Abstract

55 BTEX (benzene, toluene, ethylbenzene, m,p,o-xylene) are significant urban air pollutants. This study examines BTEX variability across seven European countries using data from 22 monitoring sites in different urban settings (urban background, traffic, industry, and suburban background). Results indicate that the relative abundance of BTEX in urban areas follows the order: toluene > benzene > m,p-xylene > o-xylene > ethylbenzene, with mean mixing ratios of 391 ± 451 , 252 ± 324 , 222 ± 297 , 92 ± 119 , and 78 ± 107 ppt from 2017 to 2022, respectively. Seasonal trends show benzene had similar median concentrations across urban background, traffic, and industrial sites, indicating mixed sources. Toluene levels were highest in traffic and industrial areas, highlighting road traffic and industrial emissions. Ethylbenzene and xylenes showed equivalent levels in traffic and industrial areas but were lower in urban backgrounds. Peak BTEX levels occurred during morning and evening rush hours, linked to traffic, heating, and atmospheric stagnation. B/T ratios ranged from 0.29 ± 0.11 to 1.35 ± 0.95 , and X/E ratios ranged from 1.75 ± 0.91 to 3.68 ± 0.30 , indicating primary pollution from local traffic, followed by solvents, coatings, and biomass burning. Lifetime Cancer Risk (LCR) values for BTEX exposure were below the definite risk threshold (10^{-4}) but above the permissible risk level (10^{-6}), suggesting moderate risk from benzene and ethylbenzene, particularly in traffic and industrial areas. This study offers essential insights into BTEX pollution in European urban environments.

1 Introduction

Atmospheric volatile organic compounds (VOCs) are significant precursors of tropospheric ozone (O_3) (Grosjean and Seinfeld, 1989) and secondary organic aerosols (SOA) (Derwent et al., 2010). Among the most prevalent VOCs, BTEX—comprising benzene, toluene, ethylbenzene, and xylenes—is a typical component of air pollution (Miri et al., 2016). Due to their reactivity with hydroxyl radicals ($\cdot OH$) during daylight and nitrate radicals ($NO_3\cdot$) both day and night, they can generate additional radicals, such as peroxyalkyl and hydroperoxy radicals, which further oxidize nitric oxide (NO) to nitrogen dioxide (NO_2) (Garg and Gupta, 2019; Ghaffari et al., 2021). This process contributes to increased concentrations of tropospheric O_3 and secondary organic aerosol (SOA) formation (Ng et al., 2007). Additionally, exposure

to BTEX is heightened by solvent evaporation, vehicular traffic, and emissions from fossil fuel extraction, which are increasingly occurring near densely populated areas (Bolden et al., 2015; Salameh et al., 2019; AQEG-EU, 2020; Liu et al., 2023). In addition, the removal of toxic octane enhancers like lead and methyl tertiary-butyl ether (MTBE) from gasoline allowed refiners to increase the volume of aromatics
85 in gasoline to meet anti-knock requirements and enhance octane ratings (Yang et al., 2019). Thus, due to its utility, ubiquity, and economic importance, BTEX is likely to remain a persistent environmental pollutant in the air for the foreseeable future (Bolden et al., 2015; Davidson et al., 2021).

Furthermore, there is a body of evidence that BTEX has the potential to irritate various organs within the human body, including the respiratory tract, lungs, bronchi, skin, and heart, and that exposure to
90 elevated concentrations can result in acute effects such as dizziness and vomiting (Davidson et al., 2021; Li et al., 2021; Ogbodo et al., 2022). According to the International Agency for Research on Cancer (IARC), benzene is recognized as a significant public health threat substance and is classified as a carcinogen (WHO, 2016). Additionally, the US EPA's carcinogenicity classification system categorizes benzene as a human carcinogen (Group A), supported by ample evidence of its carcinogenic effects in
95 humans. On the other hand, toluene, ethylbenzene, and xylenes are not classified as to human carcinogenicity (Group D) with inadequate (or no) evidence, while they have important non-carcinogenic toxic potentials (Durmusoglu et al., 2010). In 1990, the U.S. Clean Air Act Amendments classified seven categories of VOCs (<https://www.epa.gov/haps>), including BTEX and other three VOCs (n-hexane, 1,3-butadiene, and styrene) as hazardous pollutants, highlighting their potential to cause human cancer and
100 other serious health issues. Simultaneously, the Environmental Protection Directory issued by the Ministry of Ecology and Environment of the People's Republic of China designates BTEX and styrene as high-pollution and high-risk environmental pollutants (Song et al., 2018). Furthermore, the European Air Quality (Directive, 2008) establishes a limit value of 5 $\mu\text{g}/\text{m}^3$ for the annual mean of benzene in ambient air, with all member countries required to monitor and report on this carcinogenic compound to
105 the European Environment Agency (EEA) database (<https://www.eea.europa.eu/en>). Since BTEX members are small molecules with lipophilic characteristics, they easily penetrate the human body (Zahed et al., 2024). However, studies focusing on BTEX within the European Union (EU) have primarily centered on Member States. For instance, Borbon et al. (2018) conducted long-term observations of hydrocarbons, including TEX, in traffic and urban background locations in London, Paris,
110 and Strasbourg. They estimated the relative importance of traffic emissions for TEX in each city and found that traffic emissions would no longer dominate TEX concentrations in urban areas of Europe. Despite this, studies addressing the overall BTEX pollution status and health risk assessment at the EU level remain relatively insufficient.

