## 11 Abstract

12 Continental sedimentary successions are typically less complete and more poorly preserved than the marine record, leading to  
13 limited correlations between basins. Traditionally, intra-basin correlation employs radiometric dating of volcanic markers or  
14 relative dating based on the fossil record. However, volcanic markers may not always be present, and biostratigraphy relies on  
15 index fossils ~~whichthat~~ are often sparse to absent in continental ~~successionsuccession~~. Recent progress in carbonate U-Pb  
16 dating can improve correlations between continental successions by providing absolute age constraints on carbonate deposition  
17 and/or on syn- to post-depositional processes such as pedogenesis.

18 In this study, we analysed pedogenic calcite nodules within a continental Miocene succession in the southwestern Paris Basin  
19 (the important paleontological site at Mauvières quarry, France). Following multimethod petrographic characterisation of the  
20 samples, LA-ICP-MS U-Pb dating was employed to obtain formation ages on the pedogenic calcite nodules. The Tera-  
21 Wasserburg intercept ages from five nodules from the same horizon ( $19.3 \pm 1.3/1.4$  Ma,  $18.0 \pm 3.8 \pm 2.3/2.7$  Ma,  
22  $19.11 \pm 0.84/0.94$  Ma,  $19.0 \pm 2.3/2.3$  Ma and  $19.4 \pm 2.7/2.7$  Ma) are in excellent agreement with previous biostratigraphic  
23 constraints on the sequence. Petrographic evidence points to a single crystallisation event, and we conclude that the formation  
24 of the calcite nodules occurred at  $19.3422 \pm 0.5866/0.7379$  Ma (central age from a radial plot of the five Tera-Wasserburg  
25 intercept ages). This calcite formation age is regarded to represent a minimum depositional age of the strata hosting the root  
26 nodules. It provides the first ~~directabsolute~~ age for the continental Miocene succession (and Neogene mammal zone MN3) of  
27 the Paris Basin and allows correlation with other continental basins independent of their fossil assemblages or ~~when the where~~  
28 fossil content is ~~missingabsent~~.

30 **1 Introduction**

31 Biostratigraphy assigns relative ages to rock strata by using the fossil assemblages contained within them, with the goal of  
32 showing that a particular horizon in a given section represents the same a similar period of time as the same an analogue horizon  
33 in a different succession. It relies heavily on the presence of index fossils - fossils with a limited time range, wide geographic  
34 distribution, and rapid evolutionary trends. The common absence of biostratigraphically-diagnostic index fossils in continental  
35 successions is problematic, and absolute dating approaches often need to be applied to continental successions. Such  
36 approaches include geochronology of volcanic horizons such as lava flows or, ash beds, or cryptotephra (e.g., Rubidge et al.,  
37 2013; Smith et al., 2017; Poujol et al., 2023), astronomic calibration (e.g., Kerr 1992, Montano et al., 2021), and  
38 magnetostratigraphic correlation (e.g., Kalin and Kempf 2009). While volcanic horizons can provide accurate and precise  
39 absolute ages, they are not ubiquitous in the sedimentary record. Carbonates are very common in terrestrial successions (except  
40 in humid climates) where they can be classified as pedogenic or non-pedogenic, depending on whether they have formed by  
41 soil-forming processes (Zamanian et al., 2016). Pedogenic carbonates comprise calcretes and dolocretes - paleosols that have  
42 been indurated by a pervasive calcitic cement; pisoliths - globular nodules made of concentric calcitic spheres; and more  
43 generic calcitic nodules - indurated concretions with a globular or cylindrical shape, often associated with calcitic cementation  
44 around plant roots (rhizocretions; Zamanian et al., 2016).

45 The formation of carbonates nodules can be classified according to the morphology of the nodule and the postulated fluid  
46 pathway that led to the formation of the nodule (Zamanian et al., 2016). *Perdescendum* models and *Perascendum* models  
47 involve dissolution of carbonate with reprecipitation in a different horizon (a deeper horizon for *Perdescendum* and shallower  
48 for *Perascendum*) while *in situ* models do not imply significant carbonate migration through the soil profile (Zamanian et al.,  
49 2016). Biological models invoke absorption of Ca-enriched fluid by an organism, leading to calcification of Ca-bearing organs  
50 or supersaturation that induces carbonate precipitation (Zamanian et al., 2016). These biological models include rhizolith  
51 formation, whereby plant roots pump the water from Ca-enriched fluids leaving behind residual Ca<sup>2+</sup> ions that react with the  
52 CO<sub>2</sub> emitted by rhizomicrobial respiration, resulting in the earliest carbonate cements around the root (Zamanian et al., 2016).  
53 After the root dies, the void created is filled (partially to completely) by calcite resulting from the activity of bacteria, algae,  
54 or by dissolution of the early carbonate cement and reprecipitation into cavities (Aguirre Palafox et al., 2024). When  
55 compaction starts, intergranular space and compaction cracks can create new cavities for carbonate precipitation. With burial,  
56 the nodule can travel from the oxidising conditions of the vadose zone towards the more reducing environment of the phreatic  
57 zone (Aguirre Palafox et al., 2024). This results in chemical changes (e.g. in Fe, Mn, and Pb) observable in  
58 cathodoluminescence (CL) images but which also affect U-Pb geochronology (Aguirre Palafox et al., 2024).

59 U-Pb dating of calcium carbonate started in the late 1980s using isotope dilution (ID) – thermal ionisation mass spectrometry  
60 (TIMS) methods (Smith and Farquhar, 1989; Roberts et al., 2020 and references therein). Most terrestrial U-Pb carbonate  
61 dating studies have focused on non-pedogenic carbonates (e.g. speleothems, tufas, and lacustrine carbonates; see review in  
62 Rasbury and Cole, 2009 and a more recent review by Rasbury et al., 2023). The first U-Pb dating studies applied to terrestrial

63 pedogenic carbonates took place in the mid-1990s on Paleozoic uranium-rich dolocretes, developed subaerially on top of  
 64 marine limestones (Hoff *et al.*, 1995; Winter and Johnson, 1995). Over the following years, a series of ID-TIMS U-Pb dating  
 65 studies yielded meaningful subaerial exposure ages from 1) Late Paleozoic paleosol-derived sparry calcite developed on top  
 66 of marine carbonate cycloths in the southwestern USA (Rasbury *et al.*, 1997, 1998, 2000; Rasbury and Cole, 2009); 2) Late  
 67 Paleozoic dolocretes from Kansas, USA (Luczaj and Goldstein, 2000); 3) Late Paleozoic subaerially soil-modified palustrine  
 68 limestones in Ohio, USA (Becker *et al.*, 2001); and 4) Triassic calcretes developed on top of fluviatile siliciclastics deposits in  
 69 Connecticut, USA (Wang *et al.*, 1998) (Table 1).

70 Since the mid-2010s, advances in laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) have allowed  
 71 U-Pb dating of carbonates with the benefits of much greater spatial resolution, mineralogical context (being in-situ), and  
 72 sample throughput (e.g., Li *et al.*, 2014; Roberts and Walker, 2016; Nuriel *et al.*, 2017). While individual LA-ICP-MS spot  
 73 ablation U-Pb data are typically significantly less precise than ID-TIMS U-Pb analyses, the high spatial resolution of the  
 74 approach means it can commonly encounter both high and low U/Pb portions of the sample, resulting in age regressions with  
 75 superior precision compared to ID-TIMS U-Pb dating studies which employ bulk sampling (e.g., Li *et al.*, 2014); [Roberts \*et al.\*, 2020](#). The technique has been employed to date pedogenesis including 1) Eocene pedogenic calcite nodules from Montana,  
 76 USA (Methner *et al.*, 2016) and [2020](#), 2) an Upper Triassic continental succession with calcite nodules and interbedded  
 77 volcanic markers from Argentina (Aguirre Palafox *et al.*, 2024), 3) Ediacaran dolomite from subaerially weathered volcanics  
 78 in Ukraine (Liivamägi *et al.*, 2021) (Table 1), and 4) U-Pb geochronology on *Microcodium* calcite from the Spanish Southern  
 79 Pyrenees that provided more constraints on fluvial mobility during the Paleocene–Eocene Thermal Maximum event (Prieur *et al.*,  
 80 2024).

82 **Table : Summary of published U-Pb ages of terrestrial pedogenic carbonates (modified and updated after Rasbury and Cole,  
 83 2009).**

84 LA-ICP-MS U-Pb dating requires chemically homogenous and large enough zones (typically, between 50 and 200  $\mu\text{m}$  wide  
 85 circles or squares) to obtain sufficient U and radiogenic Pb signals to produce meaningful age results (Roberts and Holdsworth,  
 86 2022). Additionally, high U and low common Pb concentrations are required to produce precise U-Pb dates, but carbonates  
 87 typically incorporate low U [concentrations abundances](#) (unless the precipitation takes place in reducing environments, e.g.

89 Carbonates in general and pedogenic carbonates in particular, are also often heterogenous at the hundreds of ~~micron~~<sup>micrometre</sup>  
90 scale or below (Zamanian et al., 2016; Roberts and Holdsworth, 2022; [Aguirre Palafox et al., 2024](#)), partially explaining the  
91 paucity of reliable dating results from pedogenic carbonates. More widespread absolute dating of pedogenic carbonates  
92 ~~could~~<sup>may</sup> provide valuable chronostratigraphic constraints in continental successions, particularly those where volcanic  
93 horizons or index fossils are absent. [Aguirre Palafox et al. \(2024\) recently provided guidelines and strategies to improve the](#)  
94 [sampling and interpretation of pedogenic carbonates, and addressed the influence of redox conditions on U concentrations and](#)  
95 [potential internal zonation.](#)

96 **Table 1: Summary of published U-Pb ages of terrestrial pedogenic carbonates (modified and updated after Rasbury and Cole,  
97 2009).**

98 A recent and innovative LA-ICP-MS U-Pb carbonate dating protocol, based on the selection and pooling of pixels from 2D  
99 elemental and isotopic ratio maps (Drost et al., 2018; Roberts et al., 2020; Chew et al., 2021) is now commonly employed as  
100 a U-Pb dating strategy (e.g. Monchal et al., 2023; Rasbury et al., 2023; Subarkah et al., 2024). This in-situ technique allows  
101 for the selection of chemically homogenous zones within a chemically heterogenous ablated 2D map area, reducing the risk  
102 of incorporating U-Pb data from non-carbonate inclusions or different generations of carbonates (Drost et al., 2018). In  
103 addition, this method optimises the spread of data points in Tera-Wasserburg (TW) space increasing the precision of the results  
104 (Drost et al., 2018). Therefore, this mapping-based technique is well suited to U-Pb dating and elemental characterisation of  
105 paleosol calcite, and ~~would~~<sup>can</sup> help alleviate some of the issues caused by microheterogeneity in pedogenic carbonates. A late  
106 Paleozoic paleosol calcite, already dated by ID-TIMS (298.1 $\pm$ 1.4 Ma; Rasbury et al., 1998) has been successfully dated using  
107 this approach (294.9 $\pm$ 8.6 Ma; Rasbury et al., 2023).

