J_{\text{NO}_3-\text{HONO}}$ and OC/NO_3^-
 342 was found, with an R^2 of 0.86. In general, high corrected $J_{\text{NO}_3-\text{HONO}}$ values were mostly associated
 343 with high OC/NO_3^- ratios for aerosol samples collected in the clean areas, such as Guangzhou, where
 344 the averaged $\text{PM}_{2.5}$ level was the lowest (Figure 7c). Low corrected $J_{\text{NO}_3-\text{HONO}}$ values were mostly
 345 associated with low OC/NO_3^- ratio. Generally, cities with higher $\text{PM}_{2.5}$ levels have lower OC/NO_3^-
 346 ratios, such as Changji and Xinxiang, however, there was an exception — Wangdu, a rural site in the

347 North China Plain, where the $PM_{2.5}$ was high but dominated by OM mainly due to local residential coal
348 combustion (Liu et al., 2016; Li et al., 2024; Liu et al., 2017). As shown in Figure 5b, the OC/NO_3^-
349 ratio in clean days was generally higher than that in polluted conditions. Interestingly, different from
350 other cities, the OC/NO_3^- ratio in Guangzhou increased at polluted conditions, which was consistent
351 with the correspondingly higher corrected $J_{NO_3^- \rightarrow HONO}$ value. Guangzhou was located in the PRD
352 region, and was characterized by large fractions of OM in $PM_{2.5}$ due to large emission of VOCs from
353 numerous manufacturing industries and transport-related sources (Zheng et al., 2009), and the
354 water-soluble organic carbon (WSOC) was the dominated component in the organic aerosols
355 ($WSOC/OC=0.63$) (Chang et al., 2019). It's reported that organic compounds on the surface may act as
356 photosensitizers in the photolysis of particulate nitrate (Gen et al., 2022; Handley et al., 2007; Cao et
357 al., 2022; Wang et al., 2021). The association of particulate nitrate with organic matter may distort its
358 molecular structure and enhance the absorption cross section, resulting in significantly enhancement in
359 the photochemical production of HONO. The organic matter can also become hydrogen donors, and
360 directly transfer hydrogen from organic H-donors to NO_2 to form HONO (Gen et al., 2022). Therefore,
361 we suggested that the gradually increasing role of organic matter in $PM_{2.5}$ in China should be of great
362 concern.

363 3.3.3 Other factors

364 The acidic proton may play an important role in the photochemical production of HONO
365 and affect the release of photolysis products (Bao et al., 2018; Scharko et al., 2014). Scharko et al.
366 (2014) found that gaseous HONO production from nitrate photolysis was the highest at the lowest
367 aerosol acidity (pH, ~ 2) and decreased with pH, and reached almost zero at pH higher than 4. In this
368 work, the estimated pH of these aerosol samples was in the range of 1.83–3.46 (the Extended Aerosol
369 Inorganic Model, E-AIM (Shi et al., 2021; Wexler and Clegg, 2002; Clegg et al., 1998)) with detailed
370 information provided in the Supporting Information. As shown in Figure S4, however, the correlation
371 between pH and $J_{NO_3^- \rightarrow HONO}$ was weak, which indicated that pH was an important factor, but not the
372 key one driving the spatial differences of $J_{NO_3^- \rightarrow HONO}$ in this work. Noting that halide ions, such as
373 chlorine (Cl^-), may lead to enhancement of surface nitrate anion and promote nitrate photolysis (Gen et
374 al., 2022; Zhang et al., 2020a), we also plotted $J_{NO_3^- \rightarrow HONO}$ against the molar ratio of Cl^- to NO_3^-
375 (Cl^-/NO_3^-) in Figure 8a. Even though Guangzhou was a southern coastal city, the sampling site in this

376 work was far away from the South China Sea (>50 km). Besides, during the observation period, the
 377 aerosol collected in Guangzhou was more representative of inland aerosol instead of marine aerosol,
 378 with the air parcel usually coming from inland directions (Figure 8b) and the ratio of Cl^- to NO_3^- (0.02)
 379 much lower than that in fresh sea spray aerosol (>1.0) (Xiao et al., 2017; Pipalatkarn et al., 2014; Atzei
 380 et al., 2019; Wang et al., 2019). Therefore, we suggested that the halide ions were not the determining
 381 factor for the high $J_{\text{NO}_3^--\text{HONO}}$ value in Guangzhou, and the exact role of halide ions in HONO
 382 formation through the photolysis of particulate nitrate required further investigation.