RI-URBANS (Research Infrastructures Services Reinforcing Air Quality Monitoring Capacities in
115 European Urban and Industrial Areas, funded by the EU's Horizon 2020 research and innovation program, 101036245) is a European research project that demonstrates the application of advanced air quality service tools in urban Europe to improve the assessment of air quality policies, including a more accurate evaluation of health effects. In this context, this study focused on collecting and evaluating both online and offline BTEX data from 19 cities (total 22 monitoring sites) across seven European countries
120 (Belgium, Finland, France, Greece, Switzerland, Spain, and the United Kingdom). The study's objectives

included: (i) comparing BTEX concentrations across Europe; (ii) identifying sources of BTEX; and (iii) assessing the health impacts of BTEX. By comprehensively assessing BTEX levels in major European cities and their harmful effects on human health, this study aims to provide data support for the coordinated management of BTEX monitoring across Europe.

125

2 Methodology

2.1 Instrumentation

The instrumentation used for measuring BTEX at different stations, as described in Table 1, encompassed 3 industrial (IND) sites, 2 traffic (TR) sites, 16 urban background (UB) sites, and 1 suburban background (SUB) site. Briefly, in this study the BTEX was measured by Thermal Desorption Gas Chromatography with Flame Ionization Detectors (TD-GC-FID/2FID), Thermal Desorption Gas Chromatography-Mass Spectrometry (TD-GC-MS), Proton Transfer Reaction-Time of Flight-Mass Spectrometry (PTR-TOF-MS), PTR-Quad-MS, and passive samplers. It should be noted that comparing such heterogeneous datasets, without an intercomparison exercise, is a limitation of the study.

In addition, as shown in Table 1, the monitoring periods differed for each site. We considered only BTEX data obtained from urban sites between the years 2017 and 2022, with the exception of HEL_UB (only February 2016) and ATH_UB (only 2016-2017) that provided shorter timeseries, to reduce the uncertainties when comparing BTEX mixing ratios and health risk assessment between sites due to long term trends at each site (Table 1, Figure 1). Also, BCN_UB and PAR_SUB monitored the combined levels of ethylbenzene and xylenes. However, because the PTR-MS technique used at these sites does not distinguish between isomers (Simon et al., 2023), we excluded these data from our analysis, when comparing BTEX mixing ratios. Additionally, BAQS_UB did not detect m,p-xylene.

145

2.2 Risk assessment

Health risk assessments were conducted to evaluate the impacts on human health from exposure to atmospheric pollutants through inhalation, ingestion, and dermal penetration (Li et al., 2014; Yao et al., 2019; Nie et al., 2020; Zahed et al., 2024). Among the aforementioned pathways, inhalation is regarded as the main route. Therefore, in this study, the health risks associated with inhalation exposure were assessed. The Lifetime Cancer Risk (LCR) were performed based on the method proposed by the U.S. Environmental Protection Agency (EPA) in 2009 (EPA-540-R-070-002) (EPA, 2009). This method was employed to evaluate carcinogenic risks of inhaled benzene and ethylbenzene on the population. The formula for calculation is as follows: $LCR = CA \times IUR$, where CA represents the concentration of pollutants in the atmosphere ($\mu\text{g}/\text{m}^3$). The mixing ratio was converted into concentrations for benzene and ethylbenzene. The Inhalation Unit Risk (IUR) is the unit risk value for inhalation exposure ($\mu\text{g}/\text{m}^3$)⁻¹, indicating the maximum probability of developing cancer when exposed to a certain dose of a pollutant through inhalation. The IUR values for benzene and ethylbenzene are 7.8×10^{-6} and 2.5×10^{-6} ($\mu\text{g}/\text{m}^3$)⁻¹, respectively, as derived from the U.S. EPA IRIS (EPA, 2020).

According to U.S. EPA standards, LCR represents the probability of cancer occurrence in the exposed population, usually expressed as the ratio of the number of cancer cases per unit population. If the LCR falls below 10^{-6} (indicating an increase of 1 cancer case per 1 million people in a lifetime), it is widely considered as negligible. Some jurisdictions consider risks as high as 10^{-4} as tolerable, and those higher than this as requiring urgent action.