108 Continental sedimentary successions are often barren or poor in index fossils, which makes dating and intra-basin correlation  
109 difficult. Mammal remains have been used to create terrestrial biostratigraphic scales, such as the Neogene mammal (MN)

110 scale in Western Europe (Mein, 1975; Agustí et al., 2001). The European MN scale is similar to the North American Land  
111 Mammal “Ages” (NALMAs) and South American Land Mammal “Ages” (SALMAs) scales (see the review of Hilgen et al.,  
112 2012). However, mammal fossils are not ubiquitous in the sedimentary record, thus the MN and other mammal scales cannot  
113 always be employed. When compared to marine biostratigraphic records (which have index fossils such as planktonic  
114 foraminifera, ammonites, graptolites, etc.), they also exhibit diachronicity and a poorer temporal resolution. The poor temporal  
115 resolution, particularly in the early stages of the MN scale (see Discussion) is well illustrated by the MN3 biozone, which has  
116 a duration of between 2.8 and 5.4 Myr, depending on the absolute age chosen for the top and bottom boundaries (Mein, 1999;  
117 Steininger, 1999; Aguilar et al. 2003; Raffi et al., 2020). For comparison, the Paleogene calcareous nannofossil scale biozones  
118 all have a duration lower than 2 Myr, with most lower than 1 Myr (Agnini et al., 2014). The LA-ICP-MS calcite U-Pb  
119 geochronology approach adopted ~~herein could have in this study has~~ the potential to constrain the age of continental  
120 sedimentary horizons where pedogenic nodules are present. ~~This approach may improve inter-basins basin correlations and~~  
121 ~~better constrain the~~ temporal resolution of the MN scale, ~~as well as~~ potentially highlighting regional diachronism ~~if more~~  
122 ~~extensive sampling campaigns were conducted~~. In this study, we apply the LA-ICP-MS U-Pb mapping technique along with  
123 spot analysis to obtain absolute ages from pedogenic calcite nodules from a terrestrial Miocene succession in the Paris Basin,  
124 France, whose age is hitherto poorly constrained in terms of ~~direct absolute~~ dating.

## 125 2 Geological setting

### 126 2.1 Regional geology

127 The Mauvières paleontological site is located in the SW of the Paris Basin (France), a Mesozoic-Cenozoic intracontinental sag  
128 basin (Guillocheau et al., 2000). The site is on the northeast margin of the Neogene outcrops, which comprise continental and  
129 marine sedimentary rocks unconformably deposited on Paleogene continental sedimentary rocks (Figure 1a). Regionally, the  
130 Cenozoic sedimentary sequence reflects a dominantly continental paleoenvironment with occasional marine transgressions  
131 during the Miocene (Figure 1b, Gagnaison, 2020).

### 132 2.2 Paleoenvironment and origin of the calcite nodules

133 The pedogenic nodules were sampled from the Early Miocene (early to middle Burdigalian) Orléanais Marls and Sands  
134 Formation (Figure 1b), a few meters-thick succession of coarse and fine-grained clastic sediments (Figure 2). This  
135 ~~formation~~Formation rests unconformably over a Paleogene lacustrine silty marl (the Eocene-Oligocene Grey Marls Formation)  
136 and is overlain by Middle Miocene marine shelly carbonate sands, known locally as “*faluns*” (Gagnaison et al., 2023) (Figure  
137 1b and Figure 2).

138 The Early Miocene continental sequence at Mauvières consists of a series of eight clastic beds (numbered s1 to s8; Gagnaison  
139 et al., 2023; Figure 2a). The pedogenic nodules were found in the basal bed s1, which overlies ~~Paleocene~~-Eocene-Oligocene  
140 silty marls (Figure 2). The s1 bed is comprised of a very coarse light grey-orangey quarzitic sand with minor feldspar, in-situ

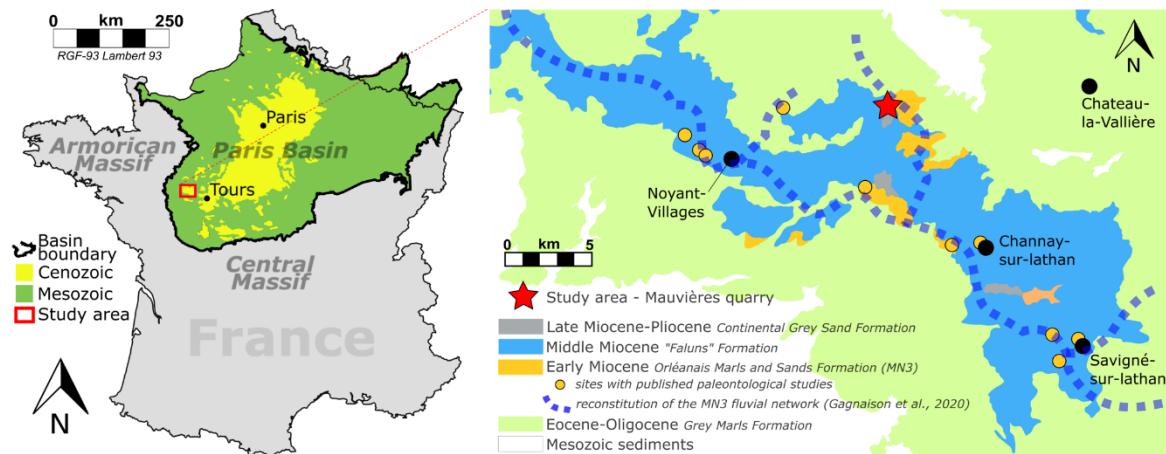

141

terrestrial vertebrate fossils, poorly preserved *Unio* shells (a freshwater mussel), and in-situ carbonate nodules and cylinders.

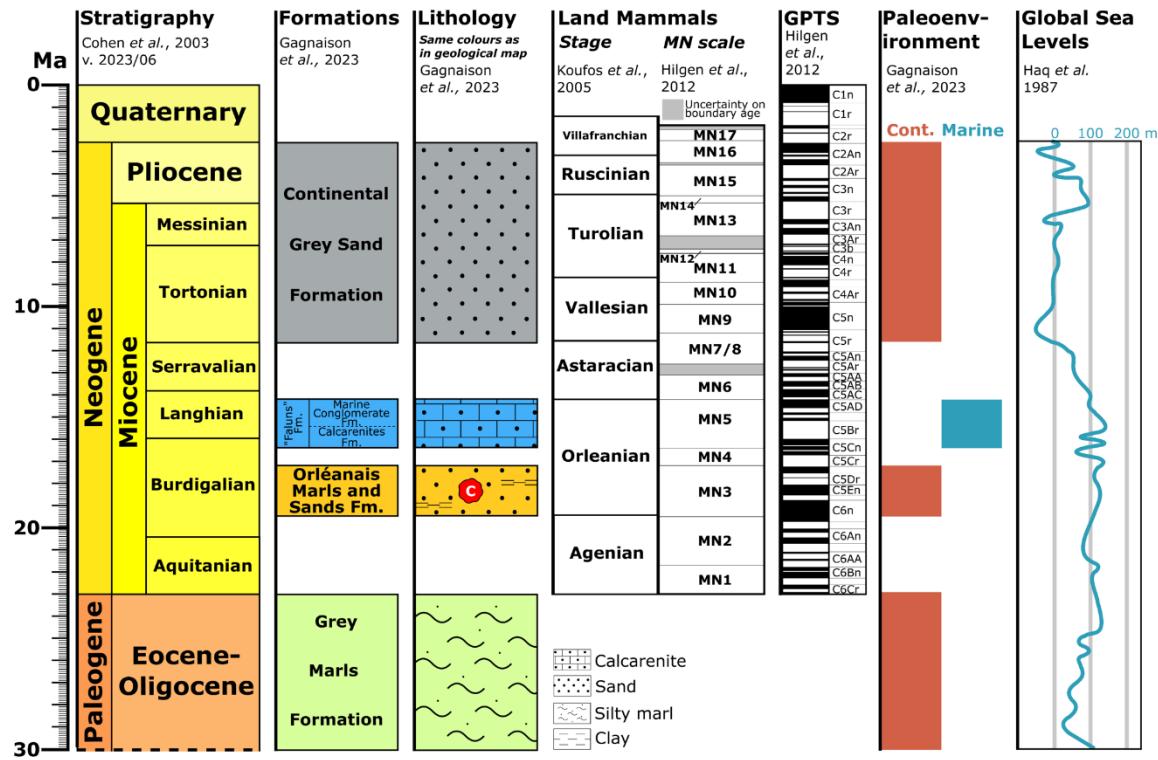

142

The sand also contains reworked material, including Cretaceous calcareous and siliceous pebbles, altered glauconite grains,

### a) Location and geological map

### b) Stratigraphic range chart

143

and Cretaceous and Oligocene / Early Miocene vertebrate fossils. The sand is loosely cemented with a clayey and calcareous

144

matrix (Gagnaison et al., 2023). Some rare *Unio* shells have been found with both valves still connected, indicating both a

145

low-energy environment and that they are in-situ (i.e. not reworked from older beds).

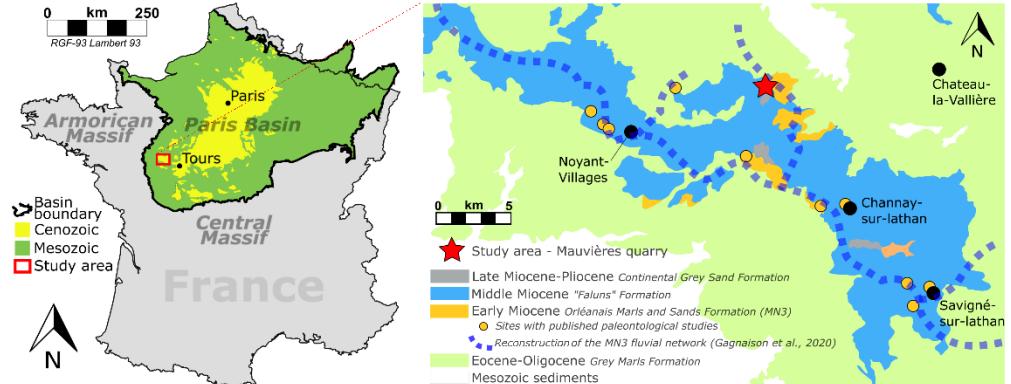

46 **Figure :** Geological context of the Mauvières section. a) Location of the Mauvières quarry and regional geology based on the  
47 BRCM 1/50,000 unified vector geological map of France (InfoTerre), modified after Gagnaison et al. (2020). b) Stratigraphy of the  
48 Mauvières section. The nodules (red symbol) come from the Orléanais Marls and Sands Formation attributed to the MN3 biozone  
49 (Gagnaison et al., 2023).

150 The occurrence of 1) hollow calcite cylinders and nodules interpreted as rhizocreations, 2) root tracks in the matrix, 3) iron  
151 oxides ~~which that~~ give the sand its orange colour ~~to the sand~~, and 4) microvacuoles interpreted as products of subaerial  
152 microbial activity, ~~suggest suggest~~ the presence of a paleosol (Gagnaison et al., 2023). The nodule-bearing s1 bed is interpreted  
153 as a water-transported, low-energy fluvial sequence with prograding sand bars, with phases of lacustrine floodings and  
154 development of paleosols. The sequence was subsequently subaerially exposed and followed by the development of a vegetated  
155 soil (Gagnaison et al., 2023). The pedogenic nodules are consequently interpreted as in-situ and not reworked from older  
156 horizons. Rasbury et al. (1997) have shown that the calcite spar typically forms rapidly following paleosol development, and  
157 therefore absolute dating of the nodules should provide robust age constraints on the ~~s1 bed~~minimum age of the s1 bed. Based  
158 on detailed petrography including CL imaging, Aguirre Palafox et al. (2024) provided more information on the environmental

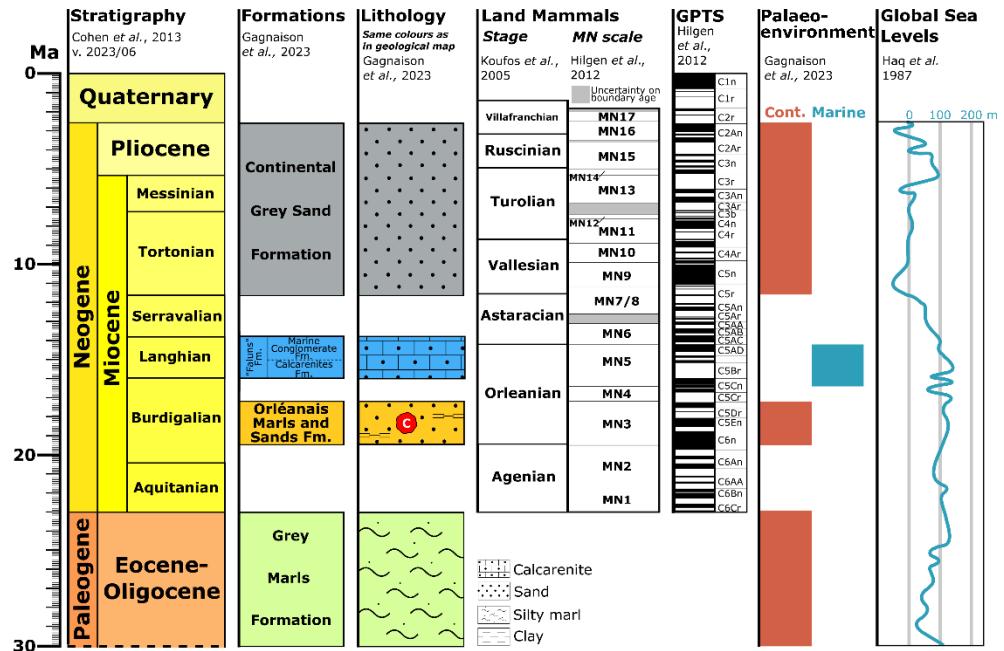

59 factors that influence the timing of nodule formation (e.g. redox conditions, burial, water table levels) that can in turn help  
 60 refine the interpretation of geochronological results.