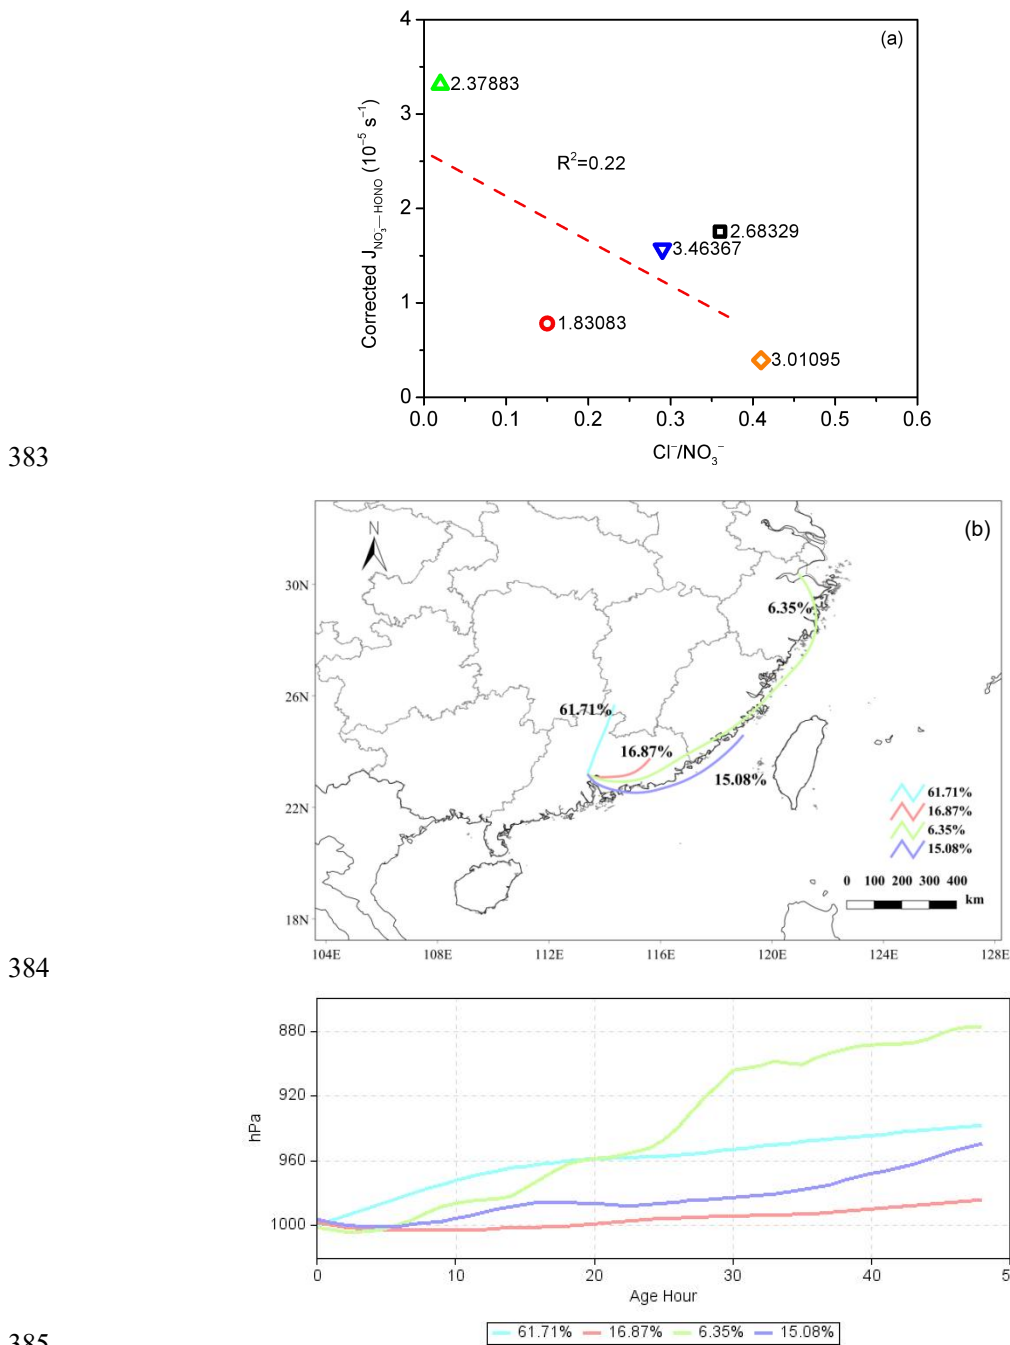

Figure 8. (a) Relationship between the average corrected $J_{\text{NO}_3^--\text{HONO}}$ and $\text{Cl}^-/\text{NO}_3^-$ under different

387 sampling locations, and (b) the back trajectory cluster analysis in Guangzhou during the sampling
388 period.

389 3.4 Environmental implication

390 The determined $J_{\text{NO}_3^--\text{HONO}}$ was closely associated with the aerosol chemical and physical
391 characteristics, especially the coexisted organic components, and distributed around the curve as
392 expressed by Eq. (6). It's the first effort to explore the photolysis of particulate nitrate in aerosol
393 samples collected from different typical regions of China. The enhanced formation of HONO from the
394 photolysis of particulate nitrate can contribute significantly to the atmospheric oxidation capacity. To
395 assess the photolysis of particulate nitrate as a HONO daytime source, the noontime source strength of
396 HONO (S_{HONO}) through this mechanism in the air column within the planetary boundary layer can be
397 calculated by the following equation (Ye et al., 2017):