2.3 Data Treatment

The data quality was assessed and evaluated by two ACTRIS CiGas (<https://www.actris.eu/topical-centre/cigas>) units at IMT Nord Europe - France and EMPA-Switzerland, based on ACTRIS recommendations and guidelines (Laj et al., 2024). Some sites indicated that they are following the ACTRIS guidelines especially for GC measurements (https://www.actris.eu/sites/default/files/inline-files/WP3_D3.17_M42_0.pdf). However, the data evaluation showed that some sites had outliers, which were deleted when analyzed. Meanwhile, the International Union of Pure and Applied Chemistry strongly recommends using mixing ratios (Schwartz and Warneck, 1995). Therefore, in this study, BTEX levels are presented as average mixing ratios (AVE) \pm standard deviation (STD) in parts per trillion by volume (ppt). Statistically significant differences in BTEX mixing ratios at various monitoring sites and during different seasons were assessed using the ANOVA on ranks (Kruskal and Wallis, 1952) and Duncan's Multiple Range Test (Duncan, 1955). These statistical analyses were performed using the SPSS Software (IBM SPSS Statistics 25, Chicago, IL, USA).

3 Results and discussion

3.1 Status of BTEX data availability and mixing ratios in urban Europe

The results showed that, in urban areas, the relative abundance of BTEX followed this order: toluene > benzene > m,p-xylene > o-xylene > ethylbenzene with mean mixing ratios of 391 ± 451 , 252 ± 324 , 222 ± 297 , 92 ± 119 , and 78 ± 107 ppt during the years 2017-2022, respectively (Figure 1). Comparing different types of locations, the average mixing ratios of BTEX were higher at IND and TR

sites, while lower levels were found at UB sites (Figure S1). These results indicate that transportation and industrial activities primarily contributed to BTEX pollutants in the studied urban areas.

Spatial variation in BTEX mixing ratios across urban Europe is significant. For example, ATH_UB had the highest BTEX levels (3831 ± 3084 ppt) among all monitoring sites, followed by BCN_UB (1646 ± 1239 ppt). This is primarily because these two sites are located in the eastern part of the Mediterranean basin, where the combination of a temperate climate (mild and rainy winters versus hot and dry summers) favors the development of severe air pollution episodes (Monks et al., 2009; Im and Kanakidou, 2012). Nonetheless, compared to the period before 2000, the levels of benzene and other BTEX compounds have shown a decreasing trend due to the successful implementation of air quality measures in Greece, such as the extension of metro lines and the use of catalytic converters in cars (Panopoulou et al., 2021). However, compared to other European cities, pollution in Athens remains relatively severe, largely due to traffic but especially to wood burning impact for heating (Panopoulou et al., 2018). For more details on the spatiotemporal variation and source apportionment of BTEX and other VOCs at this site, refer to (Panopoulou et al., 2021).

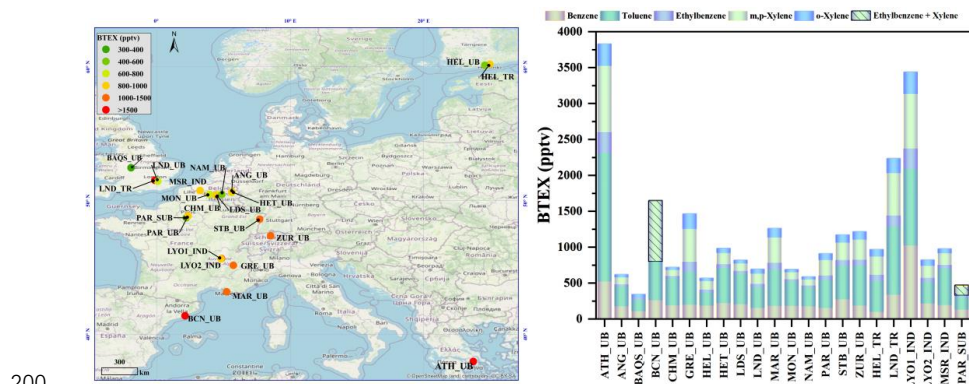

Figure 1. Average mixing ratios of BTEX at 22 European sites (left panel) and the contribution of BTEX at each monitoring site (right panel) during 2017-2022 (but HEL_UB only during February 2016 and ATH_UB only 2016-2017). Please note that the BTEX observations at BCN_UB and PAR_SUB were not able to distinguish the mixing ratios of ethylbenzene separate from xylenes, and at BAQS_UB did not include m,p-xylene data.