61 **Figure 1: Geological context of the Mauvières section. a) Location of the Mauvières quarry and regional geological map based on the**

b) Stratigraphic range chart

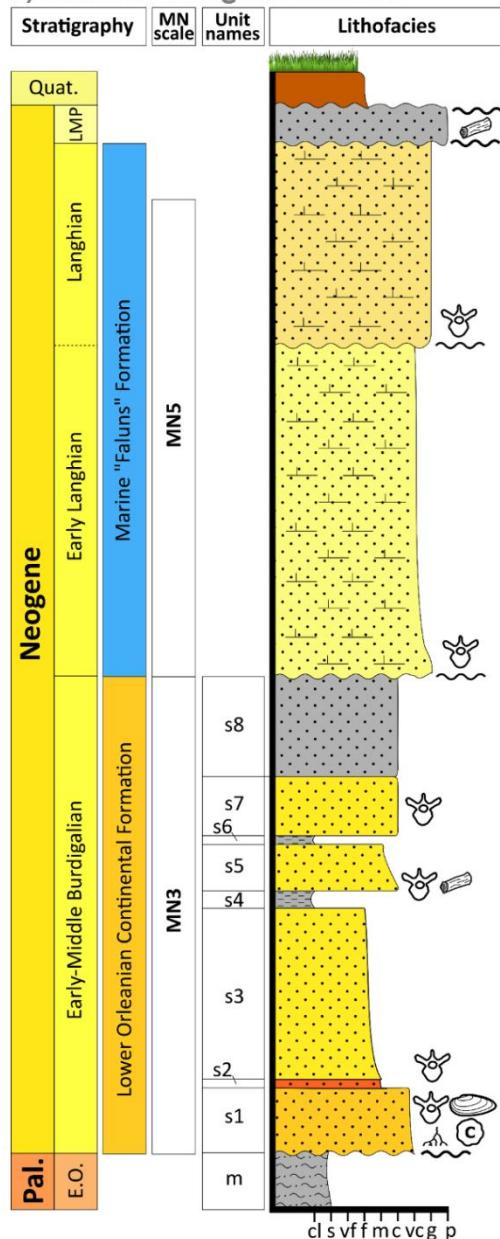

166 **2.3 Biostratigraphic age of the continental sands and nodule-bearing s1 bed**

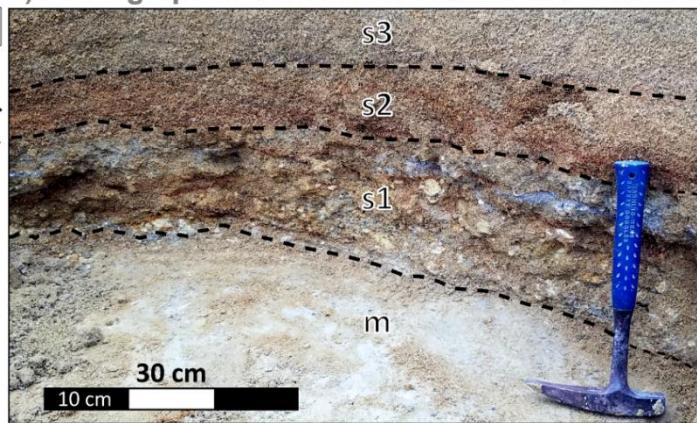

167 MN biozones were defined as a tool for inter-basin faunal comparisons (Mein, 1999). Limits of the zones are defined by 1)  
168 steps in mammalian evolutionary lineages (local evolution), 2) First Appearance Datum and/or Last Appearance Datum of  
169 species, 3) dispersal of taxa, and 4) faunal assemblages (Mein, 1999; Steininger, 1999). As discussed by Mein (1999), even  
170 when relatively inaccurate, the MN-zones are still a useful tool for regional correlation. For example, where local mammalian  
171 biozones are developed (e.g. the Mongolian Mammalian biostratigraphy proposed by Daxner-Höck et al., 2017), the MN  
172 system can still be employed since Europe and Asia often share taxa (Wang et al. 2013). However, we should keep in mind  
173 that correlation using the MN timescale is affected by ecological limits, latitudinal disparities, general diachronism in the  
174 dispersion of taxa, the presence of immigrant taxa (Mein 1999; Steininger, 1999) and local differences in taxa (even between  
175 neighbouring basins; Engesser and Mödden 1997).

176 Regionally, both the continental and marine Miocene sediments are known for their rich fauna of vertebrate fossils, including  
177 mammal taxa (Ginsburg, 2001). At Mauvières, vertebrate remains have been found within four horizons within the Orléanais  
178 Marls and Sands Formation (Figure 2a). The majority of fossils (>95%) are fresh and thus interpreted as syn-sedimentary and  
179 not reworked from older beds. In total, 53 taxa have been identified, most of them present in the s1 bed, the richest of the four  
180 fossiliferous horizons. The taxa are typical of the middle of the MN3 biozone (Gagnaison et al., 2023) (Figure 1b and Figure  
181 2a).

a) Sedimentological column

Figure 2: Geology of the Mauvières section. a) Sedimentological log and bed nomenclature (modified after Gagnaison et al., 2023). The calcite nodules are found in the Early-Middle Burdigalian basal sand s1. b) Photograph of the basal section of the outcrop, showing the basal Paleocene-Eocene silty marls unconformably overlain by an orange, very coarse fluvial sand with mammal remains, freshwater mussel shells, root tracks and pedogenic calcite nodules. c) Granule and pebble fraction after sieving of the s1 sand. The fraction is dominated by pale-coloured calcite nodules. d) Photographs of representative calcite nodules from the s1 bed showing both spherical and **eylindrie****cylindrical** irregularly-shaped nodules of varying colour.

189 **3 Materials and methods**

190 **3.1 Samples**

191 Between 2020 and 2022, a series of geological sampling campaigns were undertaken at the Mauvières site. The sample material  
192 was sieved, washed, and dried. From the coarse separate (>2 mm), numerous nodules were collected and identified as vadose  
193 carbonate nodules (Gagnaison et al., 2023). The nodules are spherical to oblong, with a yellow-orange colour and a coarse  
194 aspect. Five of these nodules were selected for SEM elemental analysis and U-Pb dating (P00, P01, P02, P04, and P14), three  
195 nodules for powder X-ray diffraction analysis (XRD), and one nodule was prepared as a thin section for detailed microscopic  
196 analysis (MIOC4). For XRD analysis, each selected nodules were crushed in an agate mortar to create a fine powder. The five  
197 other nodules selected for U-Pb dating were sawn in half to reveal an internal surface. One half of each nodule was mounted  
198 in a 25 mm mould, mounted in epoxy resin, cured and polished, with the final polishing step employing 1  $\mu$ m diamond  
199 suspension polishing fluid. The epoxy resin mounts were cleaned in an ultrasonic bath of deionized water for three minutes  
200 and imaged by optical microscopy. LA-ICP-MS U-Pb dating was undertaken on sample P00 to see if high quality age data can  
201 be obtained from the sample suite. Following LA-ICP-MS analysis of sample P00, it was repolished to remove the ablation  
202 rasters, cleaned in an ultrasonic bath of deionized water and carbon coated for SEM analysis. The other four samples were first  
203 carbon coated for SEM analysis, and later polished and then cleaned to remove the carbon before subsequent LA-ICP-MS  
204 analysis.

205 **3.2 Optical microscopy**

206 The resin pucks were imaged under reflected light using a Nikon Eclipse LV100 at the iCRAG Lab@TCD, Trinity College  
207 Dublin. Images were acquired at 5x magnification using a Nikon DS-Ri2 camera. Each tiled image is comprised of multiple  
208 frames stitched together by the Nikon NIS-Elements software. Each frame was taken with a square field of view of c. 2.8 mm  
209 in width and with an overlap of 10%. Transmitted and plane-polarised light images were also acquired for thin section MIOC4.

210 **3.3 XRD**

211 The powders were analysed using a Siemens/Bruker D5000 power X-ray diffractometer (Cu K $\alpha$  radiation, 0.01° step $^{-1}$  from  
212 5 to 60° 2 $\theta$  at 1° min $^{-1}$ , 4.5 hours per sample). Mineral identification was undertaken with DIFFRAC.EVA (Bruker) using  
213 the Powder Data File (PDF-4, The International Centre for Diffraction Data) (Gates-Rector and Blanton, 2019). XRD results  
214 and its interpretation are available in the Supplementary Materials.

215 **3.4 SEM**

216 The SEM analyses were carried out at the iCRAG Lab@TCD (Trinity College Dublin, Ireland) on a Tescan TIGER MIRA3  
217 FEG-SEM equipped with a backscatter electron detector (BSE), two Oxford Instruments Ultim Max 170 mm $^2$  SSD EDX  
218 detectors and an X4 pulse processor. Scanning electron (SE) and BSE imaging and energy-dispersive X-ray spectroscopy

219 (EDS) analyses were acquired using an accelerating voltage of 20 keV and a working distance of 15 mm above the carbon-  
220 coated pucks. The images and maps were processed using the AZtec version 6.1 X-ray microanalysis software suite (Oxford  
221 Instruments).

222 **3.5 Cathodoluminescence**

223 Polished and uncovered carbon-coated thin sections for each sample were imaged using optical CL microscopy. CL images  
224 were acquired at University College Dublin (UCD) using an HC5-LM hot-cathode CL microscope from Lumic Special  
225 Microscopes, operated at 12.2 kV with a current density of 0.24 mA.mm<sup>-2</sup>. No staining solution was applied prior to the  
226 imaging.

227 **3.6 LA-Q-ICP-MS**

228 Laser ablation Q(quadrupole)-ICP-MS U-Pb dating was performed at the iCRAG Lab@TCD, Trinity College Dublin,  
229 employing an Iridia 193 nm ArF excimer LA system (Teledyne Photon Machines, Bozeman, MT, USA) coupled to an Agilent  
230 7900 Q-ICP-MS via 1.016mm ID PEEK tubing and a medium pulse interface. One sample (P00) was dated using a  
231 mapping approach and follows the U-Pb imaging technique described in Drost et al. (2018), while the remaining samples (P00-  
232 repeat, P01, P02, P04, P14) were analysed by static spot analysis. For the latter, signal smoothing was achieved by inserting a  
233 mixing chamber (Glass Expansion) between medium pulse interface and torch. Details on the specific analytical protocol and  
234 operating conditions are given in the supplementary material (Supplementary Table 1-6 and Supplementary Document 1). This  
235 includes the selection criteria, regions of interest, map dimensions and time-equivalents for all selected pixels and pixel groups  
236 ('pseudo-analyses') for the sample analysed with the mapping approach, and the laser pit locations of the samples analysed by  
237 spot ablation. Supplementary Tables are available on the Zenodo repository system (Monchal et al., 2024) while  
238 Supplementary Document and Figure are available with the online version of this manuscript.

