Abstract. Aerosol modulation of atmospheric convection remains an important topic in ongoing research. A key challenge in evaluating aerosol impacts on cumulus convection is isolating their effects from environmental influences. This work investigates aerosol effects on maritime tropical convection using airborne observations from NASA's Cloud, Aerosol and Monsoon Processes Philippines Experiment (CAMP^{2}Ex). ~~Nine~~Eight environmental parameters with known physical connections to cloud and storm formation were identified from dropsonde data, and 92 dropsondes were matched with corresponding CAMP^{2}Ex flight "scenes." To constrain environmental conditions, scenes were binned based on their association with "low," "medium," or "high" values for each dropsonde-derived parameter. In each scene and environmental bin, eight radar- and radiometer-based parameters directly related to convective intensity and/or prevalence were correlated with lidar-derived aerosol concentrations to examine trends in convective characteristics under different aerosol conditions. Threshold values used to stratify the environments were varied across four sensitivity tests to examine how the convective-aerosol correlations within each environmental bin responded. ~~While results were mixed, some trends~~The results were generally inconclusive, with relatively weak correlations observed with limited statistical significance in many cases. Some interesting and potentially impactful comparisons identified in the convective-aerosol analyses support the idea of warm-phase convective invigoration~~.~~ ~~General~~ trends ~~suggested~~and suggest that higher aerosol concentrations were correlated with stronger and/or more-prevalent convection in some cases, while other cases saw a "Goldilocks" zone of medium aerosol concentration favoring enhanced convection. ~~These results indicate that medium-to-high aerosol concentrations may enhance convection, but these correlation analyses warrant further analysis, and our results~~Our results also stress the importance of considering environmental conditions when evaluating aerosol impacts.

Short summary

Decoupling aerosol and environmental impacts on convection is challenging. Using airborne data, we correlated convective metrics with aerosol concentrations in several different environments. ~~Medium~~Results were mixed, but some comparisons suggest that medium-to-high aerosol concentrations were occasionally strongly ~~and positively~~ correlated with convective intensity and prevalence, especially ~~in favorable environments and cases with~~when the atmosphere was relatively ~~high moisture near the surface~~unstable. Storm environment is important to consider when evaluating aerosol effects.

1. Purpose and background

The primary purpose of this study is to explore potential impacts of aerosol concentration on maritime tropical convection during NASA's Cloud, Aerosol and Monsoon Processes Philippines Experiment (CAMP^{2}Ex) from a remote-sensing perspective ~~within environmental contexts. The field phase of CAMP^{2}Ex occurred from 20 August – 10 October 2019, with instruments on NASA's P-3B Orion (P-3) aircraft sampling a wide range of environmental, cloud, radiation, and aerosol conditions across 19 research science flights (SFs) conducted out of Clark International Airport (Reid et al., 2023). The P-3 overflew a variety of cloud types during CAMP^{2}Ex, ranging in depth from shallow convection to deeper cumulus congestus and ranging in organization from isolated clouds to squall lines (Reid et al., 2023). Key instruments for this study that were flown on the P-3 during CAMP^{2}Ex include: the Advanced Microwave Precipitation Radiometer (AMPR; Spencer et al., 1994; Amiot et al., 2021), Airborne Precipitation and cloud Radar 3rd Generation (APR-3; Durden et al., 2020), High Spectral Resolution Lidar-2 (HSRL2; Burton et al., 2016), and Advanced Vertical Atmospheric Profiling System (AVAPS; Hock and Young, 2017). This research falls under the CAMP^{2}Ex science question of "To what extent are aerosol particles responsible for modulating warm and mixed-phase precipitation in tropical environments?", while also having direct implications for impacts on deeper convection and cloud meteorology (ESPO, 2020; Reid et al., 2023). A secondary purpose of this study is to expand and demonstrate the scientific utility of AMPR's geophysical retrievals (Amiot, 2023).~~

~~Aerosol impacts on convective storms have been a significant research topic.~~ while considering adjacent environmental conditions. Aerosol influences on convection have been a significant research topic and, as detailed further in section 2, were one of the main science foci of CAMP^{2}Ex. These aerosol effects impact other meteorological phenomena and have broader consequences for society, and therefore warrant considerable research attention. However, as we describe throughout this section, isolating aerosol impacts on convection from those of other (e.g., environmental) effects is challenging and requires additional study despite the wide range of past works that have investigated this topic in detail.

Increased aerosol concentration is generally associated with increased cloud condensation nuclei ~~(CCN),~~ with aerosol size distribution influencing cloud particle size distribution (Junge and McLaren, 1971). In shallow clouds, the second

indirect effect of aerosols ~~favors~~describes a decrease in precipitation formation and increase in cloud lifetime (Albrecht, 1989), resulting from reduced cloud droplet sizes due to increased competition for water vapor (e.g., Rosenfeld and Lensky, 1998; Sherwood, 2002). However, precipitation-sized hydrometeors that form in higher aerosol concentrations ~~are generally~~may be larger, owing to ample cloud droplets available for collection and droplet growth (e.g., Stroud et al., 2007; Altaratz et al., 2008; Saleeby et al., 2010). These changes in cloud coverage and precipitation reaching the surface can have a profound impact on the total radiative forcing in the atmosphere (e.g., Sokolowsky et al., 2022) and direct consequences on society (e.g., modulation of local rainfall patterns; Berg et al., 2008).

~~Many numerical modeling studies have explored aerosol warm-phase invigoration in tropical convection. Sheffield et al., (2015) demonstrated~~Many research efforts have explored aerosol invigoration of tropical convection (i.e., increases in updraft velocity), including the studies and formative discussions by Andreae et al., (2004) and Rosenfeld et al., (2008) regarding the positive and detrimental impacts of aerosols on convection. A key factor in evaluating these aerosol impacts is considering whether their strongest influences are realized in regions where condensational latent heat release is most profound below the environmental 0 °C level (i.e., warm-phase invigoration) or in regions where latent heat release via freezing occurs above the environmental 0 °C level (i.e., cold-phase invigoration) instantaneously during storm development (e.g., Igel and van den Heever, 2021). Warm-phase invigoration (Andreae et al., 2004) depends on the finite supersaturation within a cloud's updraft, and if this supersaturation is in a quasi-equilibrium state the rate of condensation onto available aerosols will depend only on the updraft's velocity (Grabowski and Morrison, 2020). As a result, if the concentration of cloud droplets increases, the quasi-equilibrium supersaturation decreases, which leads to an increase in buoyancy, updraft velocity, and condensation rate within the cloud (Grabowski and Morrison 2020). Cold-phase invigoration (Rosenfeld et al., 2008) depends on the off-loading of frozen precipitation aloft in the cloud, since the latent heat release from freezing will only balance the mass loading of any liquid hydrometeors lofted above the environmental 0 °C level, and any buoyancy increases owing to the formation and fallout of precipitation will likely be negligible (Grabowski and Morrison 2020).

The impacts of aerosol warm-phase and cold-phase invigoration of convection have received mixed results in prior observational and numerical modeling studies. Regarding warm-phase invigoration, for example, van den Heever et al., (2006) noted stronger updrafts associated with higher aerosol concentrations within a variety of aerosol profiles. Sheffield et al., (2015) explained how enhanced aerosol concentrations can increase cloud water content and produce more-vigorous updrafts via latent heat of condensation. Likewise, Marinescu et al., (2021) noted a 5–15% increase in mean updraft velocity around 4–7 km AGL when ~~CCN concentrations were relatively high. Smaller cloud droplets associated with higher aerosol concentrations may also~~ cloud condensation nuclei concentrations were relatively high. Observational~~enhance updraft/convective intensity via increased latent heat released during freezing and enhanced depositional growth above the environmental 0 °C level (e.g., van den Heever and Cotton, 2007; Rosenfeld et al., 2008). However, convective intensity increases are primarily driven by low-level condensational heating, rather than freezing above the environmental 0 °C level (Igel and van den Heever, 2021; Cotton and Walko, 2021), further~~

~~indicating the importance of evaluating aerosol concentrations within/around warm-phase regions. Numerous other modeling studies have also demonstrated increased aerosol concentrations enhancing convection (e.g., van den Heever et al., 2006).~~

~~Several observational~~ studies have also explored the impacts of increased aerosol concentrations on convection. For example, Lin et al., (2006) found enhancements in cloud height and cloud cover associated with increased aerosol concentrations in the Amazon. Likewise, Fan et al., (2018) identified increases in convective strength owing to the activation of additional ~~CCN~~cloud condensation nuclei in regions with high concentrations of ultrafine aerosols in the Amazon. Using a combination of observations and simulations, Zhang et al., (2023) described how fine aerosols enhance convection which, in turn, modulates the surrounding environment and feeds back into larger-scale atmospheric circulations. Studies have also suggested that smaller cloud droplets associated with higher aerosol concentrations may enhance updraft/convective intensity via increased latent heat released during freezing and enhanced depositional growth above the environmental 0 °C level (e.g., van den Heever and Cotton, 2007; Rosenfeld et al., 2008) in association with cold-phase invigoration. However, others have demonstrated that convective intensity increases are primarily driven by low-level condensational heating, rather than freezing above the environmental 0 °C level (Igel and van den Heever, 2021; Cotton and Walko, 2021), further indicating the importance of evaluating aerosol concentrations within/around warm-phase regions.

In contrast, ~~many~~ other studies (e.g., Grabowski and Morrison, 2016; Grabowski and Morrison, 2020; Varble, 2023) have presented evidence that increased aerosol concentrations do not invigorate convection above the environmental freezing level but may do so below the environmental freezing level. ~~The~~As mentioned previously, the former results from increased positive buoyancy, via enhanced latent heat of freezing, being offset by increased negative buoyancy, via mass loading from a greater liquid water content being lofted above the environmental freezing level (Grabowski and Morrison, 2020~~). The~~), while the latter results from higher aerosol concentrations leading to lower supersaturation values within the surrounding environment and increased buoyancy, which in turn lead to higher updraft velocities and enhanced latent heating associated with increased condensation (e.g., Grabowski and Morrison, 2017; Grabowski and Morrison, 2020). The results of Öktem et al., (2023) appear to contradict the study by Fan et al., (2018) by explaining how they identified no statistically significant relationship between aerosol concentration and convective intensity. Therefore, the role of enhanced aerosol concentration on updraft velocity can strongly depend on whether they are within regions wherein warm-phase or cold-phase processes dominate.

~~Similarly, despite numerous studies supporting the idea of convective enhancement from increased aerosol concentrations, many other studies have~~Many studies have also identified situations where higher aerosol concentrations may be detrimental for convection. For instance, entrainment of relatively dry environmental air may cause rapid evaporation of smaller cloud droplets associated with higher aerosol concentrations, decreasing cloud/storm structure (e.g., Liu et al., 2016). Veals et al., (2022) noted a tendency for weaker convection in the presence of higher aerosol concentrations in central Argentina. This raises several questions about the true impact of

increased aerosol concentrations on convection, which motivates our study herein. These differences in the outcomes of past studies also indicate that a "Goldilocks" zone of medium aerosol concentration may favor the strongest convection (e.g., Sokolowsky et al., 2022). Further, other ~~research~~works have discussed considerable difficulty in separating aerosol influences from atmospheric dynamics (e.g., Grabowski, 2018). Limitations in past numerical and observational studies are summarized by Varble et al., (2023), which highlights the continued uncertainty surrounding aerosol impacts on convection and further motivates our study ~~herein~~.

~~One remote-sensing instrument employed in aerosol analyses is lidar, including the High Spectral Resolution Lidar 2 (HSRL2) that was deployed on NASA's P-3 aircraft during CAMP²Ex (Hostetler, 2020; Reid et al., 2023; Ferrare et al., 2023). HSRL2 measures aerosol backscatter and depolarization ratio at 355, 532, and 1064 nm, with aerosol extinction and aerosol optical thickness (AOT) also measured using the HSRL2 technique at 355 and 532 nm (Hostetler, 2020). Integration for calculating AOT occurs over a vertical distance starting near the surface and ending at the top of the aerosol extinction profile, which is often around 5–6 km AGL. Lenhardt et al., (2022) demonstrated how HSRL2's extinction and backscatter coefficients, especially at 532 nm, have strong direct correlations with CCN concentrations.~~

Direct measurements of updraft vertical velocity allow for quantitative assessment of convective intensity. However, numerous remote sensing metrics serve as indirect indicators of convective intensity; these metrics and the implied microphysical processes in relation to convective intensity will be the primary focus of this study, as outlined further in the next paragraph. All else being equal, as an updraft fuels vertical development within a warm-phase cloud, continued condensation onto available cloud condensation nuclei will increase the cloud liquid water content and lead to the formation and growth of precipitation-size hydrometeors (e.g., via collision-coalescence). These increases in hydrometeor concentration and, especially, mean hydrometeor diameter within a given cloud particle size distribution can be identified by increases in equivalent radar reflectivity factor (Z_H) over the same region (Rinehart, 2010). Likewise, increased emission from these warm-phase hydrometeors will lead to increases in radiometer-retrieved brightness temperature (T_b) values (e.g., Spencer et al., 1994). If updraft velocity increases, these cloud and precipitation processes and their appearances within remote sensing products will likewise be enhanced (again, all else being equal). Additional hydrometeor formation and growth can also occur in the cold-phase region as vertical cloud development continues. As a result, increases in selected radar- and radiometer-derived products like Z_H and T_b can serve as indirect indicators of convective intensity.

~~Additional studies (e.g., Liu et al., 2016) noted a direct correlation between lidar-based AOT and CCN concentration. Therefore, extinction, backscatter, and AOT may all be considered when examining aerosol concentration. However, the height/location of an aerosol layer, which can be obtained from extinction and/or backscatter, is important to consider when evaluating diabatic heating from radiation absorption (e.g., Chand et al., 2009; Redemann et al., 2021). We will discuss HSRL2 data in more detail in section 2.~~

Based on these studies, the primary science question we address is: How do radiometer- and radar-based metrics of storm intensity ("intensity" referring to peak updraft velocity) and prevalence vary with lidar-based observations of

aerosol concentration when binned into similar environmental groups throughout CAMP^{2}Ex? It should be noted that we evaluate these metrics as indicators of storm intensity, but updraft vertical velocity is not specifically calculated in this study. The results of these analyses are important as they provide insight into science questions for a major NASA field campaign, have relevance to upcoming NASA missions [e.g., Atmosphere Observing System (AOS, 2022)], and contribute knowledge to long-standing questions of aerosol influences on convection. We hypothesized that integrated cloud liquid water path (CLW), peak ~~equivalent radar reflectivity factor (Z_H),~~Z_H, peak Ku-/Ka-band radar dual-frequency ratio (DFR), and abundance of Z_H observations ≥ 30 dBZ in a given scene would all increase under higher aerosol concentrations within an environmental group. These hypotheses were based on expectations that increased aerosol concentrations would favor development of smaller and more-numerous cloud droplets, ~~enhancing~~invigorating convection and enhancing CLW, while the presence of fewer but larger raindrops would increase maximum Z_H and overall presence of Z_H ≥ 30 dBZ along with greater Ka-band attenuation compared to Ku band (i.e., increased maximum DFR~~). Further~~), further indicating enhanced convection. In addition, we hypothesized that radar- and radiometer-based metrics of storm intensity and prevalence would all increase ~~under greater 700-hPa *w*, CAPE, K-Index, LRs, and low-level T_d~~within more-favorable environments, as revisited at the end of section 2, though this investigation is secondary to our aerosol analyses in this study. ~~Expectations for LCL altitude were more uncertain; some studies~~That ~~(e.g., Mulholland et al., 2021) have discussed the tendency for higher LCL altitude to favor stronger updrafts, but other studies (e.g., Grabowski, 2023) have presented alternate explanations, and greater low-level water vapor content would be associated with a lower LCL altitude. Thus, the influence of LCL altitude on convective intensity~~ is ~~still debated in the literature. Given~~, given the environmental stratification methods employed~~,~~ as discussed in the next section, our focus was primarily on the correlations between convective and aerosol metrics and secondarily on the convective patterns associated with environmental variations~~, as mentioned previously.~~. However, in each of these analyses, it is essential to note that correlation does not necessarily indicate causality, as a correlation between two variables may exist entirely due to indirect effects (e.g., ~~Kretschmer~~Lin et al., ~~2017~~2006). In addition, it must be acknowledged that these radar- and radiometer-based metrics of convective intensity may vary due to factors not specifically owing to changes in peak updraft intensity (e.g., cloud microphysics; ~~e.g.,~~ Varble et al., 2023). Despite these and other inherent difficulties, limitations, and uncertainties associated with separating aerosol and environmental influences on convection (e.g., ~~Grabowski, 2018),~~Grabowski, 2018; Varble, 2018), the results herein provide important insight regarding observations of aerosol influences on the radar- and radiometer-based indicators of convective intensity. Additionally, potential trends found in the CAMP^{2}Ex dataset could provide useful information to support future work. Section 2 covers the data and methods used, with Sects. 3 and 4 highlighting environmental stratification and aerosol analyses from the microwave-frequency datasets. Section 5 presents a summary, discussion of limitations, and future work.