3.2 Temporal variations of BTEX mixing ratios

Figure S2 depicts the temporal variations of BTEX mixing ratios at the different monitoring stations. The mixing ratios curves of BTEX species exhibited irregular fluctuations over the whole sampling period, but the mixing ratios of each component showed highly similar temporal variations. These results indicated a significant correlation among their concentrations, and consequently suggested similar or identical sources for the BTEX species (Table S1). The highest correlation was observed between o-xylene and m,p-xylene at all monitoring stations ($r^2=0.62-0.99$), suggesting that they had similar emission sources (e.g., paints, finishing, fuels, and solvent). Conversely, the correlation between benzene and xylene exhibited some variability across different sites. In the majority of locations, the correlation falls within the range of $r^2=0.30$ to 0.59 . However, lower correlations ($r^2<0.20$) were observed at BAQS_UB

and LY01_IND, while stronger and significant correlations ($r^2 > 0.70$) were noted at ATH_UB, HEL_TR and LDS_UB. This variability may be attributed to their respective emission sources, atmospheric lifetimes, and differences in their photo-reactivity within distinct environment (Monod et al., 2001).
 220 Indeed, benzene has a rate constant (kOH) for reaction with hydroxyl radicals ($\cdot\text{OH}$) of $1.2 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and an atmospheric lifetime of about 9.5 days. In contrast, xylene has a significantly higher kOH, ranging from $14 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for o-xylene to $23.1 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for m-xylene, with a much shorter atmospheric lifetime between 10 and 20 hours (Atkinson and Arey, 2003; Liu et al., 2023). These differing properties suggest that both photo-reactivity and source emissions
 225 crucially influence atmospheric behavior and concentrations.

3.2.1 Seasonal variation

A comparative analysis of seasonal variations (Spring, Mar-May; Summer, Jun-Aug; Autumn, Sep-Nov; Winter, Dec-Feb) in BTEX mixing ratios across different types (UB, TR, and IND) of 21 urban sites was also performed (Figure 2). The results indicate, that benzene reached very similar median
 230 mixing ratios at UB, TR and IND in all seasons, pointing to a mix of source contributions. While for toluene, the average and median mixing ratios followed this trend: $\text{TR} \geq \text{IND} > \text{UB}$ for all seasons, further indicating a relatively greater influence of traffic sources on this species (Baudic et al., 2016; Salameh et al., 2019). For ethylbenzene and xylene (EX), averaged mixing ratios measured seem to be equivalent
 235 for TR and IND (and significantly lower at UB sites).

Figure 2. Seasonal variations of BTEX (benzene, toluene, ethylbenzene, xylene) mixing ratios for the different types sites (UB, urban background; TR, traffic; IND, industry). The box represents the 5th–95th percentiles of ratios. The middle line and middle square represent the median and mean values of ratios, respectively.

240

Figure S3 shows the BTEX mixing ratios by season for each site. Overall, BTEX mixing ratios at all monitoring sites showed substantial seasonal differences using ANOVA in ranks and Duncan analyses ($p=0.05$). The extent to which there were statistically significant differences in each BTEX concentration between seasons varied slightly across different monitoring sites (Figure S3). Specifically, except for sites BAQS_UB, HEL_TR, and LYO1_IND, the BTEX mixing ratios were lower during spring and summer and higher during autumn and winter. This finding can be attributed to seasonal differences in photochemical reactions, atmospheric conditions, and the intensity of different emission sources. When analyzing meteorological data from selected monitoring sites (Figure S4), it becomes evident that winter exhibits lower temperatures and mixing layer height, unfavorable for pollutant dispersion. Conversely, summer features more conducive diffusion conditions, likely resulting in lower pollutant concentrations. Meanwhile, the increase in BTEX mixing ratios in winter may be influenced by the emissions from residential heating and road-traffic emissions (Boynard et al., 2014; Panopoulou et al., 2018), and the lower spring and summer concentrations might be also linked to a high photochemical oxidation (Hui et al., 2019). At BAQS_UB, benzene was lower in summer and higher in winter, while TEX (toluene, ethylbenzene, and xylene) did not vary significantly, suggesting that in combination urban gasoline and solvent emission rates have been stabilized (AQEG-EU, 2020). Due to only summer and autumn data being available, HEL_TR exhibited higher mixing ratios for BTEX in summer compared to autumn, which can be attributed to increased evaporative emissions during the summer months. For LYO1_IND, benzene levels were lower in summer and higher in winter, while TEX levels were lower in spring and higher in summer. This indicates that during the summer, TEX mixing ratios can mainly be influenced by additional pollution sources, such as the volatilization of paints, finishing products, solvents, and fuel evaporation.