239 Samples were first screened for suitability using line scans. Samples and sample area yielding high initial Pb concentrations  
240 and low  $\mu$  throughout were omitted from further analysis. Similarly, samples areas with  $U \leq 10$  ppb were ignored as the young  
241 sample age would result in very low concentrations of radiogenic Pb. Final locations for U-Pb analysis were selected according  
242 to the results of the test line scans in combination with mineralogical and textural observations from optical microscopy and  
243 from chemical information obtained by SEM-EDS mapping. In each dated nodule, we targeted calcite zones with minimal  
244 incorporation of other phases. For the mapping experiment, this resulted in multiple groups of raster lines spread out across  
245 the nodule surface. Final ROIs for data extraction were chosen to represent zones that couldmay be interpreted as cogenetic  
246 and thus a single age population constraining cementation. However, samples P01, P02, P04, and P14 did not feature large  
247 enough coherent calcite areas with Pb/U ratios favourable for efficient and reproducible use of the mapping protocol. Spot  
248 analysis was subsequently performed on those samples, using the chemical information from the SEM and LA-ICP-MS maps

249 to help site the spot analyses. Additionally, the U-Pb mapping data from sample P00 was also augmented by a static spot  
250 ablation experiment.

251 The mapping session employed a laser spot size of ~~80 μm~~<sup>80 μm</sup> square, a repetition rate of ~~50 Hz~~<sup>50 Hz</sup> and a fluence of ~~2.5 J~~<sup>2.5 J</sup>  
252  $\text{J}/\text{cm}^2$  while moving the sample along successive linear rasters with ~~30 μm~~<sup>30 μm</sup>/s under the static laser beam. Samples were  
253 bracketed by ~~NIST614~~<sup>NIST</sup> SRM 614 glass as the primary standard, WC-1 calcite for matrix-matching the  $^{206}\text{Pb}/^{238}\text{U}$  ratio  
254 (Roberts et al., 2017) and Duff Brown Tank limestone as quality control material (Hill et al., 2017). The total analysis time for  
255 sample P00 was c. 34 minutes. Spot analysis employed ~~85 μm~~<sup>85 μm</sup> diameter spots, a repetition rate of 12 Hz, 480 shots (40s)  
256 and a fluence of ~~2.2 J~~<sup>2.2 J</sup> $\text{J}/\text{cm}^2$ . Again, ~~NIST614~~<sup>NIST</sup> SRM 614 was used as the primary standard, but Duff Brown Tank  
257 limestone was used for matrix-matching of the  $^{206}\text{Pb}/^{238}\text{U}$  ratio as it is closer in U concentration and age to the samples than  
258 WC-1. Gas settings (optimised daily), analyte menus and integration times for all analytical sessions are reported in  
259 Supplementary Doc 1 along with the data processing protocols used.

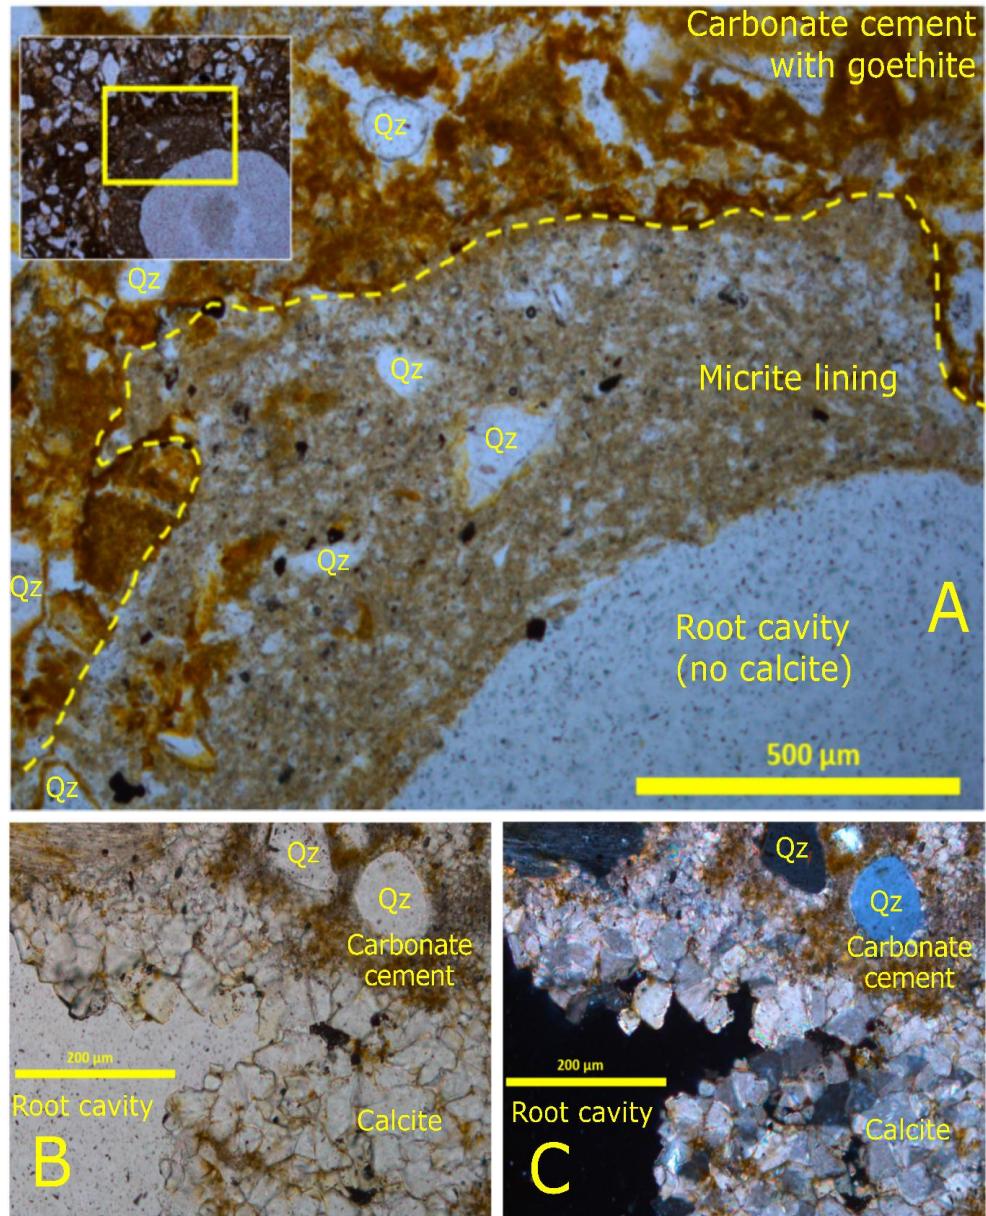

260 Uncertainties on dates in the text and figures are quoted at the  $2\sigma$  or 95% confidence level, respectively. The geochronological  
261 results are presented with two uncertainties; the first is an estimate of the session uncertainties, while the second is propagated  
262 with full systematic uncertainties (e.g., the uncertainty on the reference age of WC-1 (maps) or DBT (spots) respectively, the  
263 decay constant uncertainties, and the 2% long-term reproducibility of secondary age reference materials in the laboratory; see  
264 Supplementary Document 1).