2. Data and analysis methods

This section opens with a brief overview of the CAMP^{2}Ex field campaign followed by a description of the datasets used and the uncertainties associated with those data. Discussions are then provided of the methods employed in the analyses of the environmental, convective, and aerosol parameters examined in this study.

2.1 CAMP^{2}Ex

The field phase of CAMP^{2}Ex occurred during 25 August – 10 October 2019, with the NASA P-3B Orion (P-3) aircraft conducting 19 science flights and the Stratton Park Engineering Company Learjet aircraft conducting 13 science flights out of Clark International Airport in the Philippines (Reid et al., 2023). The primary goal of CAMP^{2}Ex was to evaluate the role of aerosols within Southeast Asia's monsoon systems by simultaneously examining aerosol characteristics alongside cloud and radiation properties (Reid et al., 2023). Out of the 19 P-3 science flights, 12 were associated with southwest monsoon conditions and seven were associated with the northeast monsoon within the Maritime Continent (Reid et al., 2023). A broad range of environmental, radiation, and aerosol conditions were observed throughout CAMP^{2}Ex, along with numerous cloud types (i.e., shallow cumulus, congestus, and altostratus clouds) and convective organization (e.g., isolated convection and squall lines) (Reid et al., 2023). Data collected during CAMP^{2}Ex included in situ and remote sensing datasets from the two aforementioned aircraft along with ground-based and ship-based observation platforms, in addition to several numerical models (Reid et al., 2023). As will be discussed in the next subsection, our study primarily uses in situ and remote sensing data from the P-3 aircraft and falls under the CAMP^{2}Ex science question of "To what extent are aerosol particles responsible for modulating warm and mixed-phase precipitation in tropical environments?", while also having direct implications for impacts on deeper convection and cloud meteorology (ESPO, 2020; Reid et al., 2023).

2.2 Datasets and their uncertainties

Key instruments for this study that were flown on the P-3 during CAMP^{2}Ex include: the Advanced Microwave Precipitation Radiometer (AMPR; Spencer et al., 1994; Amiot et al., 2021), Airborne Precipitation and cloud Radar 3rd Generation (APR-3; Durden et al., 2020b), High Spectral Resolution Lidar 2 (HSRL2; Burton et al., 2016), and Advanced Vertical Atmospheric Profiling System (AVAPS; Hock and Young, 2017). All AMPR, APR-3, AVAPS, and HSRL2 data were gathered from the CAMP^{2}Ex data repository (Aknan and Chen, 2020). Due to the direct correlations between ~~CCN~~cloud condensation nuclei concentration and lidar extinction~~,~~ (Ext), backscatter~~,~~ (Bsc), and aerosol optical thickness (AOT~~,~~), all three parameters were analyzed from HSRL2's 355- and 532-nm channels that employ the ~~HSRL2~~HSRL technique~~,~~ (Hair et al., 2008), though 532-nm backscatter was of particular interest based on discussions in Lenhardt et al., (2022). The same quality control ~~(QC)~~ processes outlined in Amiot (2023) for the AMPR, APR-3, and AVAPS data were applied for this study, including application of AMPR's multiple data quality flags. As detailed in Lang et al., (2021), AMPR data were masked if: P-3 pitch or roll magnitude was $\geq 2°$, AMPR was in its nadir-stare mode, P-3 GPS altitude was < 3 km, the given AMPR scan included at least one pixel over land, and ~~removal of the same~~ /or precipitation was present based on AMPR T_b thresholding. Further, as discussed in Amiot (2023), 10 APR-3 files ~~and 10 AVAPS~~were removed due to high levels of noise, three dropsondes~~. Starting~~ were excluded due to lack of corresponding AMPR data, and seven dropsondes were removed during data quality control (e.g., due to lack of recorded near-surface winds). Additionally, starting with the initial 144 dropsondes examined in Amiot (2023), a test was performed in this study to determine whether each dropsonde passed through cloud. Given the 3% uncertainty in AVAPS ~~RH~~relative humidity (Freeman et al., 2020), any dropsonde where more than 20% of

the dropsonde profile was associated with ~~RH~~relative humidity > 97% was removed from the analysis, which amounted to five dropsondes in total. The HSRL2 data were screened for clouds (Hostetler, 2020) to avoid potential contamination of the aerosol analyses (e.g., Liu et al., 2016). Uncertainty values associated with each instrument were deemed negligible for this study. More specifically, AMPR's CLW root-mean-square deviation and median absolute deviation are both on the order of 10^{-2} kg m^{-2} (Amiot, 2023) and AMPR's noise-equivalent differential temperature ~~(NEDT)~~ is 0.5–1.0 K (Amiot et al., 2021). APR-3's Ku-band (Ka-band) calibration uncertainty is roughly 1 dB (1.5 dB) (Durden et al., ~~2020~~2020b). The uncertainties in AVAPS's temperature, relative humidity, and pressure measurements are 0.2 °C, 3%, and 0.5 hPa, respectively (Freeman et al., 2020). ~~Systematic errors for HSRL2 are approximately 4.7% (5.0%) for the 355-nm (532-nm) channel (Burton et al, 2015). Nine~~Under typical conditions, the total systematic error for the HSRL2 532-nm extinction coefficient is estimated to be < 0.01 km^{-1}, which is within the typical state-of-the-art systematic error at visible wavelengths (Schmid et al., 2006; Rogers et al., 2009). The overall systematic error for HSRL2 backscatter calibration is estimated to be < 3% and the random errors for all aerosol products are typically < 10% for the backscatter and depolarization ratios (Hair et al., 2008; Ferrare et al., 2023).

2.3 Environmental, convective, and aerosol parameters

Eight environmental parameters with known physical connections to convective intensity were subjectively chosen for this study based on their ability to be fully captured by a statistically significant number of CAMP^{2}Ex dropsondes~~; future work would benefit from examining other environmental conditions.~~. The ~~nine~~eight selected parameters were: ~~700-hPa *w*;~~ ~~*modified*~~ *normalized* (described below) Convective Available Potential Energy (CAPE~~;~~); Lifting Condensation Level (LCL) altitude; K-Index; 850–700-, 850–500-, and 700–500-hPa ~~LRs;~~temperature lapse rate (hereafter simply "lapse rate", LR); mean dew point temperature (T_d) below the 925-hPa level; and mean T_d below 1 km AGL, which are hereafter referred to by their symbols in Table 1~~.~~

Formatted: Font: Italic

and discussed in more detail below. A significant challenge in evaluating aerosol impacts on convection is to isolate aerosol influences from other sources of convection modulation, such as atmospheric dynamics, thermodynamics, and cloud microphysical processes (e.g., Liu et al., 2016; Grabowski 2018). Since a given convective plume will be affected by synoptic-scale (> 2000 km), mesoscale (2–2000 km), and sub-mesoscale (< 2 km) dynamics (Orlanski, 1975) and environmental conditions, it is important to understand and constrain environmental conditions associated with any convective element (herein "storm") of interest. Several environmental factors with direct physical connections to convection can be evaluated from remote-sensing and in situ observation platforms. Studies have demonstrated the utility of radiosonde data, the principles of which can be applied to dropsondes (e.g., AVAPS) to the extent offered by the dropsonde's launch altitude. CAPE is a measure of parcel buoyancy that can be used to diagnose potential updraft velocity. However, since CAPE is related to integrated buoyancy between the level of free convection and equilibrium level, an issue arises with computing CAPE from AVAPS during CAMP^{2}Ex; since the P-3 did not fly above the equilibrium level during any science flight, the dropsondes did not capture the full vertical buoyancy profile associated with traditional CAPE. As such, the term "modified CAPE" is used herein and is defined mathematically as

$$\mathrm{CAPE_{mod}}\ (\mathrm{J\ kg^{-1}}) = g\int_{z_{lfc}}^{z_{P3}} \frac{(T_v - T_{v,0})}{T_{v,0}}\, dz, \quad (1)$$

where g is gravitational acceleration; T_v and $T_{v,0}$ are parcel and environmental virtual temperatures, respectively; z is altitude; z_{lfc} is the level of free convection; and z_{P3} is P-3 altitude (Markowski and Richardson, 2010). With this definition, modified CAPE would be less than true CAPE within the same environment, which limits evaluation of parcel buoyancy. Since the dropsondes were often launched when the P-3 altitude was > 4 km AGL (Vömel et al., 2020), the instability indicated by modified CAPE can be compared across the environments. Despite this, P-3 altitude would have a direct effect on modified CAPE calculated via Eq. (1), with lower altitude (e.g., around 4 km AGL) biased toward lower modified CAPE by virtue of the dropsonde capturing a lesser vertical extent of the parcel buoyancy. To mitigate this effect, we normalized the CAPE via dividing by the dropsonde launch altitude, which yields (modified) normalized CAPE (Blanchard, 1998) via the relation

$$\mathrm{NCAPE_{mod}}\ (\mathrm{m\ s^{-2}}) = \frac{\mathrm{CAPE_{mod}}}{z}, \quad (2)$$

where z is dropsonde launch altitude. In addition to normalizing the CAPE profiles by dropsonde launch altitude, an added benefit of examining $\mathrm{NCAPE_{mod}}$ is that its units are $\mathrm{m\ s^{-2}}$ as shown in Eq. (2), allowing direct evaluation of vertical acceleration over the dropsonde layer (Blanchard, 1998).

Table 1: List of symbols used to represent the environmental, convective, and aerosol variables examined in this study, along with their units and a brief description of each variable.

Symbol	Units	Type	Description
~~w_{700}~~	~~$\mathrm{m\ s^{-1}}$~~	~~Environmental~~	~~Vertical velocity at 700-hPa level~~
$\mathrm{NCAPE_{mod}}$	$\mathrm{m\ s^{-2}}$	Environmental	Modified Normalized Convective Available Potential Energy
LCL	m	Environmental	Lifting Condensation Level altitude
K-Index	°C	Environmental	K-Index value
$\mathrm{LR_{850\text{-}700}}$	$\mathrm{°C\ km^{-1}}$	Environmental	Temperature lapse rate between 850- and 700-hPa levels
$\mathrm{LR_{850\text{-}500}}$	$\mathrm{°C\ km^{-1}}$	Environmental	Temperature lapse rate between 850- and 500-hPa levels
$\mathrm{LR_{700\text{-}500}}$	$\mathrm{°C\ km^{-1}}$	Environmental	Temperature lapse rate between 700- and 500-hPa levels
$\mathrm{T_{d,press}}$	°C	Environmental	Mean dew point temperature below 925-hPa level
$\mathrm{T_{d,alt}}$	°C	Environmental	Mean dew point temperature below 1 km AGL
CLW	$\mathrm{kg\ m^{-2}}$	Convective	AMPR-derived columnar cloud liquid water path
$\mathrm{PCT_{10}}$	K	Convective	AMPR 10.7-GHz polarization-corrected temperature
$\mathrm{PCT_{19}}$	K	Convective	AMPR 19.35-GHz polarization-corrected temperature
$\mathrm{PCT_{37}}$	K	Convective	AMPR 37.1-GHz polarization-corrected temperature
$\mathrm{PCT_{85}}$	K	Convective	AMPR 85.5-GHz polarization-corrected temperature
$\mathrm{Z_{95,Ku}}$	dBZ	Convective	APR-3 Ku-band 95th percentile composite reflectivity
$\mathrm{Pixels_{Ku}}$	unitless	Convective	APR-3 Ku-band composite reflectivity pixels ≥ 30 dBZ
DFR	unitless	Convective	APR-3 Ku-/Ka-band dual-frequency ratio
$\mathrm{AOT_{355}}$	unitless	Aerosol	HSRL2 355-nm aerosol optical thickness
$\mathrm{AOT_{532}}$	unitless	Aerosol	HSRL2 532-nm aerosol optical thickness
$\mathrm{Ext_{355}}$	$\mathrm{Mm^{-1}}$	Aerosol	HSRL2 355-nm aerosol extinction

Ext_{532}	Mm^{-1}	Aerosol	HSRL2 532-nm aerosol extinction
Bsc_{355}	$Mm^{-1}\ sr^{-1}$	Aerosol	HSRL2 355-nm aerosol backscatter
Bsc_{532}	$Mm^{-1}\ sr^{-1}$	Aerosol	HSRL2 532-nm aerosol backscatter

principles of which can be applied to dropsondes (e.g., AVAPS) to the extent offered by the dropsonde's launch altitude. Vertical velocity (w) at the 700-hPa level can be used to diagnose vertical motion and associated convective support (Bony et al., 2004; Liu et al., 2016). Convective Available Potential Energy (CAPE), a measure of parcel buoyancy that is used to diagnose potential updraft velocity, is defined via

$$\text{CAPE}\ (\text{J kg}^{-1}) = g\int_{z_{ifc}}^{z_{el}} \frac{(T_v - T_{v,0})}{T_{v,0}}\, dz, \quad (1)$$

where g is gravitational acceleration; T_v and $T_{v,0}$ are parcel and environmental virtual temperatures, respectively; z is altitude; and z_{ifc} and z_{el} altitudes of the level of free convection and equilibrium level, respectively (Markowski and Richardson, 2010).

The Lifting Condensation Level (LCL) altitude indicates cloud-base height and is often used in forecasting convection (Markowski and Richardson, 2010), though the exact role of LCL altitude on convective intensity is debated in the literature (e.g., Mulholland et al., 2021; Grabowski, 2023). All CAPE and LCL values were calculated using functions within the Python programming language (i.e., May et al., 2022) as noted in the data availability statement. K-Index is used to forecast convective potential/prevalence (i.e., not intensity) and is defined as

$$\text{K-Index}(°\text{C}) = (T_{850} - T_{500}) + T_{d,850} - (T_{700} - T_{d,700}) \quad (2)$$

where T_{850}, T_{700}, and T_{500} are temperatures at the 850-, 700-, and 500-hPa levels, respectively, and $T_{d,850}$ and $T_{d,700}$ are dew point temperatures at the 850- and 700-hPa levels, respectively (George, 1960). From Eq. (2), K-Index considers: 1) low-to-mid-level temperature lapse rate (hereafter simply "lapse rate", LR), LR, 2) low-level dew point temperature (T_d), and 3) mid-level T_d depression, with the former two (latter one) being directly (inversely) related to convective potential. In addition to 850–500-hPa, 700–500-hPa LR may serve as an excellent indicator of convective potential (e.g., Sherburn and Parker, 2014). Others (e.g., Wang et al., 2015) have used 850–700-hPa LR in forecasting convective potential due to its association with parcel vertical acceleration in the lower atmosphere. Lastly, low-level T_d is important for convective intensity ("intensity" referring to peak updraft velocity) due to entrainment of relatively high-water-vapor air into an updraft's base (e.g., Lucas et al., 2000).