Additionally, seasonal variations in gasoline formulations could also play a significant role. For example, increasing ethanol content in gasoline can reduce emissions of BTEX (Yao et al., 2011; Karavalakis et al., 2014). The most common formulation in Europe is E5 (containing 5% ethanol), with ethanol concentrations generally higher in the summer than in the winter (Dunmore et al., 2016).

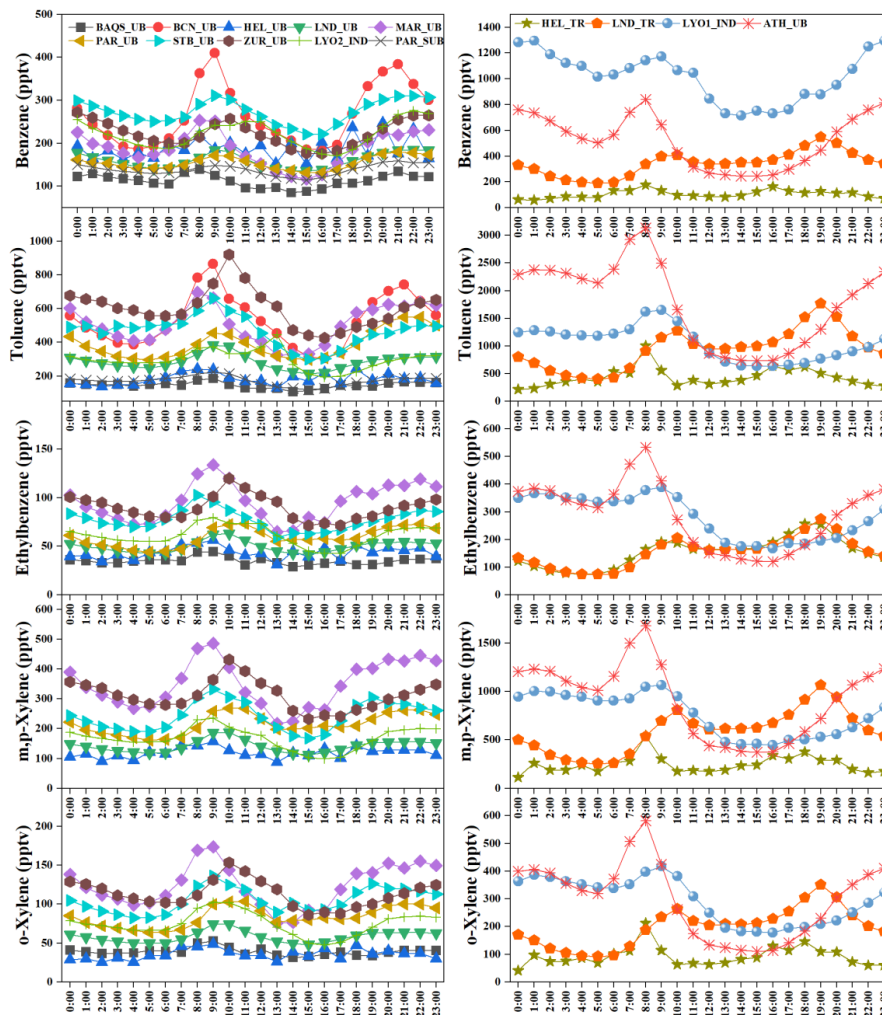

3.2.2 Diel Variation

Only online monitoring sites with hourly resolution BTEX data were considered (ATH_UB, BAQS_UB, BCN_UB, HEL_UB, LND_UB, MAR_UB, PAR_UB, STB_UB, ZUR_UB, HEL_TR, LND_TR, LYO1_IND, LYO2_IND, and PAR_SUB). Diel variations of BTEX (Figure 3) indicated that at some sites, such as ATH_UB, BCN_UB, LND_UB, MAR_UB, HEL_TR, LND_TR, and LYO1_IND, double peaks varying in intensity, amplitude, and time of the maxima. Generally, the concentration of aromatic compounds is higher at night than during the day. The chemical removal process of BTEX mainly involves photochemical reactions with OH and NO₃ radicals (Atkinson and Arey, 2003; Carter, 2007). ·OH radicals are mainly present during the daytime, and their reaction rates with VOCs are faster than the NO₃ radicals present at night (Zou et al., 2015). Additionally, the higher mixing layer height during the day aids in diluting pollutants, while nighttime emissions from activities like firewood for leisure and winter heating result in higher BTEX concentrations at night compared to daytime levels (Wu et al., 2016; Liu et al., 2020).