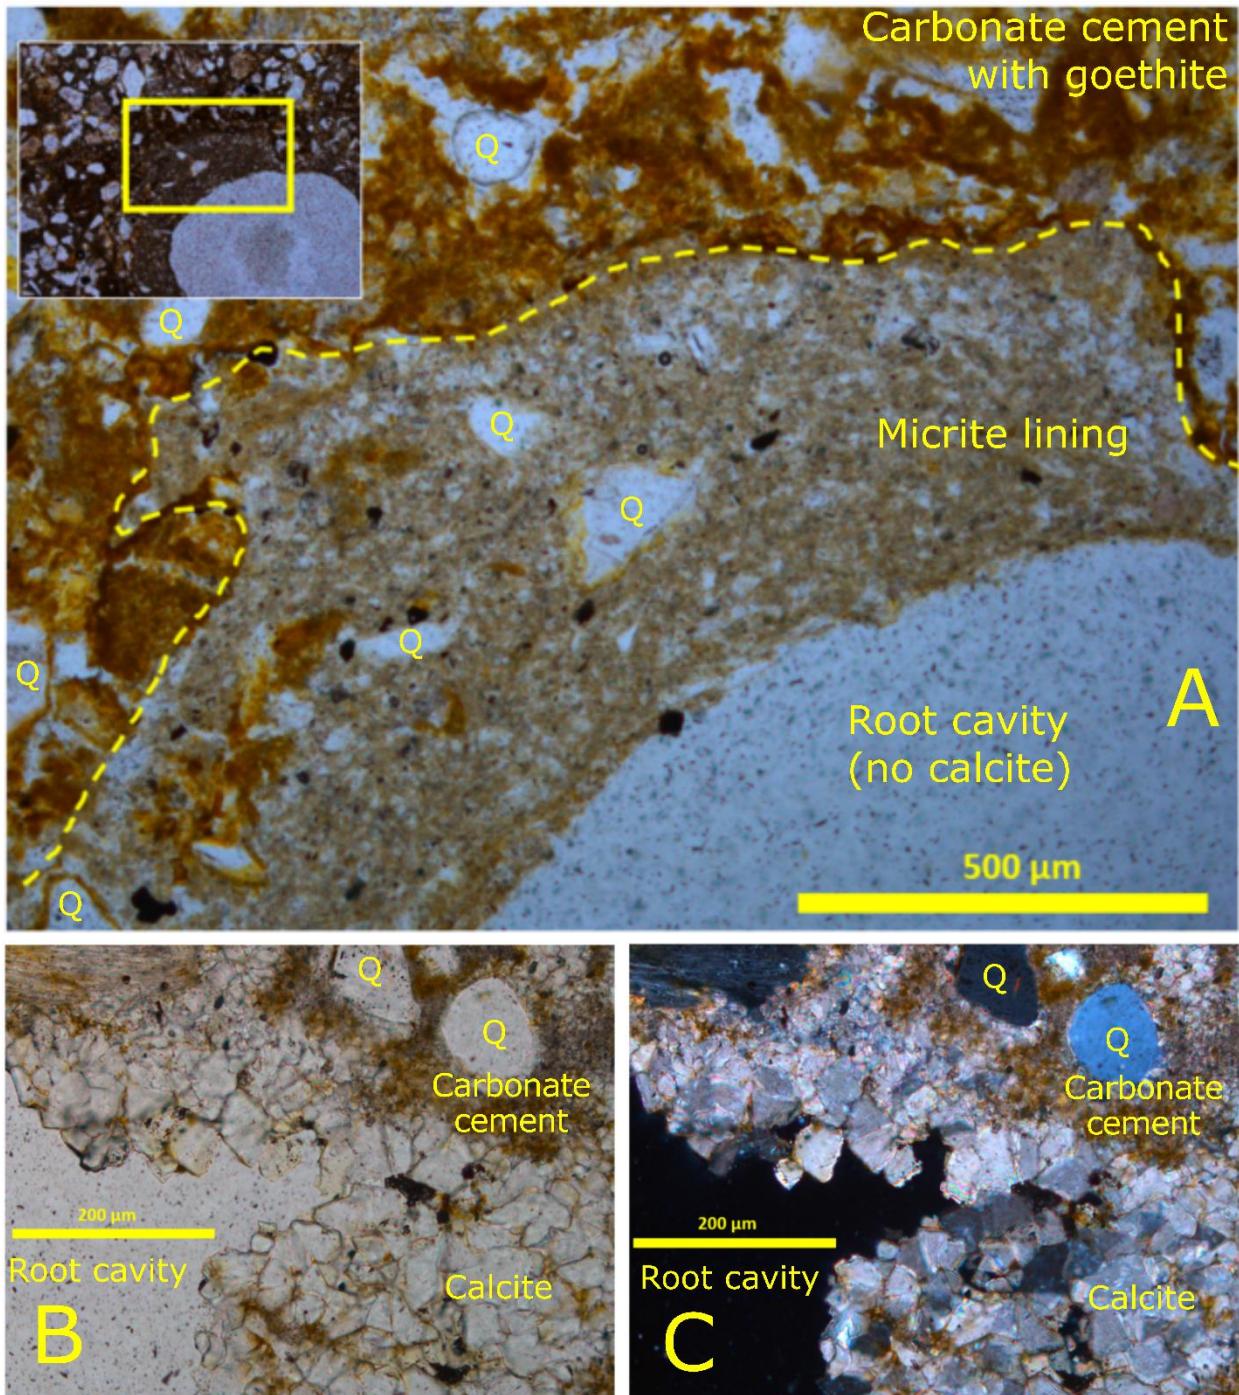

## 265 4 Results

### 266 4.1 Petrographic observations

267 The samples are composed of transparent, mostly rounded quartz grains with some more angular crystals, set in a pale orange-  
268 yellow cement with vein-like cavities, partially filled with carbonate crystals (Figure 3). The majority of the samples exhibit a  
269 main cavity that ~~sometimes in some cases~~ branches out *via* micro-cracks, typical of alpha type paleosol (Wright, 1990). We  
270 can distinguish two stages of formation. The first stage involves the formation of sedimentary concretions around roots. The  
271 concretions are rich in quartz and cemented by clear ~~calcite crystals~~<sup>carbonate</sup> as observed under the optical transmitted light  
272 microscope (Figure 3). After decomposition of the roots, ~~the~~<sup>sparry</sup> carbonate crystals precipitated predominantly into free  
273 space producing a brown layer on the edge of the cavity and filling the micro-cracks. The host-rock is composed of touching  
274 or floating terrigenous clastic elements such as quartz in a clotted carbonated matrix with authigenic goethite. The host-rock  
275 is also cross-cut by rhizolith root tubules, traces of which are still visible (Figure 3A). These relics of paleo-roots are expressed  
276 by the stack of several layers of dark microbial micrite linings (Figure 3A) and some holocrystalline microsparite. The presence  
277 of holocrystals is dependent on the degree of microbial activity and the root structure (i.e. main axis *vs* lateral roots). These  
278 early pedogenic carbonate crystals (*e.g.* ~~the calcite crystals in~~ Figure 3B-C) are classically found in many paleosols (*e.g.*  
279 Wright, 1987; Esteban and Klappa, 1983; Bain and Foos, 1993; Alonso-Zarza, 2003).

280 Sample MIOC4 is a representative nodule from the s1 bed that exhibits evidence of primarily calcified root traces (Figure 3;  
281 see also Gagnaison et al., 2023). No evidence of later crystallisation nor recrystallisation was detected, with the calcite spar  
282 homogeneous and unzoned (Figure 3B-C). Moreover, micro-cracks and alveolar structures are commonly found without  
283 calcite crystallisation (Figure 3A), especially where the primary root was located. When calcite crystals are present, they are  
284 typically associated with lateral roots.

Figure 3: Optical microscope photography of sample MIOC4. A) Primary root structure with a dark microbial micrite lining – dashed yellow line highlights the boundary of the external part of the microbial micrite lining. An alveolar structure can be seen on the zoomed out insert at the top of the microphotograph (PPL). B) Microsparitic carbonate cement B) Sparry calcite crystals; a lateral root perforation is on the lower left side of the microphotograph (PPL) and C) (XPL). Q = Quartz.

289 **4.2 Powder XRD phase identification**

290 The PXRD patterns of the three analysed nodules consistently show two dominant families of peaks  
291 identified as calcite (e.g., ICDD PDF no. 00-047-1743) and quartz (e.g., ICDD PDF no. 00-046-1045).  
292 Minor feldspar (e.g., ICDD PDF no. 00-09-0466 [Albite] and 00-19-0932 [Microcline]) (Figure 4) and  
293 several unidentified minor peaks corresponding to one or more accessory phase(s) in the nodules are  
294 also present. The confirmation that the carbonate phase is calcite allows accurate matrix matching with

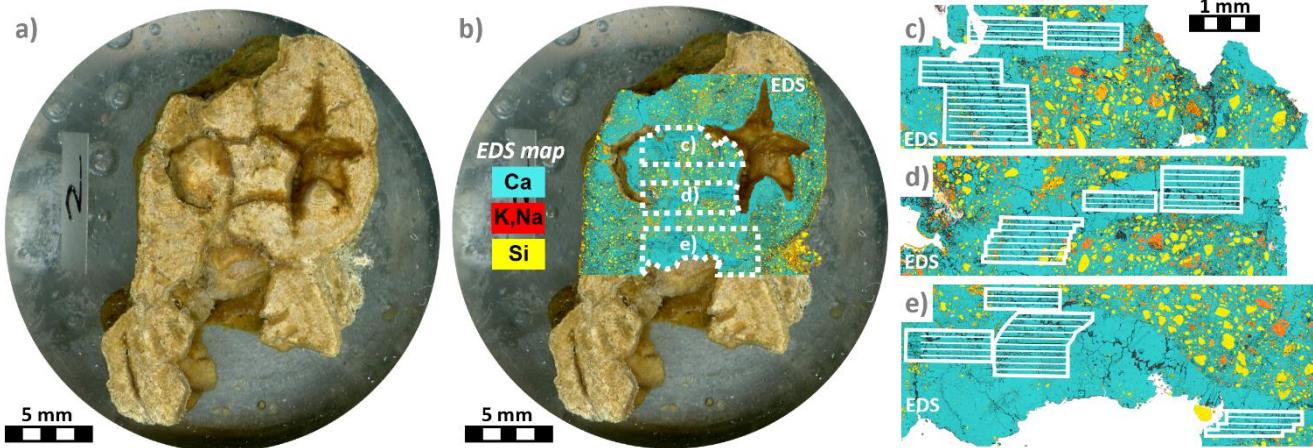

295 the WC-1 calcite age reference material in the LA ICP-MS U-Pb dating procedure (Roberts et al.,  
296 2017).

297 **Figure 4: Representative PXRD patterns from a calcite nodule showing the dominance of calcite and quartz.**

298 **4.3 SEM-EDS elemental mapping**

299 The SEM-EDS maps of the five dated nodules reveal that the nodules are composed of poorly sorted angular Si-rich minerals  
300 cemented by a Ca-rich phase (Figure 54). The two phases are interpreted respectively as quartz and calcite based on optical

301 microscopy and the PXRD results. The cemented sand also contains grains rich in Si and K, Na interpreted as feldspar and in  
302 agreement with the results of PXRD. Large cavities, oftenmostly branching or rounded are present in all the nodules. These  
303 cavities are lined by a pure Ca-rich phase interpreted as calcite that precipitated into the free cavity space. In some locations,  
304 quartz-free calcite crystals have filled the cavities entirely. These zones of pure calcite were subsequently targeted for LA-  
305 ICP-MS U-Pb dating.

306  
307 **Figure 54:** Photographic montage of nodule P00 in a polished resin puck. a) optical microscopy image b) the same image overlain  
308 by a partial EDS map of the nodule showing Ca (a proxy for calcite, blue), Si (a proxy for quartz, yellow), and K<sub>+</sub>Na (a proxy for  
309 feldspar, red). The location of the EDS maps in c), d), and e) are represented by the dashed white polygons. c), d), and e) EDS maps  
310 showing the LA-ICP-MS ablation zones and line scans for the P00 nodule. Pure calcite veins were targeted, avoiding the zones of  
311 calcite-cemented quartz-rich sand. See Supplementary Materials for pictures and EDS map of the other samples (Supplementary  
312 Figure 1).

#### 313 4.3 Cathodoluminescence imaging

314 The calcite-cemented sands in the concretions show a complex pattern of dull brown and orange to bright yellow luminescent  
315 calcite cementing quartz and minor feldspars which are highly (and variably) luminescent. Sparry carbonate crystals infilling  
316 cavities and fractures show strong oscillatory CL zoning at the <10  $\mu\text{m}$  scale (Figure 5). The calcite growth in the fractures  
317 oscillates between non-luminescent, dull brown to orange luminescence, and bright yellow and orange luminescence. Growth

morphologies from CL are euhedral to occasionally subhedral blocky with no recrystallisation of the oscillatory zoning observed.