We utilize microwave remote-sensing signatures from radar and radiometer to evaluate convective intensity and prevalence. The 30-dBZ Z_H isoline has often been used to identify precipitation regions (e.g., Straka et al., 2000) and delineate between different "storms" or "cells" (e.g., Johnson et al., 1998; Hastings and Richardson, 2016; Amiot et al., 2019). As precipitation-sized hydrometeors form and grow, Z_H increases due to hydrometeor diameter (D) weighting of D^6 associated with Rayleigh scattering, with eventual onset of non-Rayleigh resonance effects for larger values of D relative to the radar wavelength (Rinehart, 2010). This is especially important to note at finer wavelengths, such as 2.2 and 0.84 cm associated with the Airborne Precipitation and cloud Radar 3rd generation (APR-3)'s Ku and

Formatted: Font: Italic

Formatted: Font: Italic

Ka bands, respectively (Durden et al., 2020), the primary radar dataset used herein. A combination of Ku- and Ka-band radar can be powerful when evaluated using dual-frequency ratio (DFR):

$$\mathrm{DFR} = Z_{Ku} - Z_{Ka}, \quad (3)$$

where Z_{Ku} and Z_{Ka} represent Z_H at Ku- and Ka-band, respectively, on a logarithmic scale (i.e., expressed in dBZ) (e.g., Liao et al., 2008; Liao and Meneghini, 2011). In regions where Z_{Ku} and Z_{Ka} are both similar (e.g., near 0 dBZ for hydrometeors that are in the Rayleigh scattering regime at both frequencies), DFR will be near zero; however, departures in DFR from 0 dBZ can indicate differences in attenuation between the two frequencies and can be used to infer hydrometeor size and phase (e.g., Liao and Meneghini, 2011). As Ku-band Z_H increases, the DFR in rain regions generally becomes slightly negative (i.e., -1–0) before increasing to positive values for Z_H > 30 dBZ; in regions of ice hydrometeors, DFR generally increases with increasing Ku-band Z_H, with a steeper increase occurring for lower-density ice hydrometeors (Liao and Meneghini, 2011).

Microwave radiometers generally retrieve higher brightness temperature (T_b) values at increasingly lower frequencies as precipitation hydrometeors grow in the absence of ice formation aloft (e.g., Spencer et al., 1994). This makes it possible to retrieve cloud and precipitation properties using T_b combinations (e.g., Wilheit and Chang, 1980; Wentz and Spencer, 1998; Hong and Shin, 2013; Amiot et al., 2021). AMPR's integrated cloud liquid water path (CLW) retrievals often fail within precipitation regions; thus, as a cloud grows vertically, AMPR-derived CLW is expected to increase until it fails in moderate-to-heavy precipitation (Amiot et al., 2021; Amiot, 2023). However, CLW increasing around precipitation may yield useful information about the associated convective intensity; for example, precipitation is often associated with cumulus clouds at least 1.5–2 km tall (Smalley and Rapp, 2020) and CLW > 1 kg m^{-2} may indicate precipitation formation within these clouds (e.g., Jiang and Zipser, 2006).

Vertical ascent is a parameter included within the AVAPS dataset (Vömel et al., 2020) and is based on the fall-speed characteristics of the dropsonde (Freeman et al., 2020). The ascent value from the pressure array element nearest 700 hPa was used as w_{700}. Since CAPE is related to integrated buoyancy between the LFC and EL via Eq. (1), an issue arises with computing CAPE from AVAPS during CAMP^{2}Ex; since the P-3 did not fly above the EL during any science flight (SF), the dropsondes did not capture the full vertical buoyancy profile associated with traditional CAPE. As such, the term "modified CAPE" is used herein and is defined mathematically as

$$\mathrm{CAPE}_{\mathrm{mod}}\left(\mathrm{J\,kg^{-1}}\right) = g\int_{z_{0\mathrm{C}}}^{z_{P3}} \frac{(T_v - T_{ve})}{T_{ve}}\,dz, \quad (4)$$

where z_{P3} is the P-3 altitude and all other terms are the same as in Eq. (1). With this definition, modified CAPE would be less than true CAPE within the same environment, which limits evaluation of parcel buoyancy. Since the dropsondes were often launched when the P-3 altitude was > 4 km AGL (Vömel et al., 2020), the instability indicated by modified CAPE can be compared across the environments. Despite this, P-3 altitude would have a direct effect on modified CAPE calculated via Eq. (4), with lower altitude (e.g., around 4 km AGL) biased toward lower modified CAPE by virtue of the dropsonde capturing a lesser vertical extent of the parcel buoyancy. To mitigate this effect, we

~~normalized the CAPE via dividing by the dropsonde launch altitude, which yields (modified) normalized CAPE (Blanchard, 1998) via the relation~~

$$\text{~~NCAPE}_{\text{~~mod}} \text{~~(m s}^{-2}\text{)} = \frac{\text{~~CAPE}_{\text{~~mod}}}{z}, \quad \text{~~(5)}$$

~~where z is dropsonde launch altitude. In addition to normalizing the CAPE profiles by dropsonde launch altitude, an added benefit of examining NCAPE$_{mod}$ is that its units are m s^{-2}, allowing direct examination of vertical acceleration over the dropsonde layer (Blanchard, 1998). All CAPE and LCL values were calculated using functions within the Python programming language (i.e., May et al., 2022) as noted in the data availability statement.~~

K-Index was calculated semi-manually by identifying the pressure array elements nearest the 850-, 700-, and 500-hPa levels, extracting the associated T and/or T_d values from these elements, and utilizing Eq. (~~2~~3). In a similar manner, the temperature and altitude values from array elements nearest the 850-, 700-, and 500-hPa levels were used to calculate $LR_{850\text{-}700}$, $LR_{850\text{-}500}$, and $LR_{700\text{-}500}$ as

$$\text{LR}\left(^{\circ}\text{C km}^{-1}\right) = -\frac{\left(T_{upper} - T_{lower}\right)}{\left(z_{upper} - z_{lower}\right)}, \quad (\text{~~6~~4})$$

where LR is lapse rate, T_{upper} and T_{lower} are temperatures at the higher and lower altitudes, respectively, and z_{upper} and z_{lower} are the higher and lower altitudes, respectively. In addition to 850–500-hPa, 700–500-hPa LR may serve as an excellent indicator of convective potential (e.g., Sherburn and Parker, 2014). Others (e.g., Wang et al., 2015) have used 850–700-hPa LR in forecasting convective potential due to its association with parcel vertical acceleration in the lower atmosphere. Lastly, low-level T_d is important for convective intensity due to entrainment of relatively high-water-vapor air into an updraft's base (e.g., Lucas et al., 2000). ~~Lastly, mean~~ Mean low-level T_d values were calculated by finding array elements where 1) pressure was > 925 hPa, or 2) altitude was < 1 km AGL, and calculating mean T_d from the associated array elements.

We utilize microwave remote-sensing signatures from radar and radiometer to evaluate convective intensity and prevalence. The 30-dBZ Z_H isoline has often been used to identify precipitation regions (e.g., Straka et al., 2000) and delineate between different "storms" or "cells" (e.g., Johnson et al., 1998; Hastings and Richardson, 2016; Amiot et al., 2019). As precipitation-sized hydrometeors form and grow, Z_H increases due to hydrometeor diameter weighting to the sixth power associated with Rayleigh scattering, with eventual onset of non-Rayleigh resonance effects for larger hydrometeor diameters relative to the radar wavelength (Rinehart, 2010). This is especially important to note at finer wavelengths, such as 2.2 and 0.84 cm associated with APR-3's Ku and Ka bands, respectively (Durden et al., 2020b), the primary radar dataset used herein. A combination of Ku- and Ka-band radar data can be powerful when evaluated using DFR:

$$\text{DFR} = Z_{Ku} - Z_{Ka}, \quad (5)$$

where Z_{Ku} and Z_{Ka} represent Z_H at Ku- and Ka-band, respectively, on a logarithmic scale (i.e., expressed in dBZ) (e.g., Liao et al., 2008; Liao and Meneghini, 2011). In regions where Z_{Ku} and Z_{Ka} are both similar (e.g., near 0 dBZ for hydrometeors that are in the Rayleigh scattering regime at both frequencies), DFR will be near zero; however, departures in DFR from 0 dBZ can indicate differences in attenuation between the two frequencies and can be used to

infer hydrometeor size and phase (e.g., Liao and Meneghini, 2011). As Ku-band Z_H increases, the DFR in rain regions generally becomes slightly negative (i.e., -1–0) before increasing to positive values for Z_H > 30 dBZ; in regions of ice hydrometeors, DFR generally increases with increasing Ku-band Z_H as seen in Eq. (5), with a steeper increase occurring for lower-density ice hydrometeors (Liao and Meneghini, 2011). In our study, DFR values < -3 or > 15 were masked to avoid regions where the Ku- or Ka-band data were severely attenuated (e.g., Durden et al., 2020a).

Microwave radiometers generally retrieve higher T_b values at increasingly lower frequencies as precipitation hydrometeors grow in the absence of ice formation aloft (e.g., Spencer et al., 1994). This makes it possible to retrieve cloud and precipitation properties using T_b combinations (e.g., Wilheit and Chang, 1980; Wentz and Spencer, 1998; Hong and Shin, 2013; Amiot et al., 2021). AMPR's CLW retrievals often fail within precipitation regions; thus, as a cloud grows vertically, AMPR-derived CLW is expected to increase until it fails in moderate-to-heavy precipitation (Amiot et al., 2021; Amiot, 2023). Because of this, we will focus more on AMPR polarization-corrected temperature (PCT) in section 3 than CLW, though a similar CLW analysis is included in supplemental material. However, CLW increasing around precipitation may yield useful information about the associated convective intensity; for example, precipitation is often associated with cumulus clouds at least 1.5–2 km tall (Smalley and Rapp, 2020) and CLW > 1 kg m^{-2} may indicate precipitation formation within these clouds (e.g., Jiang and Zipser, 2006).

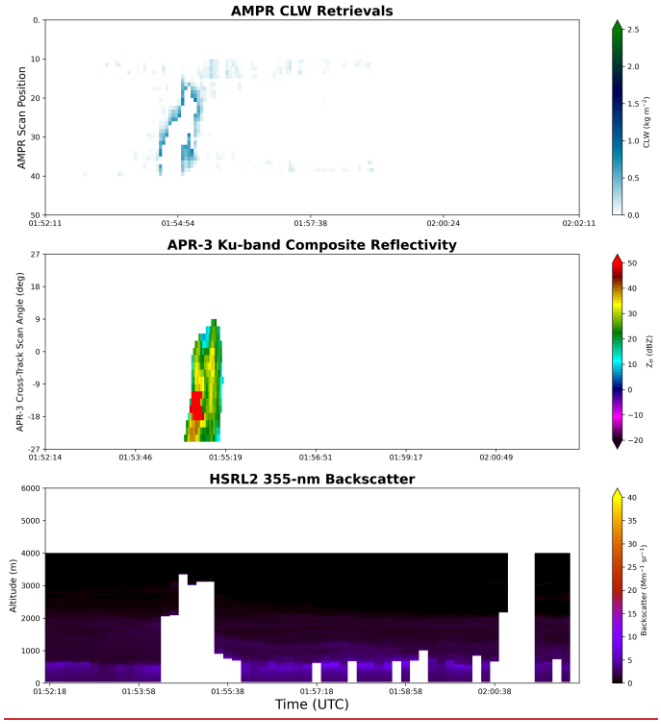
One remote-sensing instrument employed in aerosol analyses is lidar, including HSRL2 for CAMP^{2}Ex (Hostetler, 2020; Reid et al., 2023; Ferrare et al., 2023). HSRL2 measures aerosol backscatter and depolarization ratio at 355, 532, and 1064 nm, with aerosol extinction and AOT also measured using the HSRL2 technique at 355 and 532 nm (Hostetler, 2020). Integration for calculating AOT occurs over a vertical distance starting near the surface and ending at the top of the aerosol extinction profile, which is often around 5–6 km AGL when deployed from the P-3. The top altitude is typically ~1.5 km below the aircraft altitude. Lenhardt et al., (2022) and Redemann and Gao (2024) demonstrated how HSRL2's extinction and backscatter coefficients, especially at 532 nm, have strong direct correlations with cloud condensation nuclei concentrations. Additional studies (e.g., Liu et al., 2016) noted a direct correlation between lidar-based AOT and cloud condensation nuclei concentration. Therefore, extinction, backscatter, and AOT may all be considered when examining aerosol concentration. However, the height/location of an aerosol layer, which can be obtained from extinction and/or backscatter, is important to consider when evaluating diabatic heating from radiation absorption (e.g., Chand et al., 2009; Redemann et al., 2021).

2.4 Data matching in CAMP^{2}Ex scenes

Once the above parameters were calculated from each dropsonde throughout CAMP^{2}Ex ~~SFs~~P-3 science flights 05–19, they were matched spatiotemporally with ~~AMPR and~~ APR-3 and AMPR data. AMPR was inoperable during ~~SF~~science flight 01 and had un-optimized settings for its gain and offset values during ~~SFs~~science flights 02–04 (Lang et al., 2021), resulting in the exclusion of ~~SFs~~science flights 01–04 at the outset of our study. A "scene" was then established for each dropsonde, defined herein using a standard duration of 10 minutes~~.~~, calculated as ±5 minutes from the dropsonde launch time. ~~To~~The APR-3 scans nearest the start and end of this time window were identified and, to

account for situations where ~~remote-sensing~~radar data collection began shortly before or after the start and/or end time of a given scene (e.g., P-3 was turning at the calculated start or end time), a grace of ±1 minute was allowed for the total scene duration, yielding a 10% uncertainty in scene duration. Scenes where the ~~calculated duration~~time difference between the APR-3 scans nearest the start and end of the scene was < 9 or > 11 minutes (e.g., due to significant aircraft maneuvers at the start and/or end of the scene) were masked from the analysis, which amounted to 47 dropsondes in total. Out of the 144 initial dropsondes, five were removed due to the aforementioned ~~RH~~relative humidity analysis, and the removal of these 47 additional dropsondes yielded a total of 92 dropsondes retained for our study. Infrequently, applying the data masks discussed in section 2.2 also resulted in the masking of all AMPR and/or APR-3 data in a given scene. The AMPR, APR-3, and HSRL2 scans nearest the start and end times of each scene were noted, and all AMPR, APR-3, and HSRL2 data were examined over the same approximate time period within each scene; an example of these data in a single scene is provided in Fig. 1.

Eight remote-sensing parameters related to convective intensity and/or prevalence were calculated in each scene: 95th percentile (p95) of AMPR ~~CLW; p95 of AMPR polarization-corrected temperature (~~PCT~~)~~ at 10.7, 19.35, 37.1, and 85.5 GHz; p95 of AMPR CLW, p95 of APR-3 Ku-band



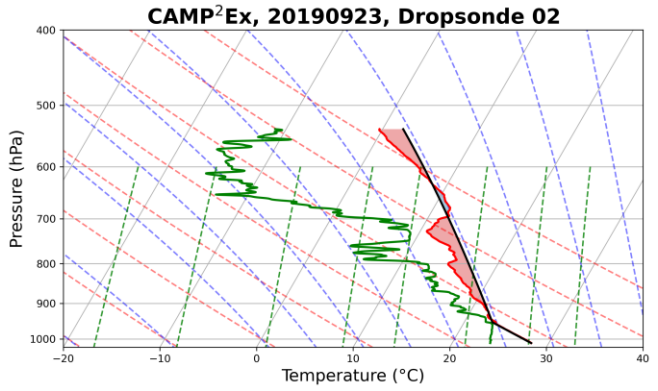


Figure 1: Strip charts (i.e., top-view time series) of AMPR CLW (top) and APR-3 Ku-band composite Z_H (second from top) along with a time-height plot of HSRL2 532-nm backscatter (second from bottom) during approximately 0152 to 0202 UTC on 24 Sept 2019 (23 Sept 2019 flight date based on takeoff time), which cover the "scene" associated with the dropsonde launched at 0157:15 UTC shown in the skew-T log-P diagram (bottom panel). All AMPR data flags have been applied in the top panel. Red shading in the bottom panel indicates CAPE, while solid red, green, and black lines denote temperature, dew point temperature, and parcel temperature, respectively.