The first of the two major diel BTEX peaks coincides with the morning road-traffic rush hours. Particularly, BTEX mixing ratios in ATH_UB and LYO1_IND are significantly ($p = 0.001$) higher than at the other sites, which may be closely related to industrial sources, off-road transport, types of vehicles, traffic flow, and other combustion-related sources. Similarly, influenced by traffic, the peaks of BTEX in LND_TR were also more pronounced. After 17:00, when people mainly leave from work, traffic increases, and the mixing layer height decreases. A similar phenomenon was observed in HEL_TR, although this site only provided data for one month in 2019 (Table 1). Consequently, an evening peak in BTEX levels is regularly observed between approximately 18:00-19:00 at these sites (Figure 3). However, LYO1_IND is hardly affected by the evening rush hour. This is primarily due to the site's exposure to industrial processes, as well as wind speed and direction, particularly when the monitoring site is downwind of the industrial area. The highest levels are observed at 23:00. These phenomena further indicate that BTEX are largely associated with anthropogenic activities and specific meteorological factors. Furthermore, in addition to traffic emissions, evaporative sources contribute significantly to the diel patterns observed in some of the BTEX. Given that evaporative emissions typically rise in the afternoon as temperatures increase (Nguyen et al., 2009), any elevation in TEX mixing ratios may be linked to their evaporative sources (Yurdakul et al., 2018). It is striking how similar the levels and variability of toluene are in BAQS_UB, HEL_UB, and PAR_SUB, likely reflecting similar traffic influences. In contrast, benzene levels show more variation, indicating regional influences. Focusing on Paris, similar to the findings of (Simon et al., 2023), we observe comparable levels and variability of benzene between PAR_UB and PAR_SUB, suggesting regional influence. However, for toluene, levels are higher in PAR_UB compared to PAR_SUB, indicating more local traffic influences in Paris.

Similarly, the analysis of the seasonal and weekly diel average variations of BTEX at 14 online monitoring sites (Figures S5 and S6) showed pattern similar to the overall diel trend. Specifically, certain monitoring sites (*i.e.*, ATH_UB, BCN_UB, LND_UB, MAR_UB, PAR_UB, ZUR_UB, HEL_TR, LND_TR, and LYO1_IND) exhibited prominent morning and evening peaks during weekdays (Monday to Friday). This phenomenon is attributed to increased emissions from vehicle exhaust, as suggested by measurements in tunnels (Ammoura et al., 2014). However, during weekends (Saturday and Sunday), particularly on Sunday mornings, there were either no peaks or much weaker ones due to lower traffic density. Compared to the corresponding peaks on weekdays, the peaks on Saturday and Sunday evenings (~ 22:00-24:00) were delayed. This delay is linked to the fact that people tend to stay at home during weekends, engaging in leisure activities, and thus leading to higher emissions from cooking and household heating, and/or go out socially in the evening. These phenomena are similar to our research on levels of lung deposited surface area (LDSA) across various monitoring sites in Europe (Liu et al., 2023) and the diel variations of black carbon across different seasons in Augsburg (Liu et al., 2022).

315

Figure 3. Diel variations of hourly average BTEX mixing ratios for 14 of the 22 studied sites, presented in local time over the entire sampling period for each site. Please note that the two vertical axis of each compound span different ranges of mixing ratios.

3.3 Specific ratios of BTEX

3.3.1 Benzene/Toluene (B/T)

Benzene and toluene have been found to be relatively more stable than xylenes having lifetimes of 9.5 days, 2.1 days and 7.8 h, respectively (Atkinson and Arey, 2003; Liu et al., 2008). Therefore, B/T remains relatively constant close to emission sources. However, this ratio can change over time and with the atmospheric processing of air masses (Seco et al., 2013). B/T values around 0.5 suggest significant influences from vehicle exhaust, while values significantly higher than 0.5 indicate that other sources such as industry, coal combustion, and biomass burning are major sources of BTEX species (Barletta et al., 2005; Baudic et al., 2016; Salameh et al., 2019). Additionally, higher B/T ratios can also be attributed

325

330 to the fact that emissions and/or air masses further away from the source are more aged, leading to relatively more toluene disappearance due to its higher reactivity compared to benzene.