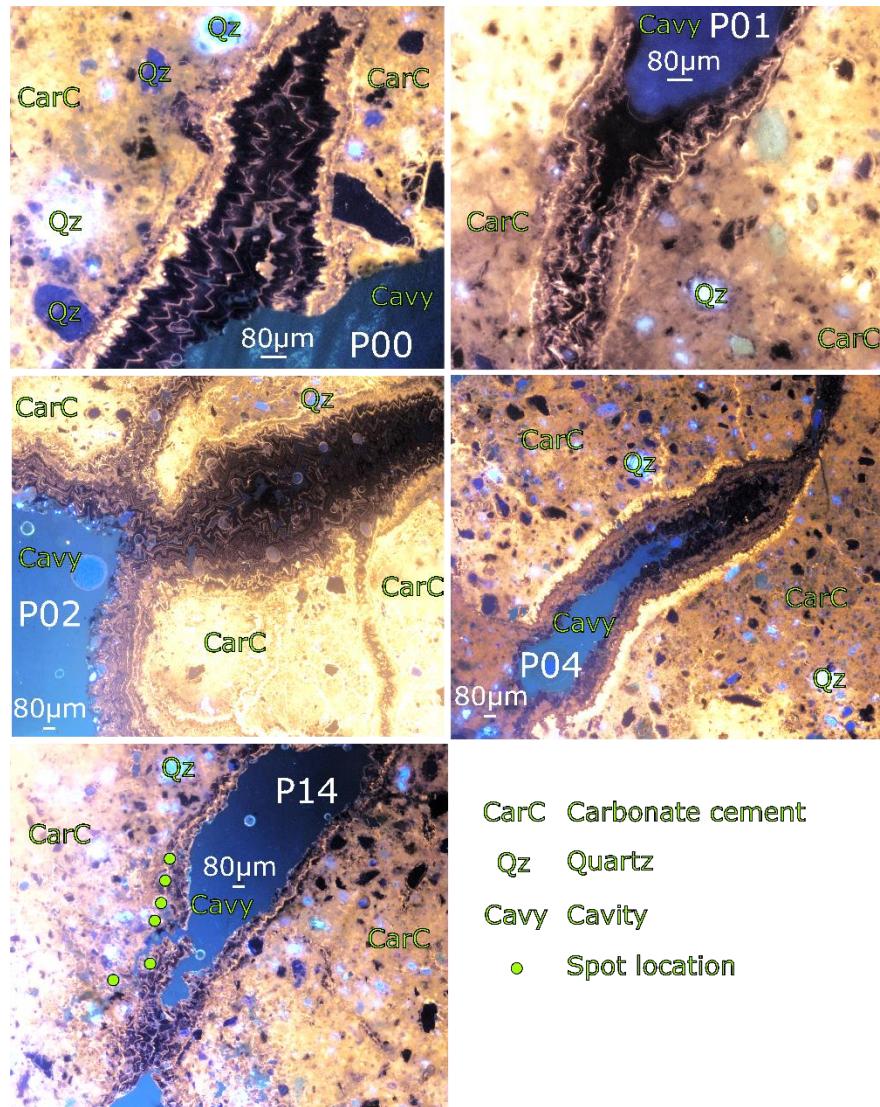

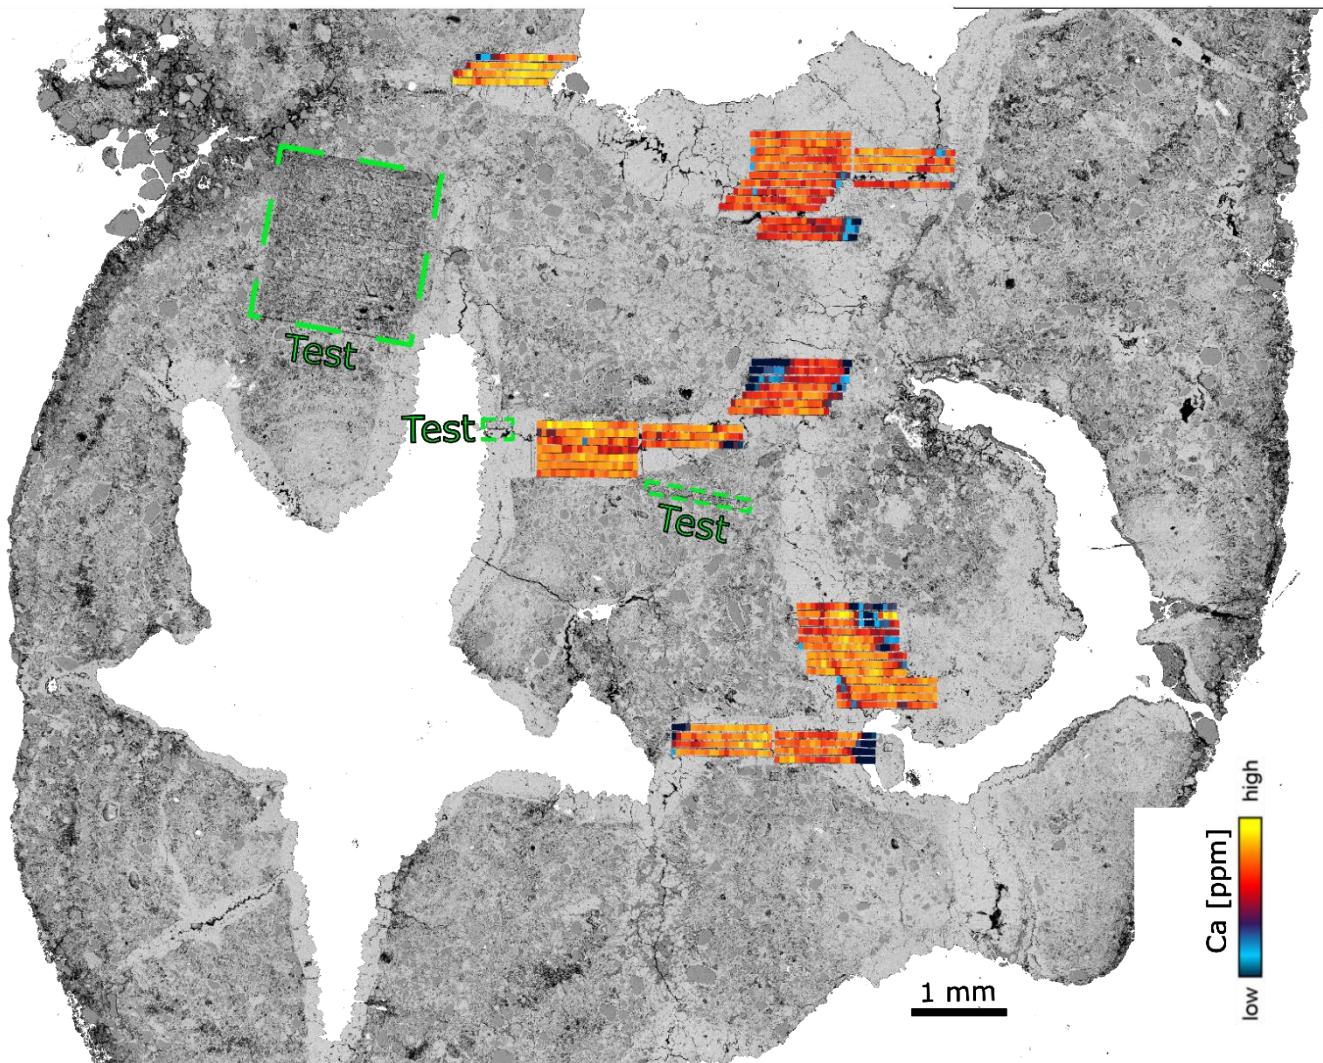

Figure 5: Cathodoluminescence images from the samples at 5x (P02/P04/P14) or 10x (P00/P01) magnification illustrating the oscillation between non-luminescent dull brown and orange luminescent zonation in the calcite crystals. Spot locations are shown on the P14 photo showing that the outer margins of the calcite zones were ablated.

#### 323 4.4 LA-ICP-MS U-Pb dating

324 Calcite crystals that have precipitated freely inside the cavities were targeted for geochronology analysis (Figure 6) as they are  
325 believed to have precipitated rapidly after the formation of the paleosol (see section 2.2 and Rasbury et al., 1997). The mapped  
326 areas in P00 targeted zones of pure calcite based on the SEM-EDS mapping. A Ca filter (e.g. retaining pixels with Ca > 350  
327 000 ppm) was applied on the P00 map to exclude any inclusions, cracks, epoxy resin or the host sedimentary rock and this

filter removed c. 7% of the pixels from the maps. The average U content is ~~~10~~ 10 ~~ppm~~<sup>μg</sup>/g (ranging from 9 to 13 ~~ppm~~<sup>μg</sup>/g), while the average Th content is ~~~0.7~~ 0.7 ~~ppm~~<sup>μg</sup>/g (ranging from <0.1 to 2.5 ~~ppm~~<sup>μg</sup>/g; see Supplementary Table 1) resulting in Th/U ratios of <0.01 to <0.2. Significant initial Pb concentrations (~0.44 to ~~33~~33 ~~ppm~~<sup>μg</sup>/g) and the long half-life of Th in combination with the young age of the ~~samplesamples~~ render the radiogenic ingrowth of radiogenic <sup>208</sup>Pb negligible (<sup>208</sup>Pb<sub>common</sub>/<sup>208</sup>Pb<sub>radiogenic</sub> ~2800 to 12000). Therefore, we used the empirical cumulative distribution function of the <sup>238</sup>U/<sup>208</sup>Pb channel for pooling of the filtered pixel data into pseudo-analyses. The <sup>238</sup>U/<sup>208</sup>Pb channel is a good estimate of the μ ratio between parent U (<sup>238</sup>U) vs initial Pb (<sup>204</sup>Pb) as the total <sup>208</sup>Pb concentration ~~strongly reflects~~ is a robust proxy for the initial Pb<sub>common</sub> component.

The spot U-Pb data ~~was~~<sup>were</sup> corrected post-analysis for any ~~shot~~<sup>ablation</sup> that went through the calcite. This correction employ the visual inspection of peaks for a significant change in Ca, Pb, Th or U composition that indicate a change in the phase ablated. The U-Pb spot analyses on samples P01, P02, P04 and P14 yielded dates of ~~18.0±3.8±2.3~~<sup>19.7</sup>/2.7 Ma,  $19.11 \pm 0.84 / 0.94$  Ma,  $19.0 \pm 2.3 / 2.3$  Ma,  $19.4 \pm 2.7 / 2.7$  Ma, respectively, while sample P00 yielded dates of  $19.3 \pm 1.3 / 1.4$  Ma (mapping) and  $20.4 \pm 1.35 / 1.46$  Ma (spots) (Figure 7). A radial plot and weighted average age were calculated using ~~these six~~<sup>the five</sup> dates from spot analysis and their respective internal uncertainties (session estimates), ~~while the~~ featuring a Mean Square Weighted Deviation (MSWD) and chi-square ( $p[\chi^2]$ ) test representing how good the results are fitting to the statistic value. The full systematic uncertainties (section 3.56) were propagated onto the resultant age (radial plot or weighed average) calculation. The radial plot in Figure 8 shows a single age group at  $19.3422 \pm 0.5866 / 0.7379$  Ma ( $p[X^2 \chi^2] = 0.6896$ ) and a weighted average age was calculated at  $19.3221 \pm 0.5864 / 0.7377$  Ma (MSWD=0.6216;  $p[\chi^2] = 0.96$ ; see Figure 8). All U-Pb spot data were also plotted in the same Terra-Wasserburg space with their individual propagated uncertainties providing a result of  $19.1 \pm 0.56 / 0.71$  Ma. The radial plot single group age of  $19.3422 \pm 0.5866 / 0.7379$  Ma is the preferred age adopted in this study as discussed in section 5.2.

349  
350 **Figure 6: BSE image of P00 overlaid by the LA-ICP-MS line rasters used to extract the age. This figure shows that the pristine  
calcite was targeted by our analysis.**

349  
350

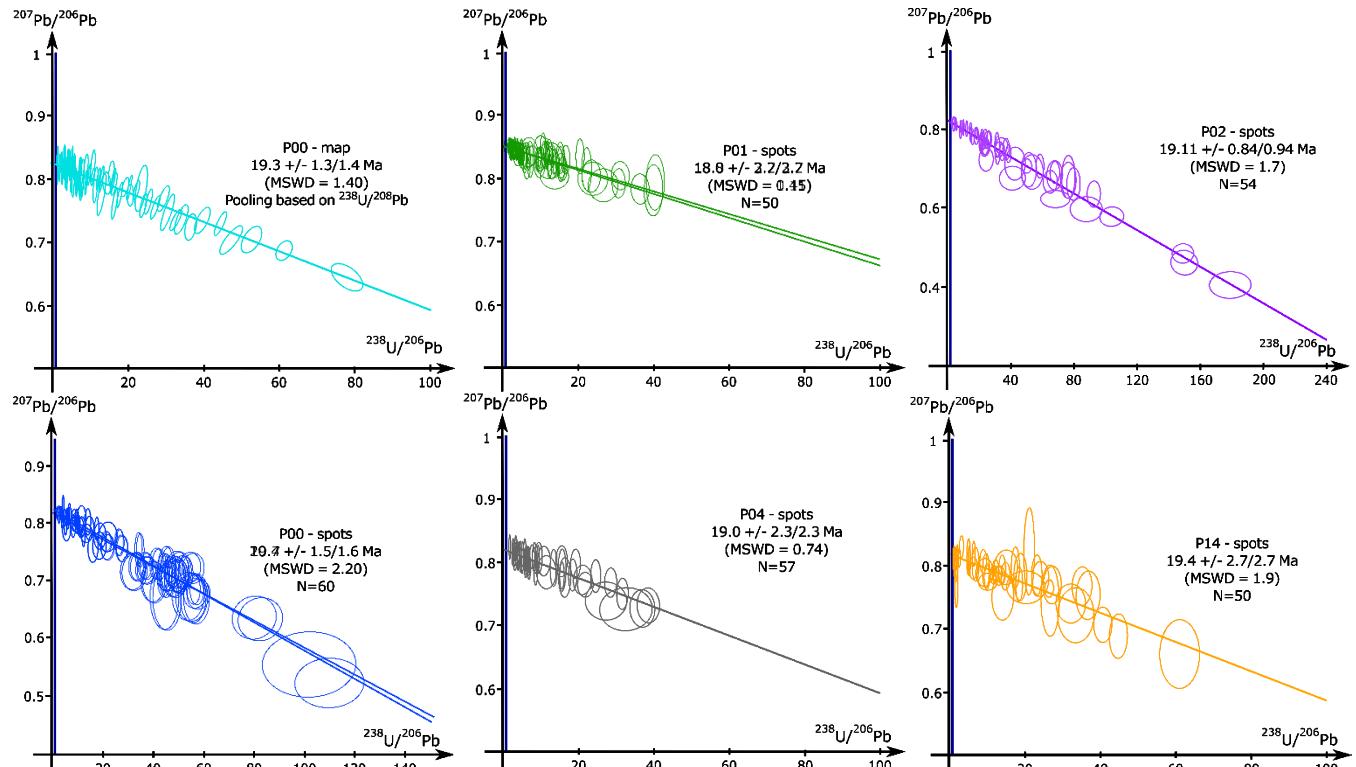

351 **5 Discussion**

352 **5.1 Accuracy and precision of the U-Pb ages**

353 The imaging techniques (optical microscopy, SEM-EDS and LA-ICP-MS mapping) have differentiated zones of pristine  
354 calcite and the pervasive cementation of the nodules. Optical microscopy evidence favours the hypothesis of preservation of  
355 pristine calcite in our samples (see Results section 4.1). In addition, prior to their extraction from the s1 bed, all the pedogenic  
356 nodules (along with clasts and fossil material) were coated with an impermeable clay layer, which likely hindered subsequent  
357 passage of fluid into the nodules. The clay coating is interpreted as syn-sedimentary (see figures 2b-d and Gagnaison et al.,

358 2023). This sealed system is another argument in favour for the preservation of pristine calcite (Perry and Taylor, 2006) in the  
359 nodule interiors (See Figures 4 and 5). The nodule morphology is preserved (not rolled or broken) and does not feature any  
360 sign of compaction nor internal collapse which supports the hypothesis of non-reworked nodules. Tubular nodules have also  
361 been found perpendicular to the stratigraphy, thus clearly marking the former position of the root. The Eocene-Oligocene marls  
362 (m on Figure 2) below the s1 bed do not contain nodules, further supporting the hypothesis that the nodules found in the s1  
363 bed are in-situ.