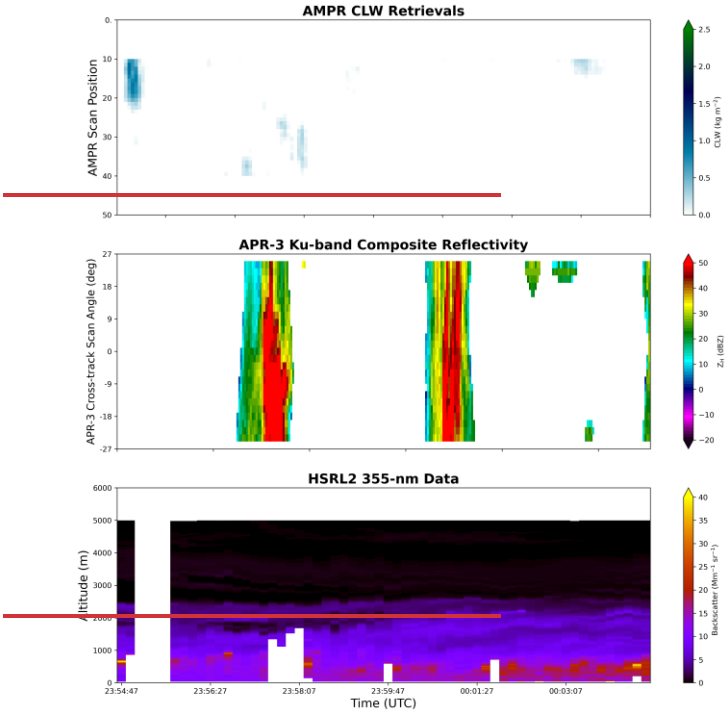
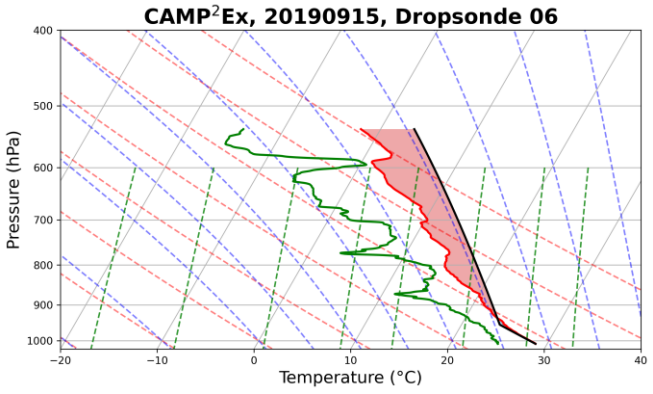
~~composite Z_H~~composite Z_H ($Z_{95,Ku}$) and DFR, and the number of APR-3 Ku-band composite Z_H pixels ≥ 30 dBZ~~,~~ ($Pixels_{Ku}$), hereafter referred to by their symbols in Table 1. The p95 values were used for the former seven parameters due to their direct association with peak convective intensity (e.g., increased raindrop size and radar reflectivity with stronger updraft, all else being equal; e.g., Kollias et al., 2001), with the 95th percentile employed to avoid potential outlier values associated with maximum values. Ku-band was used for the composite Z_H analyses given its reduced attenuation compared to a Ka-band signal over the same distance and atmospheric conditions (i.e., all else being equal). To calculate composite Z_H, the data ~~QC~~quality control described in Amiot (2023) was applied to all 25 APR-3 scan angles in each scene. Within each column of ~~QC'd~~quality-controlled APR-3 data across ~~SFs~~science flights 05–19, the maximum Z_H between the P-3 altitude and the surface was used as the composite Z_H. The presence of occasional residual near-surface range-/sidelobe effects at off-nadir scan angles was noted, which often manifested as very high composite Z_H (i.e., > 70 dBZ). As a basic restriction, all composite Z_H pixels > 70 dBZ were excluded from our analyses, but some erroneous pixels may still reside in the final dataset (e.g., isolated cases with some noisy pixels and/or near-surface range-/sidelobe effects with Z_H < 70 dBZ). Once all composite Z_H values were calculated, $Z_{95,Ku}$, DFR, and $Pixels_{Ku}$ were recorded in each scene. AMPR PCT values were calculated following the methods of Cecil and Chronis (2018), with their methods for 89.0-GHz data applied directly to AMPR's 85.5-GHz data. The p95 PCT in each AMPR channel was recorded along with the p95 of retrieved AMPR CLW in each scene.

2.5 Environmental stratification and sensitivity testing

To begin isolating potential aerosol influences on tropical convection, two steps were employed: 1) bin the environmental scenes into different groups based on a particular AVAPS parameter and magnitude, and 2) incorporate

HSRL2 data into this analysis. The ~~nine~~ AVAPS parameters ~~listed~~, which are the eight "environmental" parameters in Table 1, were ~~employed~~utilized. To stratify each environment, a single AVAPS parameter was separated into "low," "medium," and "high" values, and each scene was grouped into one of these categories based on the associated dropsonde's values. Within each environmental bin, the





~~**Figure 1: Strip charts (i.e., top-view time series) of AMPR CLW (top) and APR-3 Ku-band composite Z_H (second from top) along with a time-height plot of HSRL2 532-nm backscatter (second from bottom) from approximately 2354–0004 UTC during SF-09, which cover the "scene" associated with the dropsonde shown in the bottom panel. The dropsonde was launched at 2359:50 UTC. All AMPR data flags have been applied in the top panel. Red shading in the bottom panel indicates CAPE, while solid red, green, and black lines denote temperature, dew point temperature, and parcel temperature, respectively.**~~

eight convective parameters (Table 1) were compared against mean values of the six HSRL2 parameters ~~(~~, which are the "aerosol" parameters in Table 1~~)~~, from each scene. The main statistics examined were Pearson correlation coefficients, the number of data points used in each comparison, and the statistical significance, primarily based on whether the p-value associated with the Pearson correlation coefficient was < 0.01 (e.g., Wilks, 2011). A few subjectively selected correlations were examined in greater detail using scatterplots, wherein it should be noted that the exact number of data points varied from plot-to-plot due to variations in missing data (e.g., dropsonde launched below the 500-hPa level for any parameters that use 500-hPa data). ~~In addition, several scenes contained no unmasked APR-3 and/or AMPR data, resulting in their exclusion from the comparisons.~~

To further mitigate potential impacts of any outliers, a bootstrapping approach was utilized when examining the Pearson correlation coefficient, number of data points, and p-value in each convective-aerosol parameter pairing within each bin for each environmental parameter. To apply the bootstrapping method, 10% of the convective-aerosol data pairs were withheld randomly before calculating the Pearson correlation coefficient and associated p-value for the remaining number of data points. This process was repeated 1000 times for each convective-aerosol pairing, and mean values of the Pearson correlation coefficients, number of data points, and p-values were calculated; these mean values are reported throughout section 3 below. Though 1000 was often much greater than the number of unique combinations possible for a given data pairing, 1000 resamples for a bootstrapping approach is common in the literature and was applied uniformly across all data pairs in this study. Comparisons involving a sample size < 10 were unchanged by this approach of withholding 10% of the dataset since the remaining sample size was rounded up to the nearest whole integer, which always returned the original number of data points if the sample size was < 10.

Lastly, the exact values used to stratify each environmental condition were varied in a sensitivity test consisting of four different sets of thresholds for each parameter (Table 2). The methods used to stratify the environmental parameters in Tests 1–4 were, respectively, as follows:

1) Create campaign-wide histograms of the AVAPS parameter and visually identify approximate values that split the dataset into three roughly equal-sized groups.
2) Objectively select thresholds that split each parameter's dataset into three equal-sized groups (see the Data Availability statement).
3) Manually select thresholds that fall between the low-medium and medium-high thresholds previously identified in Tests 1 and 2.

4) Objectively select thresholds that split each parameter's dataset into three groups where the "low" and "high" categories each contain 25% of the data and the "medium" category contains 50% of the data (i.e., "medium" datasets that were approximately twice as large as the "low" and "high" datasets).

For brevity, only results from Test 2 are shown herein, but results from all four tests can be found in supplemental material. Test 2 is highlighted due to its objective stratification into roughly equal-sized groups. The bootstrapping method described above was also applied in all sensitivity tests.

Relating the parameters discussed in this section back to our hypotheses listed at the end of section 1, we hypothesized that PCT, $Z_{95,Ku}$, $Pixels_{Ku}$, and DFR would all increase under greater $NCAPE_{mod}$, K-Index, LRs, and low-level T_d, though, again, this investigation is secondary to our aerosol analyses in this study as outlined at the end of section 1. Expectations for LCL altitude were more uncertain given some differences in the results and discussions in past works that have explored LCL altitude related to convective intensity (e.g., Mulholland et al., 2021; Grabowski, 2023).

3. AMPR results

This section presents the results of comparing the AMPR-based convective parameters with HSRL2 data within environmental bins established using the ~~nine~~eight AVAPS parameters. Correlation tables are used to provide complete descriptions of the observed correlations, with more in-depth discussions and analyses performed for some subjectively selected correlations that were statistically significant and/or potentially most impactful. ~~A brief description~~Brief descriptions of the sensitivity test results ~~for environmental stratification is~~are provided ~~for each parameter~~, and all associated correlation tables from these sensitivity tests can be found in supplemental material.

~~AMPR's CLW comparisons with HSRL2 in the stratified environments are summarized in Fig. 2. From Fig. 2, many Pearson correlation coefficients between the aerosol parameters and CLW were negative and with statistical significance, especially when comparing CLW with AOT and Ext at either HSRL2 wavelength. This result was unexpected but, as will be elaborated upon further in this section, was primarily due to the masking of precipitation regions for AMPR CLW. Due to the CLW retrieval method not accounting for precipitation, regions wherein high~~

Table 2: List of the four sensitivity tests that were performed to stratify the ~~nine~~eight AVAPS parameters into "low," "medium," and "high" bins. The listed values in each bracket represent the inclusive range of the "medium" bin for the respective parameter and test; that is, values less (greater) than the lower (upper) limit were classified into the "low" ("high") bin.

~~CLW would be expected in association with heavy precipitation could easily appear as a region of failed retrieval or may return a high CLW value with an unknown uncertainty (Amiot et al., 2021). For this reason, precipitation was masked for the AMPR CLW retrievals. A similar trend across the HSRL2 parameters and environmental bins, albeit with different correlation values and changes in their statistical significances, was observed across the sensitivity tests performed (supplemental material).~~

~~To gain a more in-depth look at some correlations in Fig. 2, scatterplots were produced of CLW versus AOT_{355} when binned by $NCAPE_{mod}$ (Fig. 3a) and CLW versus Bsc_{532} when binned by $LR_{850-700}$ (Fig. 3b). These correlations were selected for scatterplot analysis based on their statistical significance in Fig. 2 while also presenting CLW comparisons with two different aerosol parameters and using two different environmental parameters for the binning. From Fig. 3a, negative correlations can be seen between CLW and AOT_{355} for each of the environmental bins, though the negative correlations are most pronounced (and most statistically significant) within the medium and high $NCAPE_{mod}$ groups. The values of AOT_{355} are relatively low (< 0.5) for the entire analysis, which limits variability in the aerosol concentrations, but we will discuss the trends relative to the AOT_{355} values present. A notable feature in Fig. 3a is the clustering of data points around CLW = 0 kg m^{-2}, which suggests that several of the scenes examined either did not contain clouds or they were masked from the analyses; these trends will be seen in other comparisons discussed for the AMPR and APR-3 convective metrics in this section and section~~ investigate AMPR data retrieved ~~4. The clustering of these data points around CLW = 0 kg m^{-2} as AOT_{355} increases seems to have contributed to the negative correlations for each environmental group. It should also be noted that CLW values > 1 kg m^{-2} are excluded from Fig. 3a; a CLW threshold of 1 kg m^{-2} has been used in prior studies (e.g., Jiang and Zipser, 2006) to separate precipitating and non-precipitating clouds, indicating that precipitation scenes were largely successfully masked from Fig. 3a. If precipitating scenes were indeed masked under the presence of higher AOT_{355} and higher $NCAPE_{mod}$ (i.e., the clustering of these data points above an AOT_{355} of 0.2), it would suggest that convection was strong enough to produce precipitation under higher aerosol concentrations and higher $NCAPE_{mod}$; however, this is speculative and cannot be determined from Fig. 3a alone, but this idea will be revisited throughout sections 3 and 4. Additionally, as will be referred throughout these discussions,~~

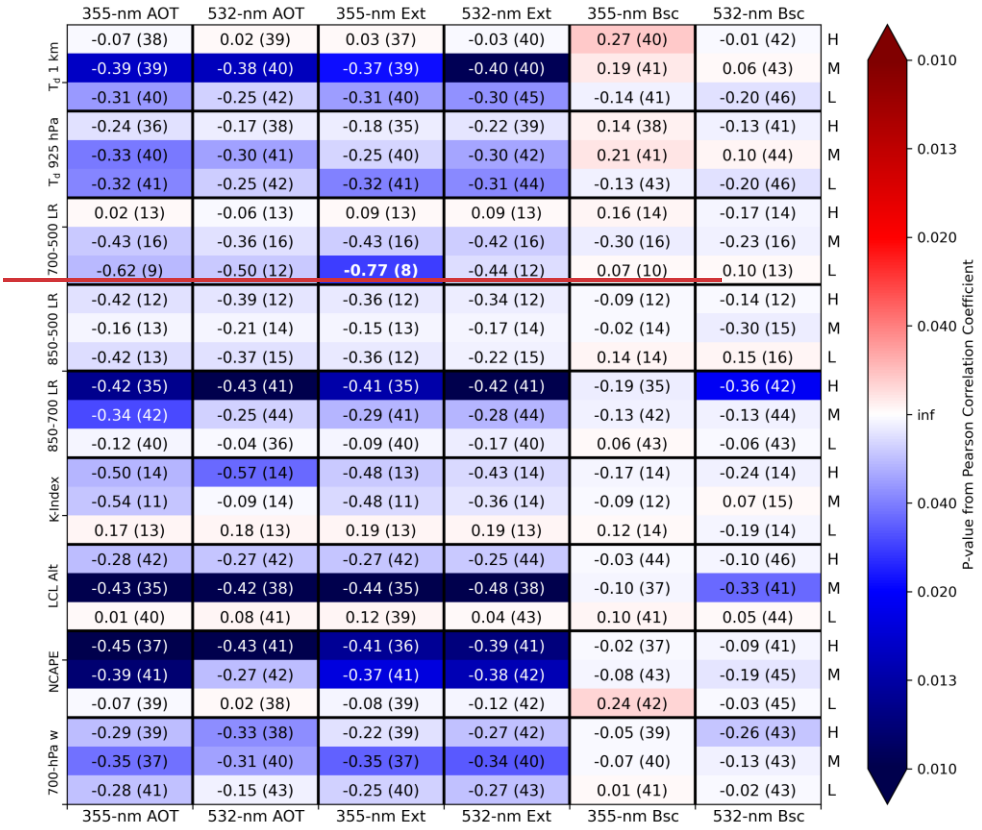

Figure 2: Pearson correlation coefficients from comparing p95 AMPR CLW with mean HSRL2 AOT, extinction (Ext), and backscatter (Bsc) at 355 and 532 nm (top and bottom borders) within environmental bins stratified by the nine AVAPS parameters (left border) at low (L), medium (M), and high (H) magnitudes (right border) across the CAMP²Ex scenes. AVAPS magnitudes were stratified using the values of Test 2 (Table 2). Within each cell, the listed value is the Pearson correlation coefficient and the parenthesized value indicates the number of data points used in the comparison. Cells with a Pearson correlation coefficient ≥ 0.70 contain bolded text. Reds (blues) represent positive (negative) Pearson correlation coefficients, and the color shading corresponds to the magnitude of the p-value according to the colorbar, with darker shades of each color associated with lower p-values (i.e., greater statistical significance). Color shading begins to increase substantially around a p-value of 0.05 and reaches a maximum for p-values around 0.01.