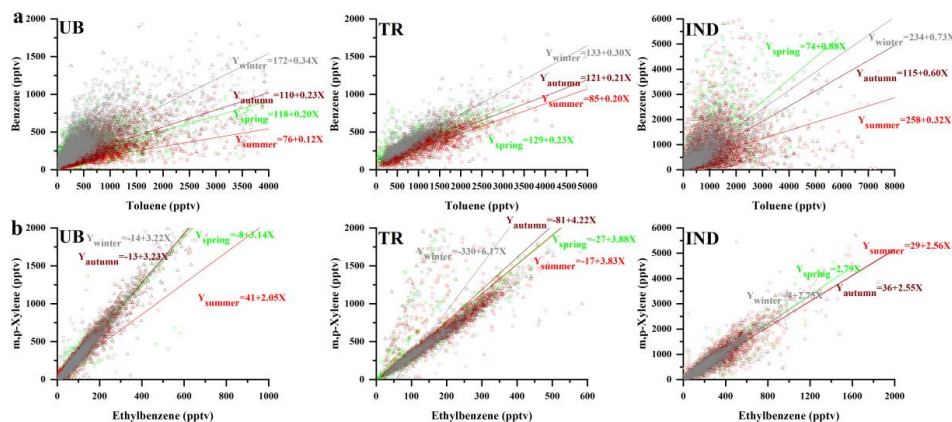

335 *Figure 4. The ratios of benzene to toluene (B/T) and meta/para-xylene to ethylbenzene (X/E) at all sites (a-1, b-1) and different types sites (UB, urban background; TR, traffic; IND, industry; a-2, b-2). The box represented the 5th–95th percentiles of ratios. The middle line and middle square represented the median and mean values of ratios, respectively. Blank means no available value.*

340 As shown in Figure 4a-1, the B/T ratio ranges from 0.29 ± 0.11 to 1.35 ± 0.95 , with the majority of sites averaging around 0.4-0.6 (BCN_UB, CHM_UB, GRE_UB, HET_UB, MAR_UB, PAR_UB, ZUR_UB, LND_TR, and MSR_IND). Similarly, (Salameh et al., 2019) found that at UB sites with weekly measurements, B/T was in the same order of magnitude as the TR sites with an average ratio of 0.34 in Paris. This finding was indirectly confirmed by the diel variation of BTEX mixing ratios (Figure 3) and the B/T trends in different site typologies (TR: 0.41 ± 0.29 ; UB: 0.73 ± 0.68 ; IND: 1.03 ± 1.00 , Figure 4a-1). Notably, based on only summer and autumn data being available (Table 1), the B/T at HEL_TR, serving as a traffic site, was 0.29 ± 0.11 , suggesting vehicular exhaust emissions as the primary source of benzene and toluene in the study area's ambient air, primarily through fuel evaporative emissions.

350 Further, considering the seasonal B/T ratios in different urban environments (Figure 5a), each monitoring site (Figure S7), and temporal trends (Figure S8) in B/T across monitoring sites, the seasonal fluctuations of benzene and toluene are consistent with B/T, showing seasonal differences to a certain extent. Specifically, the mean and median values of B/T across all monitoring sites exhibit lower values in summer and higher values in winter. This pattern is consistent across different types of environments. The higher B/T values in winter further indicate influences from biomass combustion sources.

355 Alternatively, in summer, the low B/T ratio is attributed to additional sources of toluene (potentially other non-methane hydrocarbons as well), most likely originating from industrial sources, as toluene is commonly used as a solvent in many industrial applications (AQEG-EU, 2020), and solvents and coatings readily volatilize into the atmosphere, as well as from fuel evaporation.

360 *Figure 5. Regression of benzene to toluene (a) and m,p-xylene to ethylbenzene (b) ratios in different urban locations (UB, urban background; TR, traffic; IND, industry) across different seasons (green, spring; red, summer; wine, autumn; gray, winter).*

3.3.2 m,p-Xylene/Ethylbenzene (X/E)

365 In the atmosphere, m,p-xylene and ethylbenzene are homologous and the reaction rate of m,p-xylene with the OH radical is three times faster than that of ethylbenzene (Martins et al., 2008; Han et al., 2017). Hence, the X/E ratio can serve as an indicator reflecting the extent of photochemical reactions (McKeen and Liu, 1993), where higher and lower X/E ratios suggest local sources and external transport, respectively (Zalel and Broday, 2008).

370 Typical X/E ratios measured in the urban atmosphere are around 3 (Monod et al., 2001; Hsieh et al., 2011; Amodio et al., 2013). Wang et al. (2015) observed significant variations in X/E ratios (ranging from 1.2 to 2.8) in tunnels characterized by different types of vehicles in downtown Shanghai. In this study, the mean X/E ratio across monitoring sites ranged from 1.75 ± 0.91 to 3.68 ± 0.30 (Figure 4b-1), with X/E values oscillating around 3 at all sites. Additionally, there were minimal differences in the average X/E values across seasons (Figures 5 and S9) and different types of sites (Figure 4b-2). This result suggests that pollutants at the monitoring sites are primarily emitted directly from local sources (with higher X/E values). Specifically, considering the temporal variations of X/E at each monitoring site, except for the monitoring period at HEL_UB in 2016, this ratio was generally greater than 2 at the other sites (Figure S7). This result further suggests that direct emissions from local sources dominate at