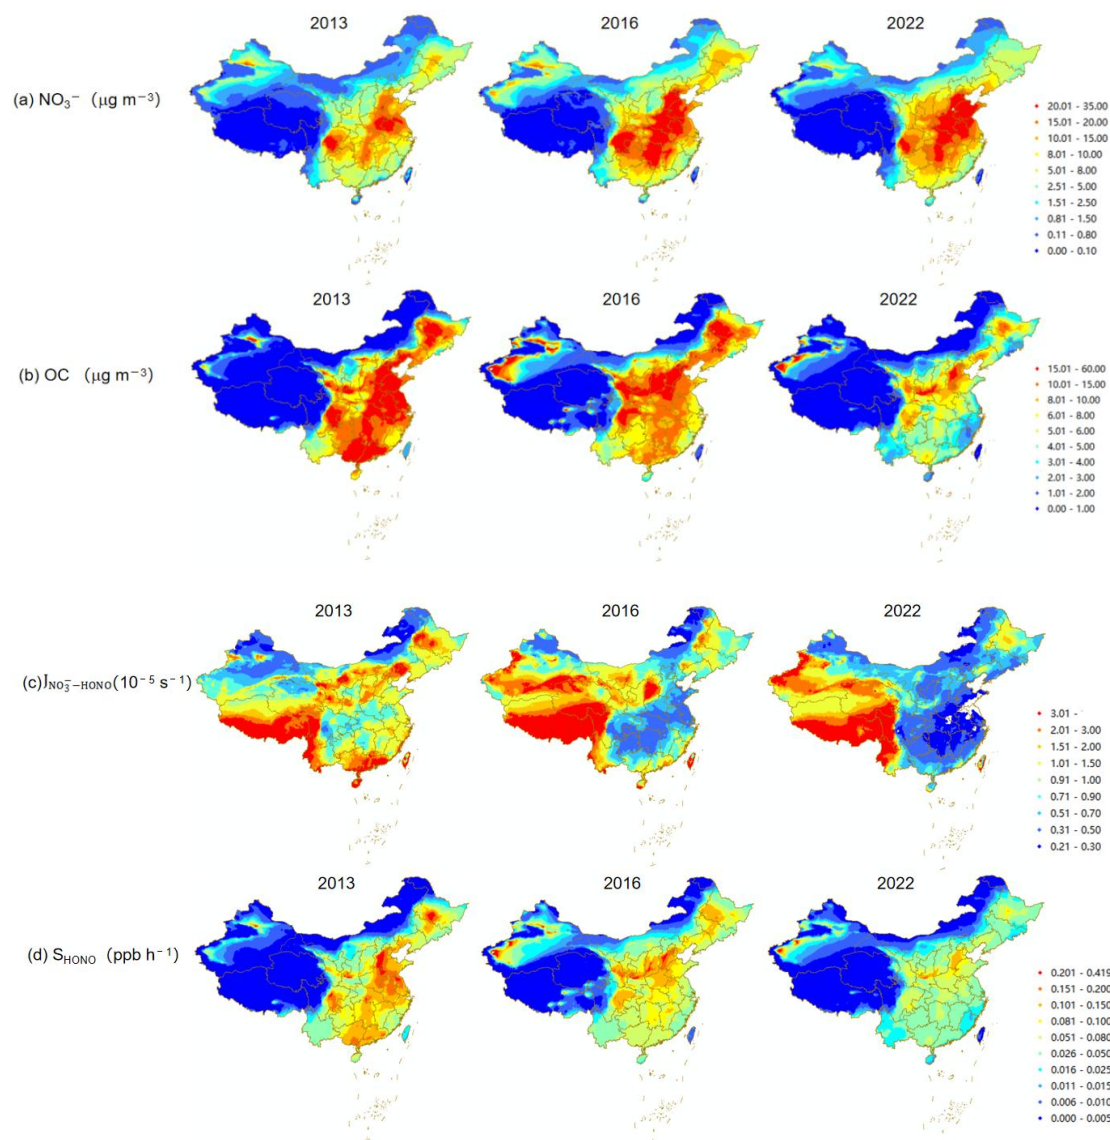

$$398 S_{\text{HONO}} (10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}) = 0.67 \times \text{NO}_3^- (\mu\text{mol m}^{-3}) \times 10^{-6} \times J_{\text{NO}_3^--\text{HONO}} \times \text{BLH} \times 3600 \quad (7)$$

399 or

$$400 S_{\text{HONO}} (\text{ppbv h}^{-1}) = 0.67 \times \text{NO}_3^- (\text{ppbv}) \times J_{\text{NO}_3^--\text{HONO}} \times 3600 \quad (8)$$

401 where BLH means the boundary mixing height (m). Here, we assumed a typical BLH of 1000 m.
402 Based on the daily measured NO_3^- and corrected $J_{\text{NO}_3^--\text{HONO}}$ value in each city, the S_{HONO} derived from
403 Eq. (7) or (8) during the observation period was showed in Table 1. It was found that, even though the
404 $J_{\text{NO}_3^--\text{HONO}}$ in polluted days was much lower than that in clean days, due to the apparent higher NO_3^-
405 concentration, the corresponding S_{HONO} was about twice the average in clean days. The calculated
406 S_{HONO} ranged from $0.03 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$ to $0.88 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$ (0.01 ppbv h^{-1} – 0.2 ppbv h^{-1}), with
407 the mean value of $0.36 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$ (0.08 ppbv h^{-1}), which was comparable or higher than other
408 HONO sources (Bhattacharai et al., 2019; Wang et al., 2023b; Ye et al., 2017). For example, the soil
409 HONO emission flux was measured in the range of $1.81 \times 10^{-6} \text{ mol h}^{-1} \text{ m}^{-2}$ – $4.55 \times 10^{-6} \text{ mol h}^{-1} \text{ m}^{-2}$ in
410 the soil without suffering nitrogen fertilizer (Bhattacharai et al., 2019). The mean value of S_{HONO} during
411 the observation period was the highest in Wangdu ($0.42 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$, 0.10 ppbv h^{-1}) and
412 Guangzhou ($0.41 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$, 0.09 ppbv h^{-1}), followed by Xinxiang ($0.35 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$, 0.08
413 ppbv h^{-1}), Beijing ($0.22 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$, 0.05 ppbv h^{-1}), and Changji ($0.13 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$, 0.03
414 ppbv h^{-1}). Even though the $\text{PM}_{2.5}$ and NO_3^- concentration was the lowest in Guangzhou, the S_{HONO} was
415 much higher than other cities with air pollution. It should be noted that the S_{HONO} calculated with the