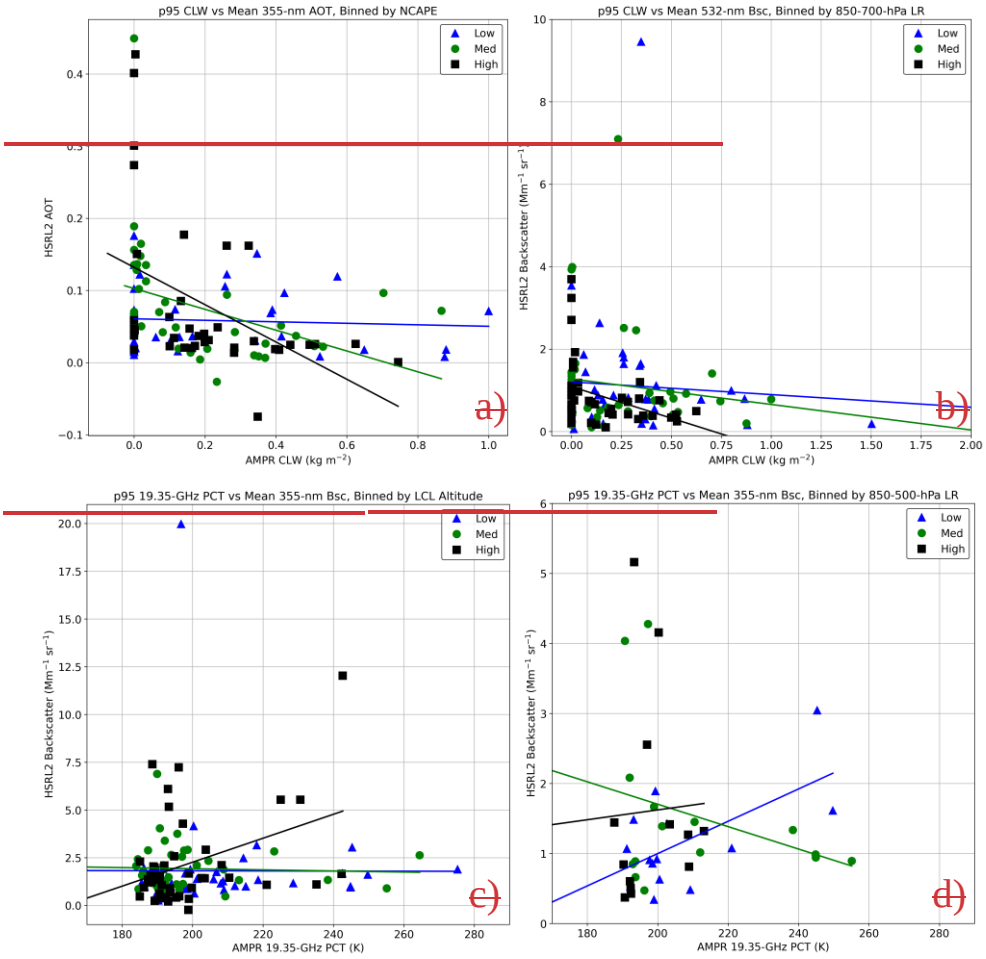
a relatively limited sample size was present for several of the comparisons/scatterplots, and all cases examined in this study would benefit greatly from a larger sample. Despite this, the statistical significance between CLW and AOT_{355} is potentially impactful and warrants further investigation.



562 **~~Figure 3: Scatterplots of p95 CLW (top row) and p95 PCT$_{19}$ (bottom row) compared with mean values of the HSRL2 parameter listed in the title and y-axis of each plot within environmental bins stratified using the~~**
564 **~~AVAPS parameter listed in the title of the corresponding plot. AVAPS threshold values were from Test 2~~**
~~(Table 2). In all plots, blue triangles, green circles, and black squares correspond to data points associated with~~
566 **~~low, medium, and high magnitudes, respectively, of the associated AVAPS parameter. Please note that the ranges of the x- and y-axes are not constant among the scatterplots shown.~~**

568 ~~Moving on to Fig. 3b, a similar trend as Fig. 3a can be seen, where there is a considerable clustering of datapoints around CLW = 0 kg m^{-2}, including for several of the highest Bsc$_{532}$ values (i.e., > 2 Mm^{-1} sr^{-1}). This further raises the~~
570 ~~question of cloud-free versus cloud-masked scenes, which will be explored more in this section and the next. It was interesting to see that the highest CLW values (e.g., > 0.5 kg m^{-2}) were associated with some of the lowest aerosol~~

~~concentrations and low-to-medium $LR_{850-700}$ values, both of which are the opposite of our hypotheses. As noted previously, the lack of precipitation in the QC'd AMPR data likely contributed to these unexpected trends. The statistical significance of the high $LR_{850-700}$ group seems to have been impacted by the data points with Bsc_{532} < 1 Mm^{-1} sr^{-1} and AMPR CLW between 0.25–0.75 kg m^{-2}. Because of these data clusters and masking, it is difficult to discern some of the convective-aerosol correlations in Fig. 3b, but it is apparent that, within the precipitation-masked AMPR data, aerosol concentration is not directly correlated with the convective metric. However, the statistical significance is worthy of additional examination as part of future work.~~

~~To look into regions where AMPR's CLW retrievals were masked~~ in and around precipitation, AMPR T_b values can be used to obtain PCTs in these regions. Correlation coefficients between AMPR's 19.35-GHz PCT and the HSRL2 parameters are shown in Fig. 42. For brevity, only PCT_{19} is detailed herein given its sensitivity to clouds and precipitation, with additional PCT results presented in supplemental material. From Fig. ~~4 the correlation coefficient magnitudes were considerably lower than the AMPR CLW analysis but~~2 some positive correlations were present~~,~~ ~~including ones with statistical significance. This~~ and statistically significant, which illustrates the benefits of examining PCT in regions of precipitation ~~as opposed to solely relying on the CLW~~ wherein AMPR CLW retrievals~~.~~ ~~To examine~~ may fail, as discussed below and in supplemental material. However, most of the correlations throughout Fig. 2 were fairly weak and had limited statistical significance, especially when comparing PCT_{19} with the extinction parameters which indicates a level of inconclusiveness that remains in these results. Despite this, some of the correlations with greatest positive statistical significance were examined in more detail~~, we have produced~~ using scatterplots ~~of~~, in particular PCT_{19} versus Bsc_{355} when binned by LCL (Fig. ~~3c~~3a) and PCT_{19} versus Bsc_{355} when binned by $LR_{850-500}$ (Fig. ~~3d~~3b).

When examining the PCT_{19} values in Fig. ~~3c~~3a, many data points are ~~are~~ < 200 K, which indicates a relative lack of considerable precipitation in ~~those~~the scenes examined (Amiot et al., 2021; Amiot 2023); however, several data points with PCT_{19} > 200 K can be seen in Fig. ~~3c~~3a, including values > 260 K, which indicates that PCT_{19} is indeed capturing precipitation. There is considerable clustering of the data between a PCT_{19} of 185–200 K and Bsc_{355} of 0–~~7~~4.5 Mm^{-1} sr^{-1}, suggesting the presence of several instances of clouds that were generally not precipitating. The association of the highest PCT_{19} values with relatively low aerosol concentrations (i.e., < 43 Mm^{-1} sr^{-1} in this case) within the low and medium LCL groups, combined with the clustering of data points mentioned previously, seems to have caused the extremely low correlation values for these low and medium groups. It appears that the high ~~–~~LCL correlation was sensitive to the ~~three~~two outlier values with PCT_{19} > 220 K and Bsc_{355} > 5 Mm^{-1} sr^{-1}, which contributed to its high value; however, the fact that this correlation was found to have statistical significance indicates that it is worthy of further examination. In general, increased aerosol concentration was not strongly associated with enhanced convection in Fig. ~~3c~~3a. However,~~–~~ it is noteworthy that over half of the data points with PCT_{19} > 240 K were associated with a low LCL; this would indicate a relatively high amount of low-level water vapor content, wherein warm-phase convective invigoration may take place (e.g., Grabowski and Morrison, 2020); however, there are only

Formatted: Line spacing: Multiple 2.5 li

Formatted: Font: Italic

~~nine~~seven data points with PCT_{19} > 240 K and the aerosol concentrations are relatively low, so this potential connection needs further analysis.

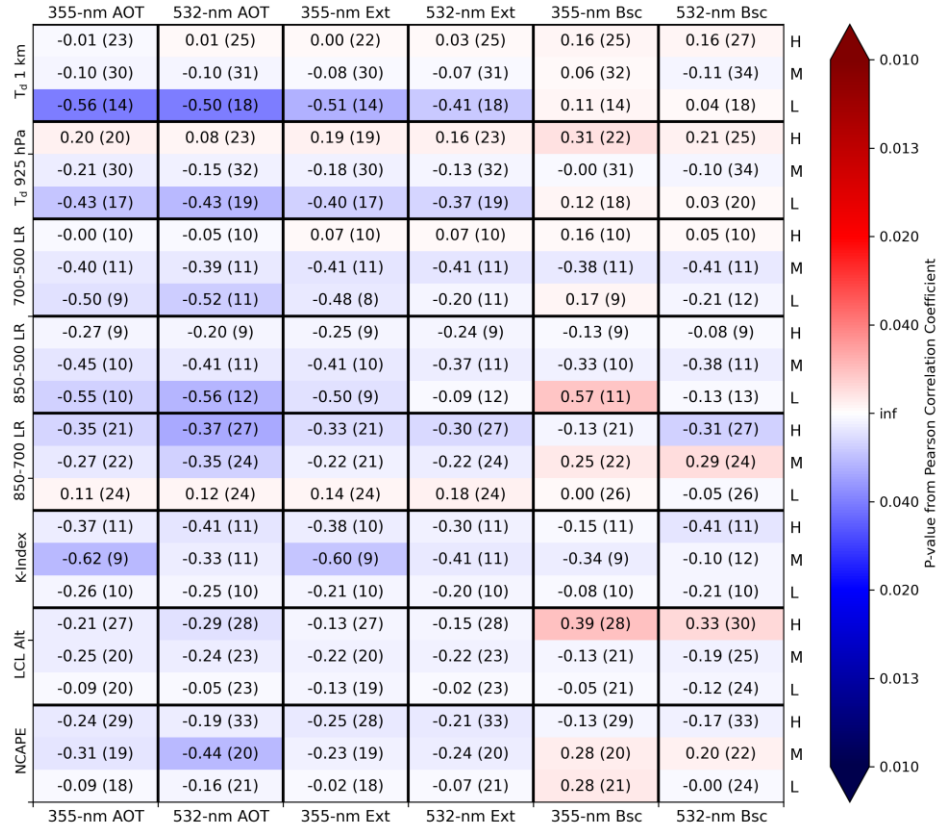


Figure 2: Pearson correlation coefficients from comparing p95 AMPR 19.35-GHz PCT with mean HSRL2 AOT, extinction (Ext), and backscatter (Bsc) at 355 and 532 nm (top and bottom borders) within environmental bins stratified by the eight AVAPS parameters (left border) at low (L), medium (M), and high (H) magnitudes (right border) across the CAMP²Ex scenes. AVAPS magnitudes were stratified using the values of Test 2 (Table 2). Within each cell, the listed value is the Pearson correlation coefficient and the parenthesized value indicates the mean number of data points used in the (bootstrapped) comparison. Cells with a Pearson correlation coefficient > 0.70 contain bolded text. Reds (blues) represent positive (negative) Pearson correlation coefficients, and the color shading corresponds to the magnitude of the p-value according to the colorbar, with darker shades of each color associated with lower p-values (i.e., greater statistical significance). Color shading begins to increase substantially around a p-value of 0.05 and reaches a maximum for p-values around 0.01.

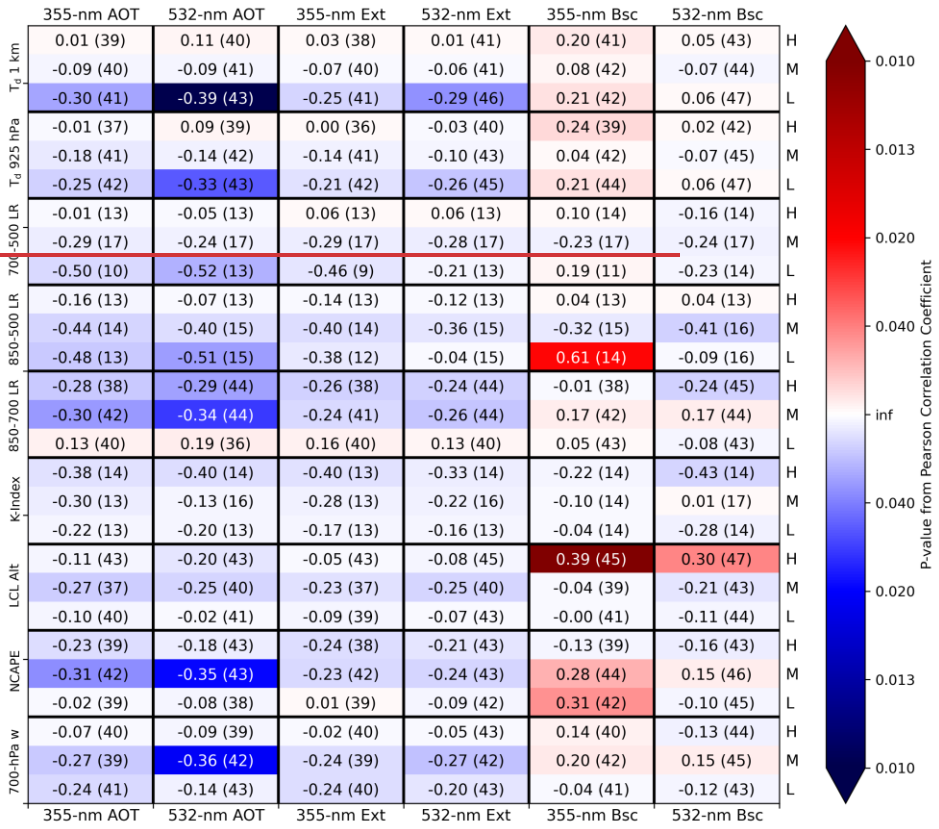
The impact of a reduced dataset size can be seen to an even greater degree in Fig. ~~3d~~3b, which contains far fewer data points compared to Fig. ~~3c~~3a due to $LR_{850\text{-}500}$ requiring data from the 500-hPa level. Despite this, a statistically significant positive correlation was found between the aerosol and convective metrics, but it was unexpected that this



~~**Figure 4: As in Fig. 2 but using p95 AMPR 19.35-GHz PCT as the convective parameter.**~~

occurred for the low $LR_{850\text{-}500}$ group and not the medium or high groups. From Table 2, the low $LR_{850\text{-}500}$ values were still conditionally unstable and thus supportive of convection, so this result is physically plausible and ~~deserved~~deserves further

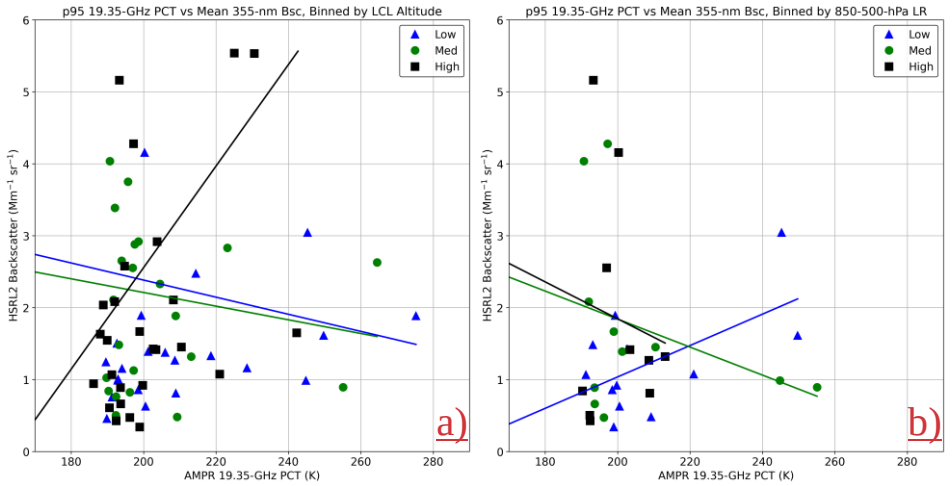


Figure 3: Scatterplots of p95 PCT_{19} compared with mean values of the HSRL2 parameter listed in the title and y-axis of each plot within environmental bins stratified using the AVAPS parameter listed in the title of the corresponding plot. AVAPS threshold values were from Test 2 (Table 2). In all plots, blue triangles, green circles, and black squares correspond to data points associated with low, medium, and high magnitudes, respectively, of the associated AVAPS parameter. Please note that the ranges of the x- and y-axes are not constant among the scatterplots shown.

analysis. However, it ~~does seem~~seems that the data points with PCT_{19} > ~~230~~240 K greatly influenced the correlations for the low and medium groups, which is ~~to be~~ expected with a relatively limited sample size. The increase in PCT_{19} with increasing aerosol concentration (within the low group) matches the hypothesized correlations, but the highest aerosol concentrations in Fig. ~~3d~~3b (i.e., Bsc_{355} > 2 Mm^{-1} sr^{-1} in this case) were associated with relatively low PCT_{19} values < 205 K in all but one instance. Thus, the overall trends in correlation between aerosol concentration and PCT_{19} in Fig. ~~3d~~3b are fairly mixed.