364 The growth morphologies from optical and CL microscopy indicate gradual growth competition took place, indicative of a  
365 crystallisation in a cavity that remained open (e.g. Wendler et al., 2016; Prajapati et al., 2018). The oscillatory zoning with  
366 multiple bright concentric subzones observed under CL (Fe is the main CL quencher and Mn the main activator) can be  
367 explained by small yet rapid variations in Eh/pH conditions accompanied by changes in oxidation state (e.g., Pagel et al.,  
368 2000). With increasing oxidation,  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  sensitized by  $\text{Pb}^{2+}$  and/or  $\text{Ce}^{3+}$  (Pagel et al., 2000) are replaced by  $\text{Fe}^{3+}$  and  
369  $\text{Mn}^{3+}$  or  $\text{Mn}^{4+}$  ions (e.g. Richter et al., 2003; Boggs and Krinsley, 2006). A plot of  $\log [\text{Fe}]/\log [\text{Mn}]$  ppm can predict if calcite  
370 will be bright, dull or non-luminescent in CL (Machel and Burton, 1991; Boggs and Krinsley, 2006) (see Supplementary  
371 Material). The specific CL patterns are consistent with redox fluctuations caused by water table fluctuations in a vadose or in  
372 a fluid-saturated environment (Mason, 1987; Barnaby and Rimstidt, 1989), which is also in agreement with the previous paleo-  
373 environment reconstitutions for the s1 bed (Gagnaison et al., 2023). Given the above observations and since the oscillatory  
374 zoning is continuous, we interpret a single continuous event of calcite formation to have occurred inside the nodules. The  
375 differing thickness of the CL bands appears related to the size of each cavity in the nodules, with P00/P01/P02 having the  
376 largest cavities and bands while nodules P04 and P14 have thinner bands.  
377

378  
379 **Figure 7: Tera-Wasserburg concordia diagrams and lower intercept ages of all samples. For the map analysis of P00, the pooling**  
380 **was based on the ECDF  $^{238}\text{U}/^{208}\text{Pb}$ . For the spot analysis, the number of spots is indicated by N.**

380 The LA-ICP-MS mapping technique adopted herein is recognised for its potential (see Rasbury et al., 2023) in dating  
381 pedogenic nodules by allowing the selection of only pristine calcite in the extraction and processing of the U-Pb data. However,  
382 only one sample had large enough coherent zones of pristine calcite with Pb/U ratios suitable for U-Pb dating and a spot  
383 analysis strategy was used to date the remaining four samples. All six analysesresults yield ages with a precision of 5 to 4814%,  
384 which is considered precise for LA-ICP-MS carbonate U-Pb dating of such young samples (Roberts et al., 2020). The accuracy  
385 of our data set can be assessed by the fact that the five samples provide the same age and initial  $^{207}\text{Pb}/^{206}\text{Pb}$  within uncertainties,  
386 along with the radial plot confirming that there is only one age group (Figure 8). The accuracy of the mapping experiment is  
387 also demonstrated by the similar agesdates (within uncertainties) yielded using three different isochron approaches. SampleThe  
388 mappingapproach data for sample P00 (using  $^{238}\text{U}/^{208}\text{Pb}$  as the pooling channel) yields  $19.3 \pm 1.3/1.4$  Ma for the TW intercept  
389 age,  $19.6 \pm 1.7/1.8$  Ma for the  $^{238}\text{U}/^{208}\text{Pb}_{\text{common}}$  isochron (e.g., Getty et al., 2001) and an 86TW age (Parrish et al., 2018) of  
390  $19.4 \pm 1.6/1.7$  Ma (section 3.4 and Supplementary Table 1).

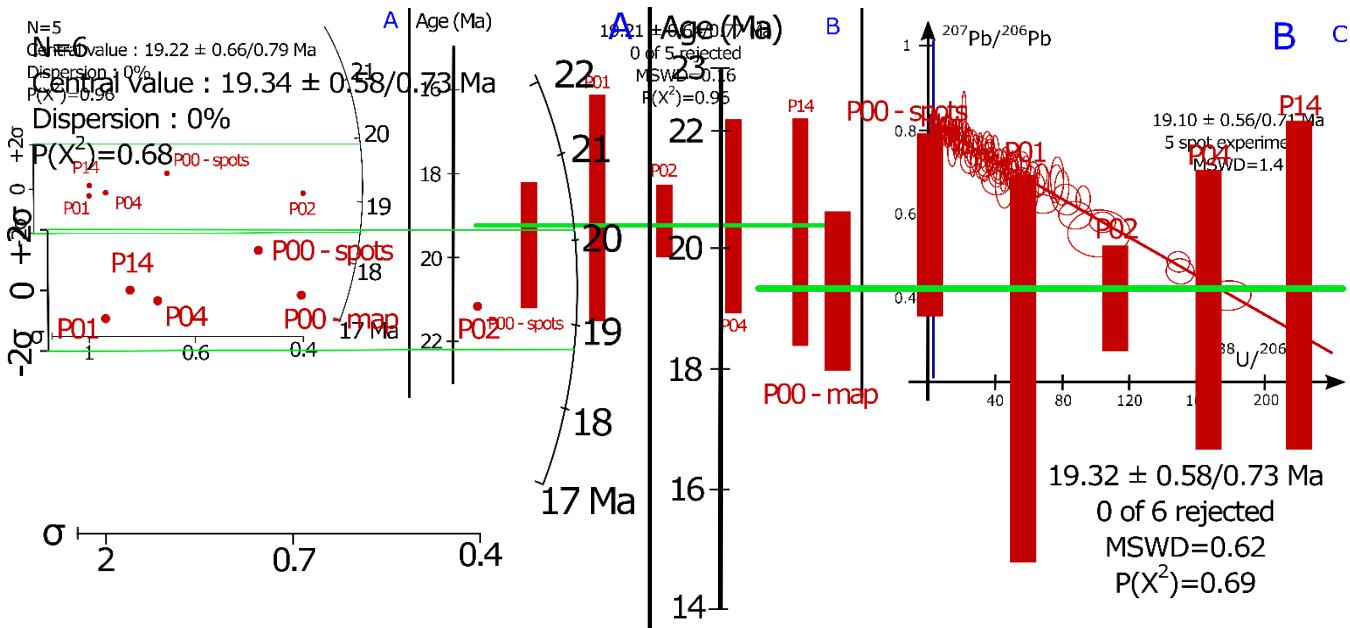

Figure 8: A) Radial plot and B) weighted average of the samples used in this study. Radial plot central value and the weighted average value are indicated with  $2\sigma$  internal uncertainties (session estimates). The full systematic uncertainties (section 3.56) were propagated onto the resultant age calculations with the same method as for the individual sample ages. C) Tera-Wasserburg concordia diagram of all five spot ablation experiments. See text for the interpretation and discussion of the data.

## 5.2 Age of the nodules and paleosol

Our age data are compatible within uncertainty with the proposed biostratigraphic age of the continental biozone MN3, which is correlated with the Burdigalian marine stratigraphic age (20.44–15.98 Ma; Cohen et al., 2013 [updated 2023/09]) and the Orléanian continental stratigraphic age (19.5–14.2 Ma; GagnaissonHilgen et al., 2023[2012]). Dating the pedogenic calcite should provide a minimum age for the paleosol formation (Rasbury et al., 1997). The nodules are found within the same sedimentary layer (section 2.2) and we can therefore reasonably assume that the crystallisation of the calcite inside each nodule arose from the same process(es). Even if these process(es) involve multiple phases of growth, we do not see any evidence of incremental growth of more than one generation of calcite from petrography and SEM-EDS mapping.

CL and SEM-EDS mapping. The U/Pb dates obtained on these five nodules are identical within age uncertainty of our method (Fig. 8) and do not exhibit evidence for more than one stage of calcite growth, diachronous growth across different nodules or a substantial time span between initiation and termination of calcite formation. We therefore assume that formation of the analysed nodules (which are identical within age uncertainty of our method) was effectively synchronous. The age of formation of the nodules was statistically determined following the recommendations of Vermeesch (2018) using the radial plot central age of the TW intercept ages from the six experiments.

To determine the minimum age of nodule formation, there are several possible approaches: 1) the U/Pb date with the lowest uncertainty (P02:  $19.11 \pm 0.84/0.94$  Ma), 2) the date derived from the combined TW regression of spot analyses from all five

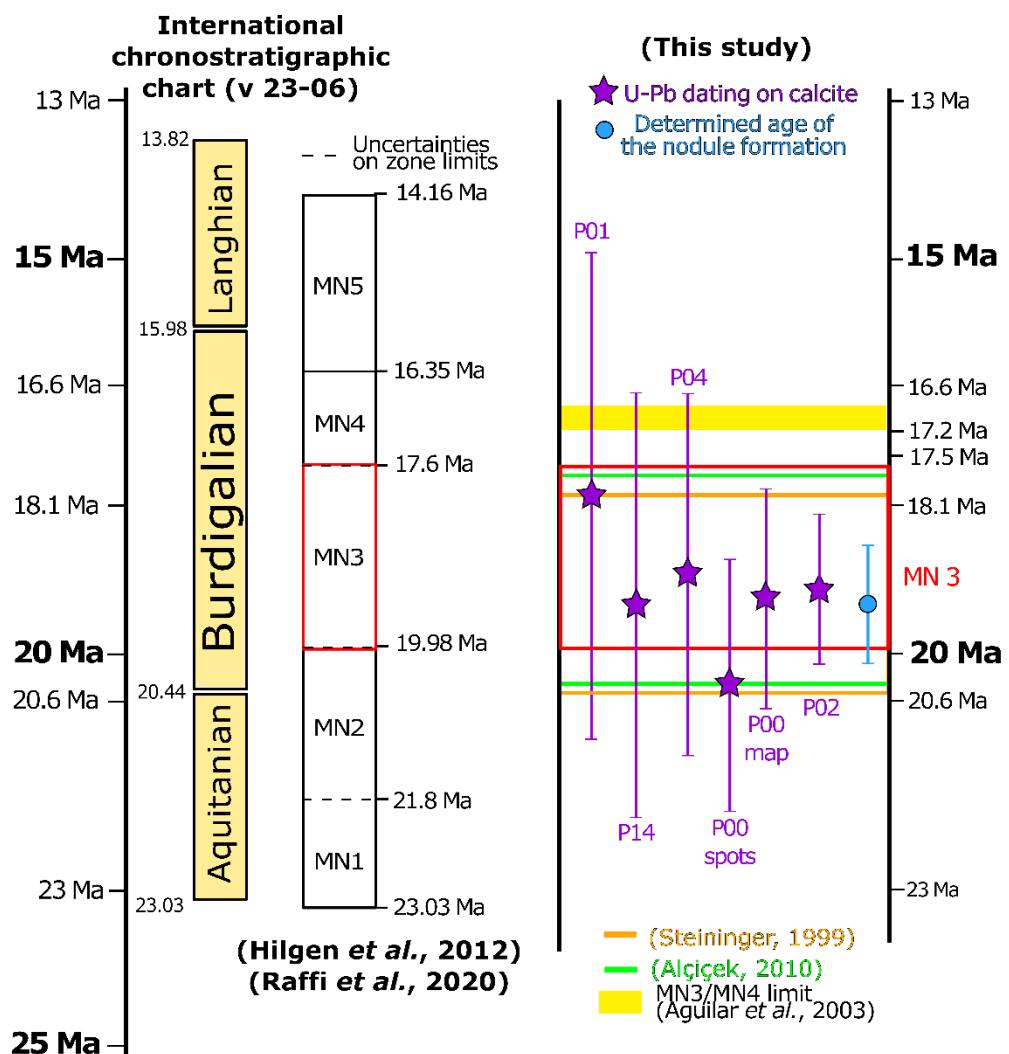

414 samples (Fig. 8C;  $19.10 \pm 0.56/0.71$  Ma), 3) a weighted mean of the U/Pb dates from all analysed samples (Fig. 8B; 415  $19.21 \pm 0.64/0.77$  Ma) or 4) the radial plot age (Fig. 8A;  $19.22 \pm 0.66/0.79$  Ma). The former two methods may introduce some 416 bias as they may overly rely on the data points with the highest  $^{238}\text{U}/^{206}\text{Pb}$  ratios coming all from the same sample (P02), while 417 the latter two methods put more emphasis on the similarity of the results associated with individual samples. The radial plot 418 shows only one age group, and the central age from the radial plot and the weighted mean of the TW intercept ages are identical 419 within age uncertainty. The weighted mean age calculation assumes the data follows a normal distribution, while the radial 420 plot assumes that the log of the values follows a normal distribution curve (Vermeesch, 2018). Geochronological data are less 421 likely than other data to conform to a normal distribution due to the presence of outliers, and the range of age values must be 422 positive, thus the distribution is asymmetric (Vermeesch, 2018). The log of the outliers used in radial plots will smooth these 423 deviations and heteroscedastic variation (unequal uncertainties) and make it fit to the normal distribution curve (Galbraith et 424 al. 1999), which is why the radial plot central age is preferred. This age of  $19.3422 \pm 0.5866/0.7379$  Ma for the s1 bed allows 425 precise correlation with other directly dated sequences, independently of the lithofacies or fossil assemblages present. This age 426 is the first absolute age for the continental Miocene facies of the Paris Basin and to the best of our knowledge the youngest U- 427 Pb age from pedogenic carbonates in the literature (Table 1).