416 daily changed NO_3^- and $J_{\text{NO}_3^--\text{HONO}}$ value in this work was much lower than the value reported by Bao
417 et al. (2018) (0.78 ppbv h^{-1}), which applied the average NO_3^- ($6.64 \mu\text{g m}^{-3}$, 2.62 ppbv) and the
418 $J_{\text{NO}_3^--\text{HONO}}$ range ($1.22 \times 10^{-5} \text{ s}^{-1}$ – $4.84 \times 10^{-4} \text{ s}^{-1}$) to simulate S_{HONO} (0.12 ppbv h^{-1} – 4.57 ppbv h^{-1}). Other
419 works, such as Fu et al. (2019) and Gu et al. (2022a), applied the mean value of $J_{\text{NO}_3^--\text{HONO}}$ (8.3×10^{-5}
420 s^{-1}) and the observed NO_3^- concentration to calculate S_{HONO} . However, due to the significant decrease
421 of $J_{\text{NO}_3^--\text{HONO}}$ along with the increase of NO_3^- , the S_{HONO} calculated with mean NO_3^- or $J_{\text{NO}_3^--\text{HONO}}$
422 will be largely overestimated, thus directly influencing the identification of HONO sources. For
423 example, $J_{\text{NO}_3^--\text{HONO}}$ was the highest in Wangdu in November 23, 2023 with the value of $19.6 \times 10^{-5} \text{ s}^{-1}$,
424 while the corresponding NO_3^- concentration was low ($0.39 \mu\text{g m}^{-3}$). If applying the average NO_3^-
425 concentration ($12.53 \mu\text{g m}^{-3}$, equivalent to 4.53 ppbv) and the maximum $J_{\text{NO}_3^--\text{HONO}}$ value, the
426 determined S_{HONO} value would be $9.56 \times 10^{-5} \text{ mol h}^{-1} \text{ m}^{-2}$ (2.14 ppbv h^{-1}), which was about 30 times
427 higher than the actual result (0.07 ppbv h^{-1}). Therefore, we suggested to estimate S_{HONO} with the
428 observed concentration of NO_3^- and the $J_{\text{NO}_3^--\text{HONO}}$ value derived from the parameterization equation
429 with OC/NO_3^- , thereby reducing the large uncertainties and improving estimations of HONO budget.

430

431

432 **Figure 9.** Spatial distributions of the daily average (a) NO_3^- , (b) OC, (c) $J_{\text{NO}_3^--\text{HONO}}$, and (d) S_{HONO}
 433 from November 15 to December 15 in the year of 2013, 2016, and 2022 in China. The daily average
 434 concentrations of NO_3^- and OC were extracted from the Chinese high resolution $\text{PM}_{2.5}$ Component
 435 simulation concentration dataset (Kong, et al., 2024). The $J_{\text{NO}_3^--\text{HONO}}$ and S_{HONO} estimated in this work
 436 were derived under the same environmental conditions (RH=65 %, temperature=20 °C, and light
 437 intensity=150 kW m^{-2}), thus were more representative of the potential of HONO production rather than
 438 the actual value in the real ambient environment.

439 On the basis of the daily average concentrations of NO_3^- and OC extracted from the Chinese high
 440 resolution $\text{PM}_{2.5}$ Component simulation concentration dataset (CAQRA-aerosol,
 441 <https://www.capdatabase.cn>, 15 $\text{km} \times 15 \text{ km}$) (Kong, et al., 2024), the $J_{\text{NO}_3^--\text{HONO}}$ and S_{HONO} can be
 442 estimated by Eq. (6) and (8), respectively. As shown in Figure 9, significant spatio-temporal change