Due to the presence of ~~several~~ statistically significant and potentially impactful results in Figs. 2~~, 3,~~ and ~~4~~3, future work should examine these and other AMPR data in greater detail. Several trends were consistent across the sensitivity tests (supplemental material). However, it should be acknowledged that many correlations throughout Fig. 2 were fairly weak (i.e., magnitude < 0.3) and/or had low statistical significance. Additionally, as will be referenced throughout these discussions, a relatively limited sample size was present for several of the comparisons/scatterplots, and all cases examined in this study would benefit from a larger sample (e.g., incorporating satellite and/or modeling data to expand the number of data points throughout the study domain, especially in and around deeper convection). Lastly, as is true for all analyses ~~in this study~~herein, while high correlation between two parameters is interesting and potentially significant, it does not guarantee a cause-and-effect situation ~~between the parameters.~~ Thus, the most noteworthy trends identified in this study (e.g., Fig. 3) should be examined further to evaluate their significance and

potential aerosol influences on convection. ~~Many of these trends were also fairly consistent across the sensitivity tests (supplemental material).~~

AMPR's CLW comparisons with HSRL2 in the stratified environments are summarized via Figs. S1–S3 in supplemental material. Due to the CLW retrieval method not accounting for precipitation, regions wherein high CLW would be expected in association with heavy precipitation could easily appear as a region of failed retrieval or may return a high CLW value with an unknown uncertainty (Amiot et al., 2021). Since we focus on the strongest convection observed in this study, these uncertainties make it more difficult to assess AMPR CLW in relation to the study focus, which is why we have chosen to present this information in supplemental material. From Fig. S1, when low CLW values (i.e., < 1 g m^{-2}) were included in the dataset, many Pearson correlation coefficients between CLW and the aerosol parameters were negative and with statistical significance, especially when comparing CLW with AOT and Ext at either HSRL2 wavelength. This can be seen further in the scatterplots of CLW versus AOT_{355} when binned by $NCAPE_{mod}$ (Fig. S2a) and CLW versus Bsc_{532} when binned by $LR_{850\text{-}700}$ (Fig. S2b), wherein the broad distribution of AOT_{355} and Bsc_{532} values around a CLW value of 0 kg m^{-2} greatly contributed to these negative correlations. Masking CLW < 1 g m^{-2} removed much of the statistical significance throughout the correlations, as seen in Fig. S3. Many of the remaining correlations were negative, as seen in Figs. S2c, S2d, and S3, but these correlations were generally weak. Thus, despite the presence of some stronger and more statistically significant correlations in Figs. S1–S3, the abundance of weaker correlations indicates a considerable degree of inconclusiveness that remains in these results. Moreover, these trends persist across the sensitivity tests (supplemental material). This further emphasizes the difficulty in truly separating aerosol influences from environmental effects, in addition to the limitations associated with the observational datasets and the relatively small sample sizes employed in our study.

4. APR-3 results

Similar analyses are presented in this section using $Z_{95,Ku}$~~,~~ $Pixels_{Ku}$, and DFR as the convective parameters. All figures utilize the AVAPS thresholds from Test 2 (Table 2), with the full sensitivity~~-~~ test results presented in supplemental material. To begin, Pearson correlation coefficients between $Z_{95,Ku}$ and the HSRL2 variables can be found in Fig. 4. ~~seen in Fig. 5. From Fig. 5, there is no widespread presence of statistically significant negative correlation coefficients was previously observed for the AMPR CLW, which further suggests that the precipitation flagging in AMPR CLW may explain the negative correlations observed therein to some degree. On the contrary, several~~Several statistically significant positive correlations can be seen between $Z_{95,Ku}$ and the HSRL2 variables in Fig. ~~5. This is~~4, most ~~notable~~notably for some comparisons when ~~binning these correlation analyses~~binned according to $NCAPE_{mod}$, ~~LCL, lapse rate~~$LR_{850\text{-}700}$, and ~~low-level T_a. While some~~ $LR_{700\text{-}500}$. However, most of the correlations ~~between $Z_{95,Ku}$ and the HSRL2 variables~~throughout Fig. 4 were relatively ~~high (i.e., > 0.5) for the medium and high categories of some environmental parameters (e.g., $LR_{850\text{-}500}$), it is interesting that the~~weak and had limited statistical significance. Interestingly, many of the strongest correlations ~~within~~with the highest statistical significance (albeit still fairly limited) were often associated with the low category of ~~the~~a given environmental group. To examine some of these trends in greater detail, the two parameters selected for more in-depth analysis from Fig. ~~5~~4 were: 1) Bsc_{355} binned by

682 $LR_{700\text{-}500}$ (Fig. 5a), and 2) Bsc_{532} binned by ~~LCL (Fig. 6a), and 2) Bsc_{355} binned by~~ $NCAPE_{mod}$ (Fig. ~~6b); the former was~~5b), which were selected ~~based on its~~due to their relatively high statistical significance~~, while~~ in the low category
684 of the ~~latter was selected to investigate the interesting negative correlations for medium $NCAPE_{mod}$~~environmental groups.

686 In Fig. ~~6a~~5a, many $Z_{95,Ku}$ values ~~>~~≥ 30 dBZ were present in the CAMP^{2}Ex scenes, indicating that precipitating systems were indeed ~~flown over~~overflown by the P-3 aircraft and further suggesting that AMPR's precipitation flags ~~yielded~~
688 contributed to many of the unexpected negative ~~results~~correlations in section 3. The standout feature of Fig. ~~6a~~5a is the statistically significant positive correlation between $Z_{95,Ku}$ and ~~Bsc_{532}~~Bsc_{355} when binned by low ~~LCL~~$LR_{700\text{-}500}$
690 values. That is, as aerosol concentration

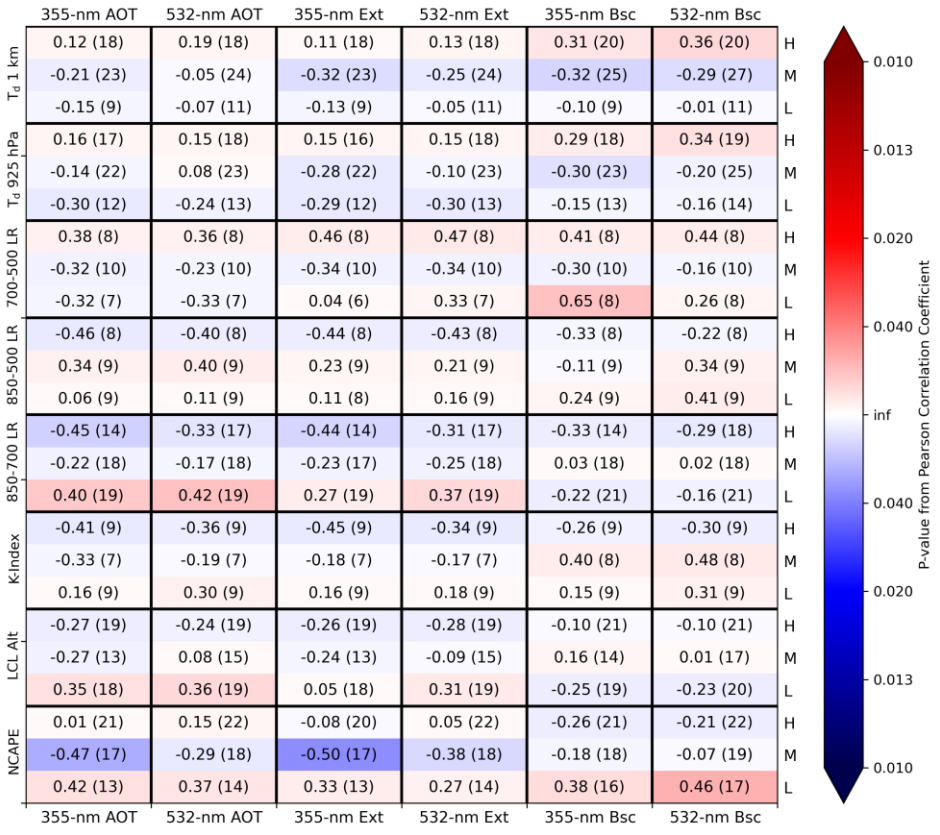

Figure 4: As in Fig. 2 but using p95 APR-3 Ku-band composite Z_H as the convective parameter.

Formatted: Line spacing: 1.5 lines

increased within low-~~LCL~~$LR_{700\text{-}500}$ conditions, the peak Ku-band Z_H within the same scene increased as well, suggesting the development of larger raindrops. These large raindrops would dominate Z_H, but this analysis also highlights the importance of considering environmental conditions. ~~This trend also supports the notion that, within low-LCL group, which would have higher lower-level water vapor content (all else being equal), higher $Z_{95,Ku}$ was associated with higher Bsc_{532} values. While~~ Further, this comparison is hindered by the limited ~~by the relatively small~~ sample size ~~herein, this result matches the warm-phase invigoration~~, and thus a few data points may significantly impact the correlations. ~~While~~ the general trend of ~~convection discussed in prior studies (e.g., Grabowski and Morrison, 2020), and warrants further analysis. The~~ the $LR_{700\text{-}500}$ comparisons is similar across the sensitivity tests (supplemental material), the magnitude of the correlation ~~was also positive for the medium-LCL group but with a lower correlation value and lesser~~and its statistical significance~~, indicating the trend was not as robust as the low-LCL group. Despite this, the trends of increasing $Z_{95,Ku}$ with increasing aerosol concentration in these groups matches physical expectations. It is also noteworthy that these trends were constant across the sensitivity tests, increasing the reliability of these results. However,~~ varied depending on the values used to stratify, the ~~negative correlation in the high-LCL group was unexpected and seems to have been influenced by the upper-left data points in Fig. 6a.~~

~~Comparing $Z_{95,Ku}$ with Bsc_{355} when binned by $NCAPE_{mod}$ (Fig. 6b), positive correlations between $Z_{95,Ku}$ and Bsc_{355} were present for the low- and high-$NCAPE_{mod}$ groups, which matches expectations. However, the negative correlation~~

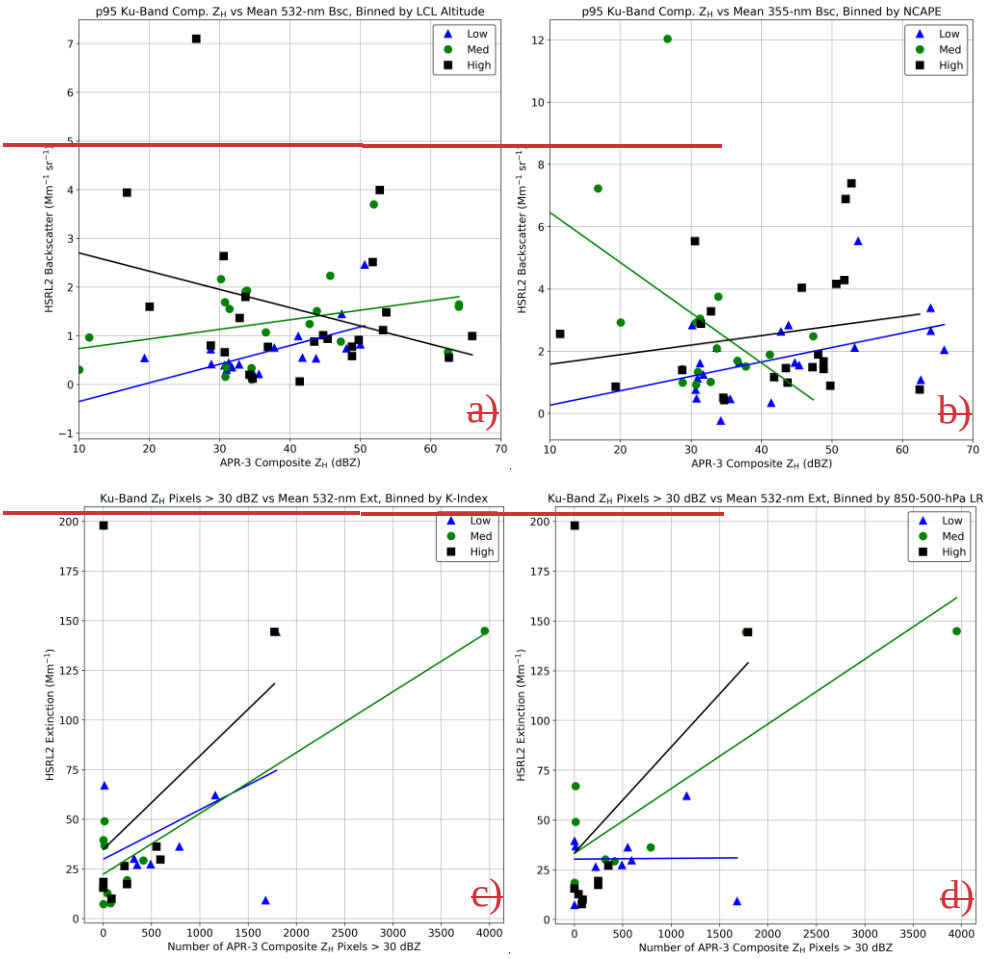
Figure 5: As in Fig. 2 but using p95 APR-3 Ku-band composite Z_w as the convective parameter.

within the medium $NCAPE_{mod}$ group was unexpected – this appears to be the result of only two data points with $Z_{95,Ku}$ > 40 dBZ in this medium group, unlike the low and high groups, which suggests that the medium $NCAPE_{mod}$ values were not as supportive of convection. The presence of Bsc_{355} > 4 Mm^{-1} sr^{-1} associated with $Z_{95,Ku}$ > 50 dBZ within the high $NCAPE_{mod}$ is interesting as it suggests that the aerosol conditions may have supported the development of deeper convection when environmental conditions were more suitable for convection in general; however, this trend was not constant, as the highest $Z_{95,Ku}$ values were associated with Bsc_{355} < 4 Mm^{-1} sr^{-1} and low $NCAPE_{mod}$ values, which indicates that this analysis warrants further examination. It should also be stressed that the presence of high correlations do not guarantee causality, further indicating that these results should be examined further.