375

380 each monitoring site. Notably, in general, the slightly lower X/E value observed at the UB sites (*i.e.*, ANG_UB, CHM_UB, GRE_UB, HET_UB, MON_UB, NAM_UB, LDS_UB, and ZUR_UB) in summer and the higher X/E value observed at the TR site (*i.e.*, LND_TR) in winter can be attributed to seasonal differences in photochemical reactions and atmospheric conditions, the impact of changing gasoline

formulations, as well as the significant increase in BTEX concentrations during winter cold starts
 385 (George et al., 2015; Zhang et al., 2022) (Figure 5b). In summer, increased solar radiation and higher
 temperatures promote photochemical reactions (Rad et al., 2014), and since the reaction rate of m,p-
 xylene with the OH radical is three times faster than that of ethylbenzene, the X/E ratio decreases.
 Conversely, in winter, the formation of a stable atmospheric layer and lower temperatures may cause
 pollutants to remain in the atmosphere for longer periods, leading to an increased X/E ratio.

390

3.4 Health risk assessment of BTEX

Figure 6 presents LCR values associated with benzene and ethylbenzene exposure through
 inhalation at all monitoring sites. Across all sites, the average LCR values range from 2.6×10^{-6} to $1.9 \times$
 395 10^{-5} , showing that all values are below the definite risk of cancer threshold (10^{-4}) but exceeding the
 threshold established by the US (EPA, 2001) guidelines of 1×10^{-6} . This result indicates that the risk
 from benzene and ethylbenzene is at a moderate level and still warrants attention, especially in TR and
 IND environments. The variability in LCR values across different sites highlights the importance of
 localized assessments and tailored interventions. Urban areas, for example, might need different pollution
 400 control strategies due to differences in pollutant sources and population density. Industrial and traffic-
 related areas often have higher concentrations of these pollutants due to emissions from vehicles and
 industrial activities. Therefore, populations in these areas might be at greater risk and require more
 stringent monitoring and regulatory measures to mitigate exposure.

Furthermore, the PTR-MS systems used at BCN_UB and PAR_SUB were not able to distinguish
 the mixing ratios of ethylbenzene separate from xylenes. This limitation affects the comparability of LCR
 405 values across different monitoring sites, as the absence of ethylbenzene data at these sites results in an
 incomplete assessment of the total carcinogenic risk. Despite these limitations, the comparisons still offer
 valuable insights into the spatial distribution of cancer risks and highlight areas where more
 comprehensive monitoring is needed.

To enhance the reliability and comprehensiveness of future assessments, it is crucial to establish a
 410 standardized observation platform. Such a platform would ensure consistent data collection methods,
 pollutant measurement techniques, and risk assessment criteria across all monitoring sites. This would
 facilitate more accurate comparisons and trend analyses over time, enabling better-informed decision-
 making for public health interventions.

415 *Figure 6. The lifetime cancer risk (LCR) values for the carcinogenic risk of benzene and ethylbenzene through inhalation for individuals at all sites. Please note that the LCR values of BCN_UB and PAR_SUB have only been calculated with benzene data (marked gray).*

4 Conclusions

This study conducted a comprehensive assessment of long and short-term mixing ratios of benzene, toluene, ethylbenzene, m,p-xylene, o-xylene (BTEX) across 22 monitoring sites in seven European countries (Belgium, France, Finland, Greece, Spain, Switzerland, and the United Kingdom.). These sites included 3 industrial (IND) sites, 2 traffic (TR) sites, 16 urban background (UB) sites, and 1 suburban background (SUB) site. The average of BTEX mixing ratios was 1199 ± 898 ppt across all monitoring sites. Our findings demonstrate significant seasonal and diel variabilities in BTEX mixing ratios ($p=0.01$) at each monitoring site, indicating the influence of changes in traffic volume, emission sources, photo-reactivity, and meteorological factors. The B/T ratio ranged from 0.29 ± 0.11 to 1.35 ± 0.95 , and the X/E ratio ranged from 1.75 ± 0.91 to 3.68 ± 0.30 , demonstrating spatial variations in BTEX emission sources across monitoring sites. These results highlight that local traffic emissions are the major source of BTEX pollution, with additional contributions from industrial processes, solvents use, coatings, biomass burning, and fuel evaporation. Furthermore, our health risk assessment indicates the lifetime cancer risk (LCR) from inhaling benzene and ethylbenzene, although relatively low ($<10^{-4}$), still warrants attention due to the potential effects for long-term exposure.

In conclusion, this study provides new insights into the temporal and spatial variabilities of BTEX mixing ratios across different types of sites in multiple European countries. It emphasizes the significant impact of traffic-related emissions and seasonal factors on BTEX levels, and underscores the need for continued monitoring and regulation to mitigate potential health risks. The findings also suggest that future studies should focus on the impact of changing gasoline formulations and vehicle technologies on BTEX emissions, as well as the effectiveness of current air quality regulations in reducing BTEX exposure.