### 428 5.3 Biostratigraphic significance

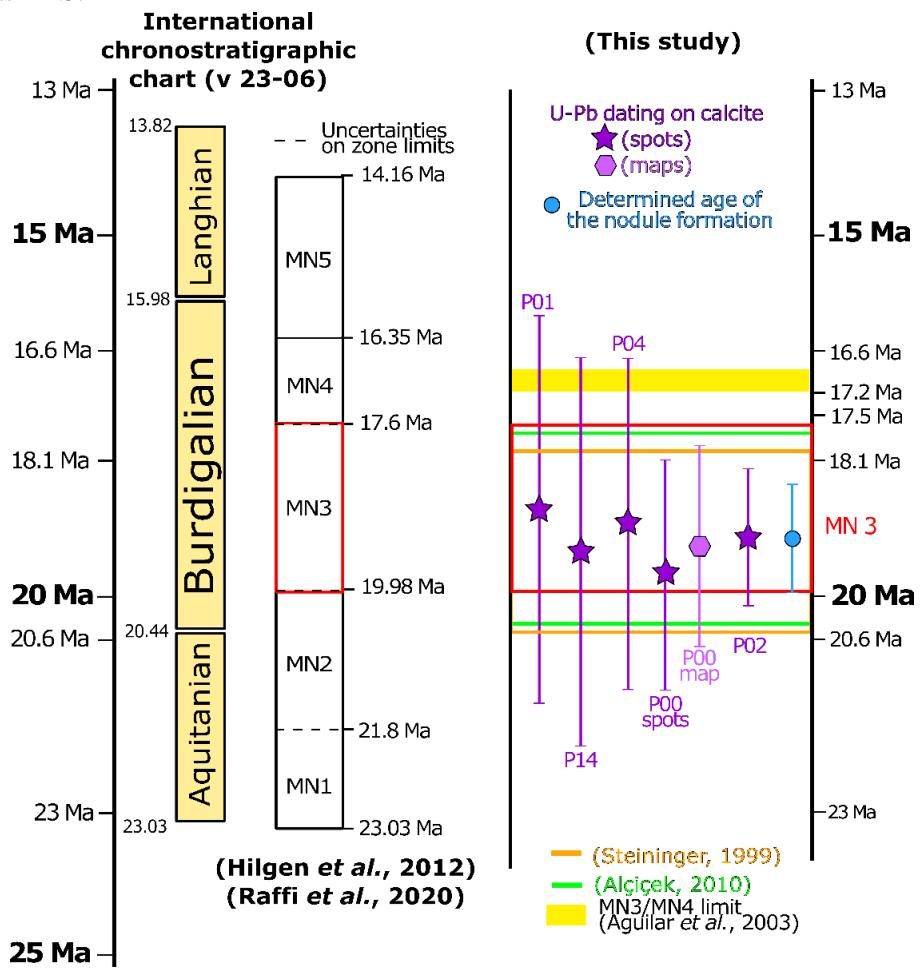

429 The MN (Mammal Neogene) stratigraphic timescale is based on faunal calibration. The appearance and disappearance of taxa 430 result in a given combination of species that can be linked to a given time (Mein, 1999). The MN scale incorporates a 431 stratigraphic component as well as classical stratigraphic correlations and magnetostratigraphy to help refine the age control 432 (Hilgen et al., 2012). MN units were initially defined without boundaries or clearly defined limits (e.g. Mein, 1975), but 433 nowadays the scale is often presented alongside a chronostratigraphic scale, with an absolute age associated with each biozone 434 boundary (e.g. Agustí et al., 2001; Van Dam et al., 2001; Aguilar et al., 2003; Gagnaison et al., 2023). The absolute ages of 435 the boundaries remain debated (see the example of MN3 below) due to diachronicity and incomplete paleontological and 436 magnetostratigraphical data (Fortelius et al., 2014; Ezquerro et al., 2022). Each zone is characterised by a specific fauna found 437 at a reference locality (for Europe these are mainly in Spain, France, and SwitzerlandGermany) that can be asynchronous by 438 up to 1-2 MaMyr in the Late Miocene (Van der Meulen et al., 2012; Fortelius et al., 2014; Ezquerro et al., 2022). The 439 majority of the MN zones have uncertainties attached to their age boundaries (Figure 9), while the application of the MN 440 timescale typically involves comparison to the most proximal and well-constrained reference section to circumvent potential 441 diachronicity. Local modifications to the MN timescale are thus often adopted for selected biozones (Hilgen et al., 2012; Van 442 der Meulen et al., 2012; Fortelius et al., 2014; Ezquerro et al., 2022).  
443 To improve the precision of this scale, the incorporation of magnetostratigraphy has helped to better define the MN unit 444 boundaries within basins (e.g. Agustí et al. 2001; Kälin and Kempf 2009). Steininger (1999) used magnetostratigraphic data 445 to propose that magnetochron C6r (20.5 Ma) represented the base and C5Dr the top (18.5 Ma) of MN3. The top boundary of 446 MN3 was then extended to chron C5Cn.2r, dated between 16.6 and 17.2 Ma, based on magnetostratigraphy of sections in the

447 North Alpine foreland (Agusti et al., 2001). The MN3 faunal reference site ~~is~~<sup>was</sup> defined as Wintershof-West with a  
 448 sedimentary succession dated between 17.5 and 18.5 Ma (Hilgen et al., 2012). ~~Refined~~ thus only partially covering the time  
 449 interval defined by the magnetostratigraphic ages. The MN3 boundaries were refined by magnetostratigraphic ages for C6r (19.979 Ma) and  
 450 C5Dr (18.007 – 17.634 Ma) Ma (*i.e.*, ~~which are~~ the chronos defined by Steininger (1999) as bracketing the MN3 biozone ~~are~~  
 451 ~~presented in~~, the ages of these magnetostratigraphic ages are subsequently updated by Raffi et al. (2020). It should be noted that  
 452 magnetostratigraphy requires thick sections (typically >10 m thick profiles) and cannot always be employed. Our results are  
 453 compatible within uncertainties with the different magnetostratigraphic ages proposed for MN3 and are not challenging the actual  
 454 consensus around the absolute age of the base or the top of MN3 (Figure 9).

455 Absolute U-Pb dating of in-situ pedogenic carbonates enables a better understanding of the spatio-temporal distribution and  
 456 evolution of continental mammalian faunas. This method is not affected by the limits detailed above, (*i.e.* diachronicity, index  
 457 fossil scarcity, insufficient profile thickness), thus offering a reliable opportunity to improve the local ~~constrain~~<sup>constraints</sup> on

458 the MN scale. Our age is compatible with an early Orleanian stage assignation (Figure 1) and the MN3 unit (Hilgen et al.  
459 2012). The age constraints on the Mauvières fossil locality are thus significantly improved by our results, but it should be  
460 noted that an age for one locality does not improve the precision of the MN3 boundaries at a European scale. Therefore, more  
461 studies employing similar method are needed for further improvement of the MN scale, especially zones with large  
462 uncertainties such as MN3.

463 Figure 9: Overview of MN timescales in the literature compared to the age data from this study. The red box defining the MN3  
464 biozone is taken from Raffi et al., (2020) currently accepted boundaries of the MN3 biozone is taken from Raffi et al. (2020) by taking  
465 the base of magnetochron C6r at 19.979 Ma and the top of C5Dr as 17.634 Ma. The age of nodule formation is the result of the radial  
466 plot using the six U-Pb geochronology dates and their respective internal uncertainties; the full systematic uncertainty was  
467 propagated on to the radial plot result age calculation (see sections 4.4 and 5.2).

## 468 6 Conclusions

469 The application of LA-ICP-MS U-Pb dating of carbonate pedogenic nodules as employed in this study is an efficient and robust  
470 and reliable way to provide absolute age data for terrestrial strata. Our samples yield a precise and accurate age of 19.3422 ±

471 0.7379 Ma in accordance with earlier biostratigraphic estimates (Orleanian), demonstrating the suitability of the method and  
472 confirming the feasibility of the technique to dating continental sedimentary facies that do not contain any index fossils or  
473 volcanic horizons such as lavas or ash beds.

474 Our results are in good agreement with the biostratigraphic age (MN3 of the Neogene Mammalian timescale) of sedimentary  
475 horizon s1 from Mauvières (Gagnaison et al., 2023) and represent the first absolute age constraint for the MN3 unit in France.  
476 This absolute age dating approach has the potential to advance chronostratigraphy and climatic reconstructions (Liivamägi et  
477 al., 2021) by improving inter-basin correlations in continental successions and extending such correlations to the marine  
478 sedimentary record. In order to refine the geochronological constraints, the use of a more precise reference material would  
479 decrease the external uncertainties (i.e. ASH15, Nuriel et al., 2021; JT, Guillong et al., 2020; RA138, Guillong et al., 2024).  
480 The protocol for U-Pb dating of carbonate nodules proposed by Aguirre Palafox et al. (2024) offers a uniform approach and a  
481 basis for comparisons between studies. While their study was published during the review process of this manuscript, it should  
482 be noted that our study nevertheless broadly conforms with this protocol.

#### 483 **Author contribution**

484 VM contributed to the conceptualisation, the formal acquisition, the investigation, the methodology, the project administration,  
485 the visualisation and the writing (initial draft and edits). RR contributed to the conceptualisation, the formal acquisition, the  
486 investigation, the methodology, the project administration, the visualisation and the writing (edits and part of initial draft). KD  
487 contributed to the methodology, the supervision and the writing (edits). CG and BM contributed to the resources, the  
488 conceptualisation and the writing (edits). RT contributed to the writing (edits). DC contributed to the supervision, the funding  
489 acquisition and the writing (edits).

#### 490 **Competing interests**

491 The authors declare that they have no conflict of interest.

#### 492 **Acknowledgments**

493 The authors would like to acknowledge the Poirier family who allowed us to sample the shell bed (falun) in Mauvières quarry.  
494 We would also like to thank Didier Memeteau and Bruno Cossard for assistance sampling the nodules. We acknowledge the  
495 support of Science Foundation Ireland, the Environmental Protection Agency, and Geological Survey Ireland under  
496 Investigators Programme grant 15/IA/3024. Comments by reviewers Perach Nuriel, Andreas Möller and associate editor Axel  
497 Schmitt significantly improved this manuscript and are gratefully acknowledged.