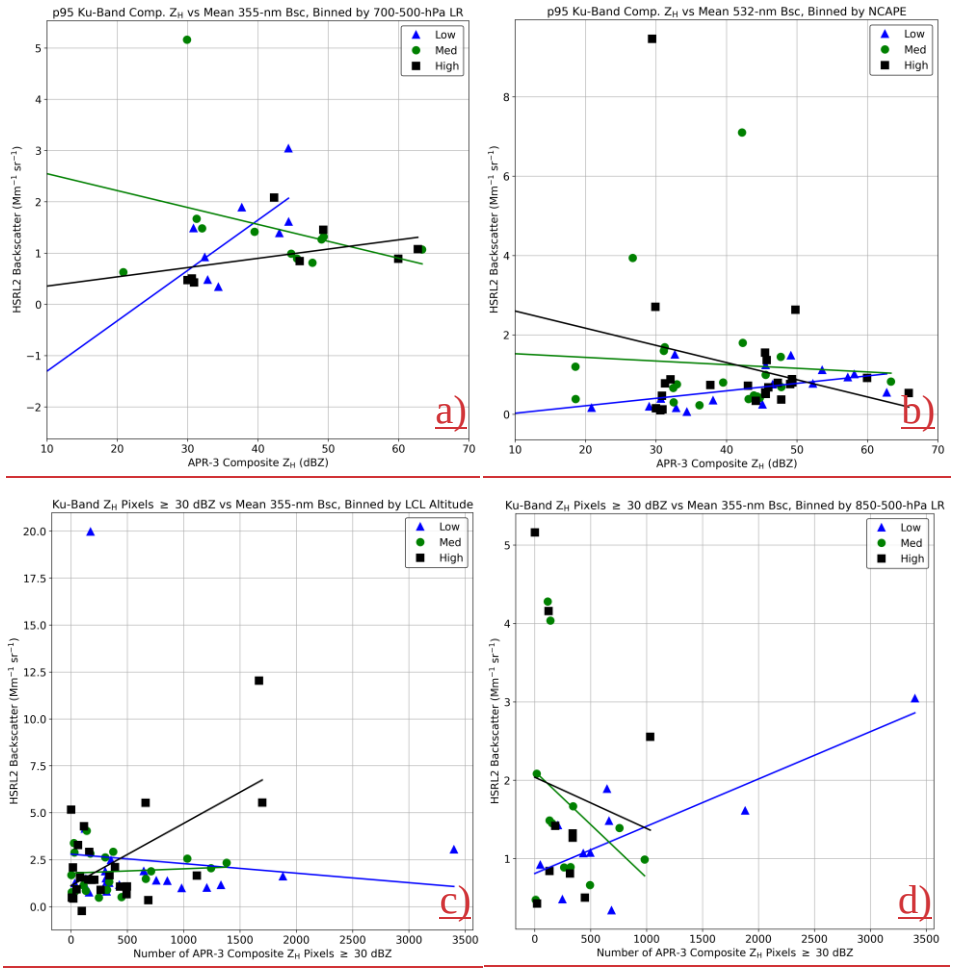
Next, the number of APR-3 Ku-band composite Z_w pixels ≥ 30 dBZ (i.e., $Pixels_{30}$) was used as the convective parameter (Fig. 7). Several more highly positive correlations were present compared to Figs. 2, 4, and 5, likely due

Formatted: Line spacing: 1.5 lines

Formatted: Font color: Auto



lapse rates. Further, the highest $Z_{95,Ku}$ values were associated with relatively low values of Bsc_{355} < 2 Mm^{-1} sr^{-1}, suggesting that the largest raindrops were not necessarily correlated with the highest aerosol concentrations. Despite this, the positive correlations observed in this comparison warrant further exploration in future work.



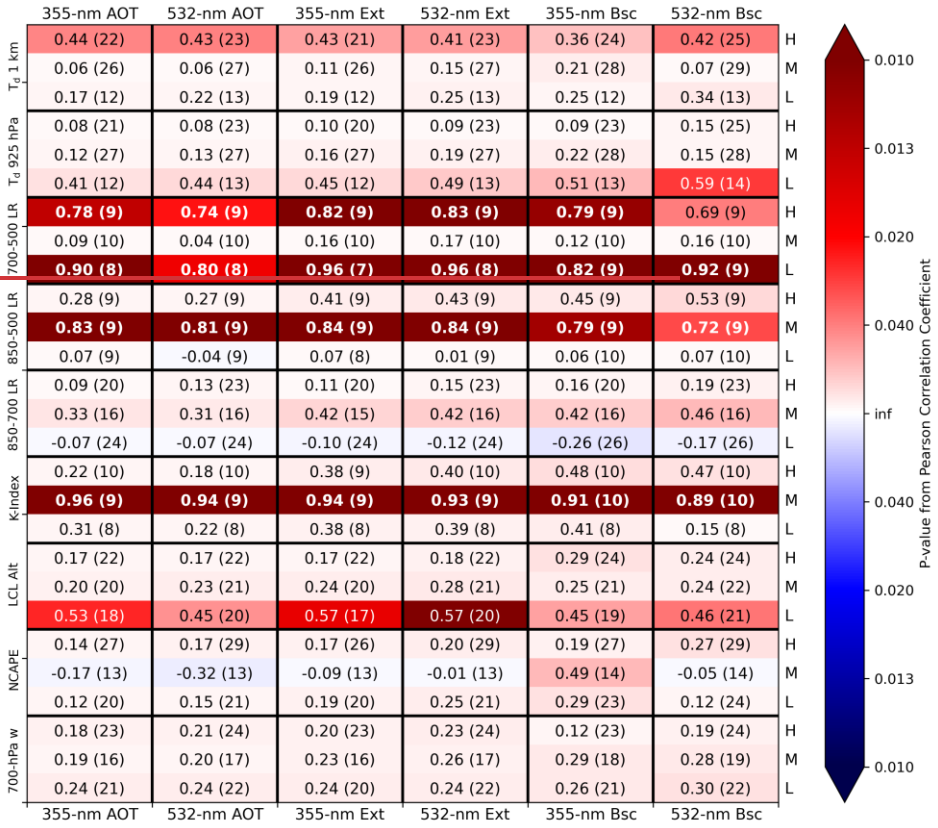
722 **Figure ~~6~~5: As in Fig. 3, but these are scatterplots of p95 APR-3 Ku-band composite Z_H (top row) and the number of APR-3 Ku-band composite Z_H pixels ≥ 30 dBZ (bottom row) compared against the mean value of the HSRL2** 724 **parameter listed in the title of each plot. The AVAPS parameter used to stratify the environments is also listed in the title of each plot.**

726 Comparing $Z_{95,Ku}$ with Bsc_{532} when binned by $NCAPE_{mod}$ (Fig. 5b), a positive correlation between $Z_{95,Ku}$ and Bsc_{532} was present for the low $NCAPE_{mod}$ group, which matches expectations. However, the negative correlations for the 728 medium and high $NCAPE_{mod}$ groups were interesting to see and seem to have been influenced by the Bsc_{532} values > 2 Mm^{-1} sr^{-1}, all of which were associated with $Z_{95,Ku}$ < 50 dBZ. The scattered data points with Bsc_{532} < 2 Mm^{-1} sr^{-1} 730 across the observed range of $Z_{95,Ku}$ indicates some inconclusiveness with these results, as higher $Z_{95,Ku}$ was not

necessarily observed with higher Bsc_{532}. As noted previously, these comparisons would benefit from additional analyses using a larger sample size that incorporates satellite and/or modeling data throughout the study domain.

Next, the number of APR-3 Ku-band composite Z_H pixels ≥ 30 dBZ (i.e., $Pixels_{Ku}$) was used as the convective parameter (Fig. 6). Several more strongly positive and statistically significant correlations were present compared to Figs. 2 and 4, likely due to $Pixels_{Ku}$ focusing on the abundance of convection rather than a peak value in a given scene. The strongest positive correlations with a statistically significant p-value were found between $Pixels_{Ku}$ and lapse rate, K-Index, and LCL~~.~~, which suggest some potentially interesting trends that warrant further exploration. However, considerable variability in the results can be seen across Fig. 6 as evidenced by the presence of many fairly weak correlations with limited statistical significance. Some correlations varied considerably depending on which aerosol parameter was examined (e.g., correlations with AOT_{532} were moderately negative in the low $LR_{850\text{-}500}$ group but correlations with Bsc_{355} were moderately positive in the same group). Several factors contribute to these differences and, as discussed previously, are difficult to account for entirely. Given their statistical significance, the decision was made to examine the relatively strong correlations between $Pixels_{Ku}$ and ~~Ext_{532}~~Bsc_{355} within environments binned by ~~K-Index (Fig. 6c) and $LR_{850\text{-}500}$~~ LCL (Fig. ~~6d~~5c) and $LR_{850\text{-}500}$ (Fig. 5d). From Fig. ~~6c~~5c, most scenes featured at least one Ku-band composite Z_H observation ~~>~~≥ 30 dBZ, further indicating the precipitating clouds the P-3 passed

Formatted: Font color: Auto



~~Figure 7: As in Fig. 2 but using the number of APR-3 Ku-band composite Z_{Ku} pixels ≥ 30 dBZ as the convective parameter.~~

over during CAMP^{2}Ex. In Fig. ~~6c~~5c, with the available data, the general trend was an increase in $Pixels_{Ku}$ with increasing ~~Ext_{532} for all categories of K-Index. The general trend matches expectations that~~ Bsc_{355} for a higher ~~aerosol concentrations would be correlated with a general abundance of convection and the formation of fewer but larger raindrops in a given scene. Further, it seems that higher aerosol concentrations supported the development of convection in general within a given scene~~LCL, regardless of whether these APR-3 pixels were part of a single large convective storm or several individual ~~plume. However, it was also anticipated that the highest $Pixels_{Ku}$ would be associated with the highest K-Index values, which is generally not the case. This may be explained by the considerably small sample size in Fig. 6c, which limits the statistical significance of results obtained from Fig. 6c. The impact of the small sample size also causes the best-fit lines to be impacted by some of the outlier values, such as the data points in the medium and high K-Index group with $Pixels_{Ku}$ > 1500~~plumes. However, this trend appears to have been greatly

influenced by the two "high" values with $Pixels_{Ku}$ > 1500, which further suggests the limitations associated with using a relatively small dataset and would benefit from expansion in future work. The best-fit line for the low LCL group also appears to have been influenced by the $Pixels_{Ku}$ values > 1500. Mixed results from this comparison are further indicated by the highest aerosol concentration, around 20 Mm^{-1} sr^{-1}, being associated with a low value of $Pixels_{Ku}$, < 250.

~~Similar trends can be found when comparing $Pixels_{Ku}$ with Ext_{532} in environments binned by $LR_{850-500}$, particularly for the medium and high groups (Fig. 6d). That is, increased aerosol concentration was generally correlated with increased $Pixels_{Ku}$ for each of the environmental bins, suggesting the potential for the higher aerosol concentrations to yield larger raindrops throughout the scene. However, the correlation was only statistically significant for the medium group and was nearly zero for the low group. These results further indicate the impact of the small sample size on this comparison, but the statistical significance of the correlations for the medium group of $LR_{850-500}$ warrant further examination. As with the prior analyses, it must also be noted that correlation does not guarantee causation, and thus the statistically significant results would benefit from expanded analyses using a larger sample size.~~

When comparing $Pixels_{Ku}$ with Bsc_{355} in environments binned by $LR_{850-500}$, the limitations of the reduced sample size can be seen further, particularly for the low $LR_{850-500}$ group (Fig. 5d). Most notably, the correlation of 0.78 within the low group appears to be heavily influenced by the two data points with $Pixels_{Ku}$ > 1500. Thus, while a strong and statistically significant correlation exists between $Pixels_{Ku}$ and Bsc_{355} within environments of low $LR_{850-500}$, this relationship should be examined in more detail. This result was also unexpected, as greater conditional instability associated with higher lapse rates would generally indicate greater convective potential. In Fig. 5d, the results from the medium and high groups were scattered with $Pixels_{Ku}$ < 1100, and the highest aerosol concentrations were associated with some of the lowest $Pixels_{Ku}$ values. Despite the limited sample in Fig. 5d, it was interesting to see cases such as this where the convective parameter was maximized for relatively medium aerosol concentrations, which indicates the potential for a "Goldilocks" zone of aerosol concentration enhancing convection.

Lastly, DFR was used as the convective metric (Fig. ~~8~~7). As with $Z_{95,Ku}$ and unlike $Pixels_{Ku}$, DFR focuses on the intensity of a given convective storm rather than the overall abundance of convection. From Fig. ~~8, the most~~7, many statistically

Formatted: Font color: Black

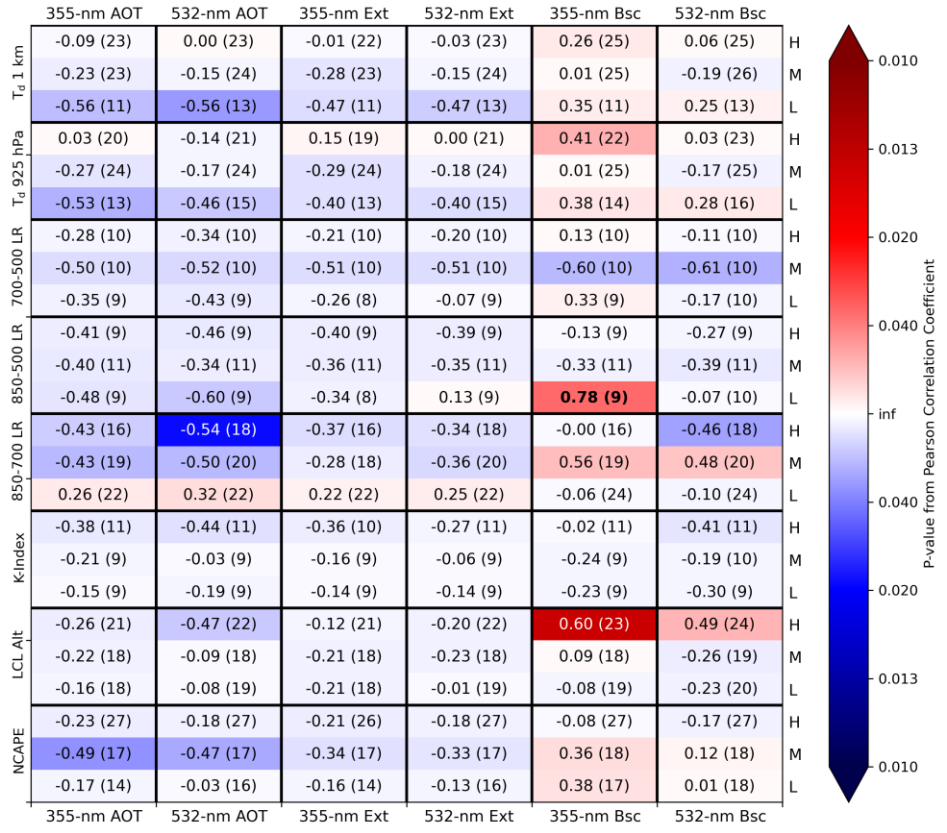


Figure 6: As in Fig. 2 but using the number of APR-3 Ku-band composite Z_H pixels ≥ 30 dBZ as the convective parameter.