443 characteristics of NO_3^- , OC, $J_{\text{NO}_3^--\text{HONO}}$ and S_{HONO} were demonstrated in autumn-winter seasons from
444 2013 to 2022 in China. The high $J_{\text{NO}_3^--\text{HONO}}$ were concentrated in the ‘clean’ environments (e.g.,
445 Tibetan Plateau area, South Xinjiang Basin, Yunnan-Guizhou plateaus, and Sichuan basins) and
446 followed by those air polluted regions (e.g., NCP, Fenhe-Weihe Basin, Northeastern China, and PRD).
447 From 2013 to 2022, with OC decreasing significantly, while NO_3^- keeping stable or even increasing,
448 $J_{\text{NO}_3^--\text{HONO}}$ showed a downward trend in most regions. Although the $J_{\text{NO}_3^--\text{HONO}}$ in polluted regions
449 was comparatively lower than that in ‘clean’ environments, the higher values of S_{HONO} were mostly
450 distributed in these polluted regions resulting from the much higher NO_3^- concentration. However, it
451 should be noted that the photolysis of particulate nitrate contributed only a small fraction to the needed
452 daytime HONO source in these polluted regions, such as 1.26–3.82 ppbv h^{-1} in the cities in the North
453 China Plain (Hou et al., 2016; Wang et al., 2017; Lian et al., 2022; Li et al., 2018), 0.75 ppbv h^{-1} in the
454 Western China (Huang et al., 2017), and 0.77–4.90 ppbv h^{-1} in Southern China (Li et al., 2012; Su et al.,
455 2008). We noted that uncertainties still exist in our simulations. Given the paucity of filed
456 measurements of HONO production from aerosol samples in ‘clean’ environments, the deviation of
457 $J_{\text{NO}_3^--\text{HONO}}$ derived from the parametrization in this work may be large in these regions. Additionally,
458 the concentrations of NO_3^- and OC extracted from the CAQRA-aerosol in ‘clean’ environments were
459 around the mean deviation level. Therefore, more field observations and simulation experiments should
460 be taken in these ‘clean’ regions in the future, to enrich and improve the parametric equations of
461 $J_{\text{NO}_3^--\text{HONO}}$, and further evaluate the contribution of nitrate photolysis to the formation of HONO in
462 different regions in China.

463 **4 Conclusions**

464 This study for the first time systematically analyzed the production of HONO from the photolysis
465 of particulate nitrate in $\text{PM}_{2.5}$ samples from multiple sites across China, shedding light to the
466 contribution of this photolysis process to HONO daytime source in different environments. A total of
467 20 pairs of comparative photochemical experiments were conducted in Wangdu to evaluate and
468 quantify the shadowing effect. We found that the corrected $J_{\text{NO}_3^--\text{HONO}}$ values varied with sampling
469 periods and locations over a wide range, distributing from $0.16 \times 10^{-5} \text{ s}^{-1}$ to $19.60 \times 10^{-5} \text{ s}^{-1}$. The
470 coexisted organic components in $\text{PM}_{2.5}$ can promote the photolysis of particulate nitrate, with higher

471 $J_{\text{NO}_3^--\text{HONO}}$ generally associated with higher OC/NO_3^- ratio. Considering the logarithmical decrease of
472 $J_{\text{NO}_3^--\text{HONO}}$ with increased NO_3^- , we suggested that the S_{HONO} should be calculated with $J_{\text{NO}_3^--\text{HONO}}$
473 derived from the parameterization equation with OC/NO_3^- instead of the average value. The
474 photolysis of particulate nitrate can become a potential daytime HONO source in southern urban cities,
475 such as GuangZ, which was characterized by large VOCs emissions and enhanced formation of
476 secondary particulate organic matter. Our work has provided an important reference for the research
477 in other areas in the world with high proportion of organic components in aerosol samples, such as
478 United States (Hass-Mitchell et al., 2024) and Europe (Bressi et al., 2021). To note, the filter samples
479 collected in this work may not cover all representative environments in China, especially the
480 background sites, more field observations and simulation experiments are needed in the future to better
481 constrain the parameterization and mechanism of particulate nitrate photolysis.

482 **Data availability.** The data used in this paper can be provided upon request from the corresponding
483 author.

484

485 **Author contributions.** **J W, B L and K Z** conceived the study and designed the experiments. **J W, B**
486 **L, J G, C C, L W, Y Z, J L, Y Z, and X D** analyzed the data. **J W and B L** prepared the manuscript
487 and all the coauthors helped improve the manuscript.