significant and ~~strongest~~strong correlations were ~~found when binning the environments according to $NCAPE_{mod}$ and $LR_{850-700}$~~associated with several of the environmental parameters but, unexpectedly, were ~~typically in association with~~often found within low values of these environmental conditions. While there was greater presence of statistically significant positive correlations in Fig. 7 compared to some of the other correlation analyses in this study, many of the correlations were relatively weak and/or statistically insignificant in these DFR analyses as well. To provide a detailed example of a convective-aerosol pair wherein the correlations were relatively weak for all environmental thresholds, we examined DFR compared with Bsc_{355} when binned by $LR_{850-700}$ (Fig. 8a). That is, in Fig. 8a, all three environmental groups were associated with weakly negative or weakly positive correlations between $LR_{850-700}$ and Bsc_{355}. This resulted from most of the aerosol backscatter values falling within the range of 0–5 Mm^{-1} sr^{-1} while also covering

nearly the full range of (masked) DFR values observed (i.e., near 0 to 15). The few data points with Bsc_{355} > 5 Mm^{-1} sr^{-1} were mainly associated with DFR < 10, which contrasts our hypothesis that greater Ka-band

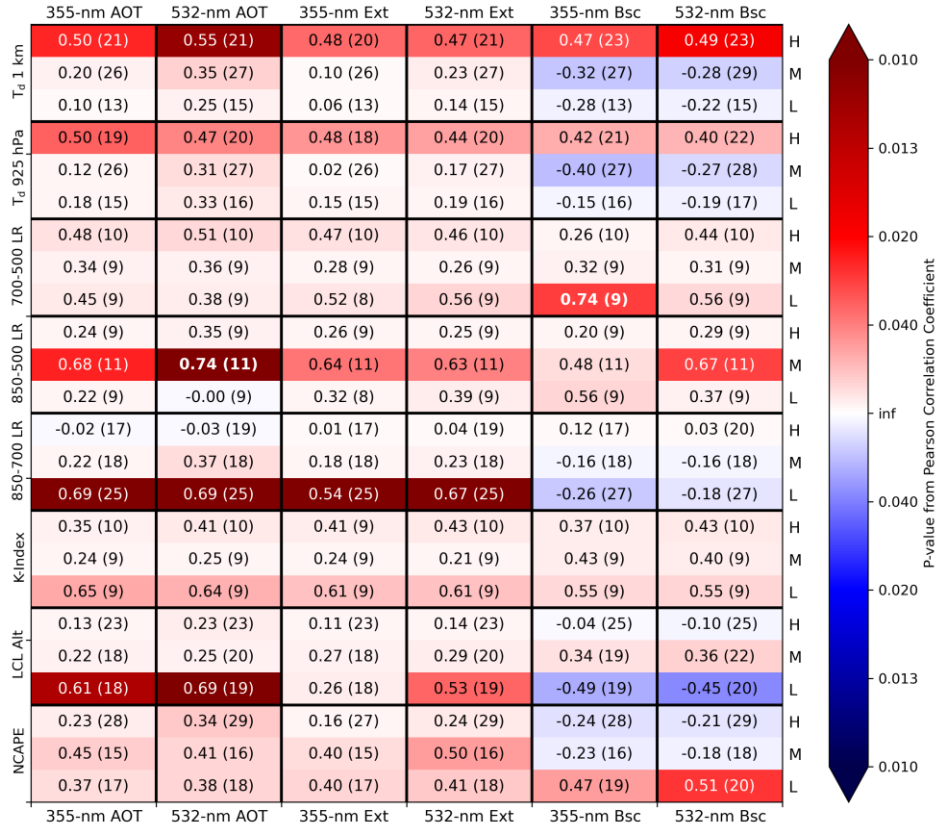

Figure 7: As in Fig. 2 but using p95 Ku-/Ka-band DFR as the convective parameter.

attenuation would be associated with higher aerosol concentrations. The clustering of Bsc_{355} between 2.5–5 Mm^{-1} sr^{-1} with DFR between 12 and 15 is interesting and is more closely in line with the anticipated increase in attenuation, which warrants further investigation especially given the relatively small number of data points within this cluster.

Due to the presence of ~~several~~ statistically significant correlations~~, these two environmental parameters were selected for a more in-depth analysis. In particular, DFR was compared~~ associated with Bsc_{532} when binned by $NCAPE_{mod}$, we also examined it in greater detail (Fig. 8b). Some similar trends can be seen in Fig. ~~$LR_{850-700}$ (Fig. 9a) and~~ 8b as in Fig. 8a, such as the negative correlations that occurred in scenes with medium values of the environmental parameter (i.e., $NCAPE_{mod}$ ~~(Fig. 9b). Examining Fig. 9a, all three environmental groups were associated with positive~~

Formatted: Font color: Auto

correlations between DFR and). This was largely due to the clustering of data points with Bsc_{532}, though these two parameters had essentially no correlation in of 0–2 Mm^{-1} sr^{-1} across the medium aerosol group.full range of DFR values while the highest Bsc_{532} values were associated with DFR < 10. The strongest and most statistically significant positive correlation was in association with the low $LR_{850-700}$ group; this was unexpected but, as seen in Table 2, these lapse rate values were still conditionally unstable and supportive of convection in the maritime tropics. The trend of increasing DFR with increasing aerosol concentration matcheswithin the low $NCAPE_{mod}$ group follows expectations that, as raindrops grow, the Ka-band APR-3 signal would become more attenuated and yield a higher DFR. It is also noteworthy that the highest DFR values > 30 dBZ (albeit a relatively limited sample size) were associated with relatively "medium" aerosol concentrations (i.e., Bsc_{532} of approximately 1.0–2.5 Mm^{-1} sr^{-1}). This matches the "Goldilocks" zone of medium aerosol concentration favoring enhanced convection (e.g., Sokolowsky et al., 2022). Given the potential presence of these "Goldilocks" conditions and the statistical significance within the low group in Fig. 9a, these trends warrant further investigation.

Some similar trends can be seen in Fig. 9b, where binning the environment by $NCAPE_{mod}$ yielded statistically significant correlations between DFR and Bsc_{532} within low $NCAPE_{mod}$ scenes. This statistical significance occurring in the low $NCAPE_{mod}$ group was unexpected but, as seen in Table 2, these $NCAPE_{mod}$ values were still associated with upward acceleration (i.e., conditions favoring enhanced convection). For each $NCAPE_{mod}$ group, higher aerosol concentrations were generally correlated with higher DFR values, suggesting conditions wherein raindrops may have grown large enough to significantly attenuate the Ka-band APR-3 signal. The "Goldilocks" zone of medium aerosol concentration with Bsc_{532} of approximately 1.0–2.5 Mm^{-1} sr^{-1} is present in Fig. 9b as well, indicating its persistence across different environmental binning techniques. Many of the DFR trends, including those examined in Fig. 9, were

Formatted: Font color: Auto

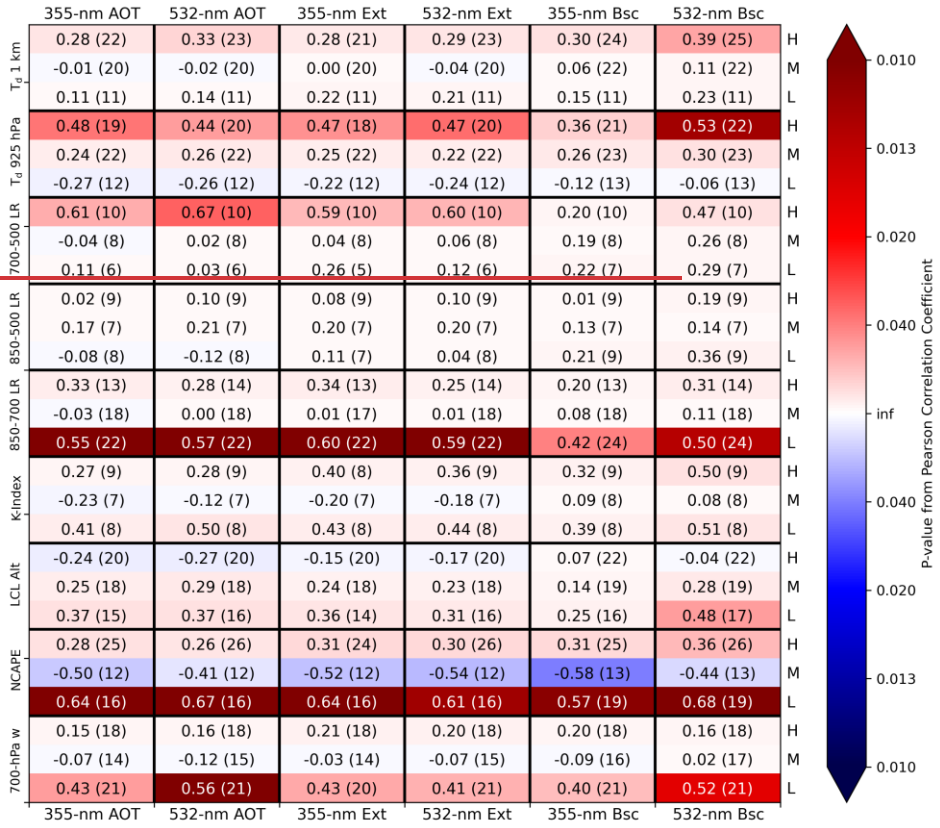

Figure 8: As in Fig. 2 but using p95 Ku-/Ka-band DFR as the convective parameter.

relatively consistent across the sensitivity tests (supplemental material), but other trends varied across the sensitivity tests and suggests that several of data points may have fallen at the edges of the values used to bin the environments.

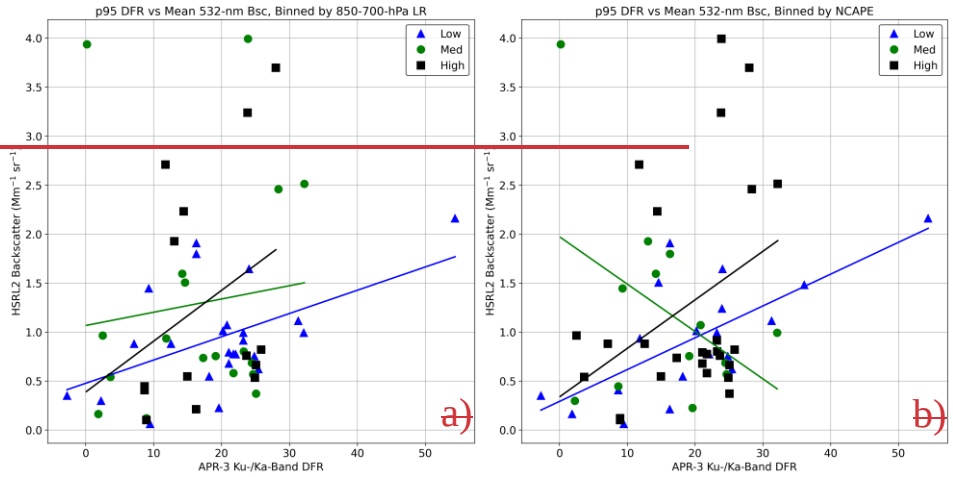
5.1. Summary, limitations, and future work

This study focused on examining potential impacts of aerosol concentration on maritime tropical convection using remote-sensing data in environmental contexts. Nine parameters from 92 AVAPS dropsondes across CAMP²Ex SFs 05–19 were used to stratify the environments: 700-hPa vertical velocity; modified CAPE; LCL altitude; K-Index; 850–700-, 850–500-, and 700–500-hPa temperature lapse rates; mean T_d below 1 km AGL; and mean T_d below 925 hPa. Each dropsonde launch time was associated with a corresponding APR-3 scan, whose file start and end times



greater attenuation would occur within stronger convection, but this comparison benefits from the relatively limited range of Bsc_{532} observed within the low $NCAPE_{mod}$ group (i.e., Bsc_{532}

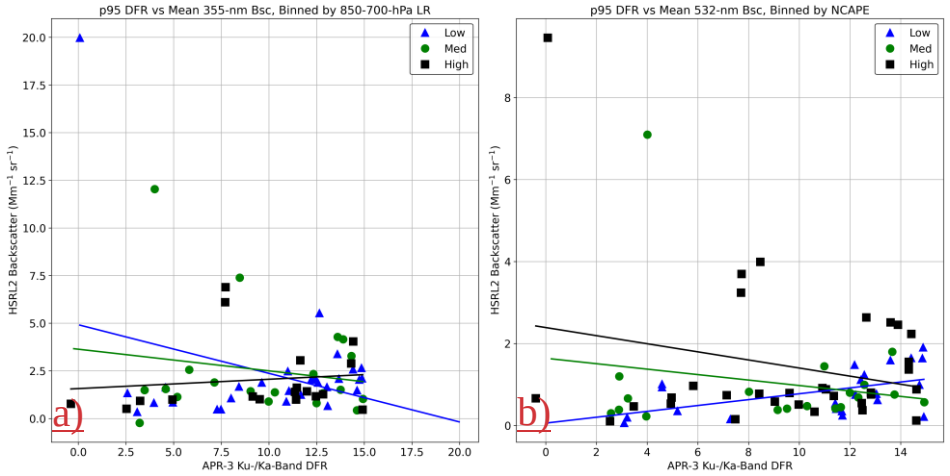


Figure ~~9~~8: As in Fig. 3, but these are scatterplots of p95 APR-3 Ku-/Ka-band DFR compared against the mean value of the HSRL2 parameter listed in the title of each plot. The AVAPS parameter used to stratify the environments is also listed in the title of each plot.

~~were used to develop a 10-minute "scene" for all comparisons associated with the given dropsonde.~~of 0–2 Mm^{-1} sr^{-1}). The trends in DFR compared to the aerosol parameters were also fairly consistent across the sensitivity tests (supplemental material).

5. Summary, limitations, and future work

This study focused on examining potential impacts of aerosol concentration on maritime tropical convection using remote-sensing data in environmental contexts. Eight parameters from 92 AVAPS dropsondes across CAMP^{2}Ex P-3 science flights 05–19 were used to stratify the environments: modified normalized CAPE; LCL altitude; K-Index; 850–700-, 850–500-, and 700–500-hPa temperature lapse rates; mean T_d below 1 km AGL; and mean T_d below 925 hPa. Each dropsonde was associated with a 10-minute "scene," ±5 minutes from its launch time, wherein all aerosol-convective comparisons were performed in relation to the given dropsonde-derived environment. Threshold values were selected to divide scenes into "low," "medium," and "high" groups based on each AVAPS parameter, and sensitivity testing examined four different sets of threshold values used for each stratification. Eight AMPR and APR-3 metrics related to convective intensity and/or prevalence were compared with HSRL2 backscatter, extinction, and AOT at 355 and 532 nm within the binned environments using Pearson correlation coefficients and their associated p-values. These convective parameters were: p95 of ~~AMPR CLW; p95 of~~ PCT at 10.7, 19.35, 37.1, and 85.5 GHz; p95 of AMPR CLW, p95 of APR-3 Ku-band composite Z_H; number of Ku-band composite Z_H pixels ≥ 30 dBZ; and Ku-/Ka-band DFR.

The correlations between the convective metrics and aerosol parameters varied depending on which convective metric was examined. ~~Largely because of masking regions of precipitation in its analysis, AMPR CLW and PCT$_{19}$ were often unexpectedly negatively correlated with aerosol concentration within each environmental group examined, including to a statistically significant degree in many cases. The masking of precipitation regions in~~During AMPR's CLW analyses ~~yielded,~~ several ~~unexpected~~ negative correlations ~~and~~were observed, likely owing at least in part to the precipitation masking and the presence of very low CLW values < 1 g m^{-2}, which limited the aerosol-convection conclusions that could be drawn solely based on AMPR CLW. This was mitigated when examining AMPR PCT$_{19}$, which includes precipitation regions and yielded several positive aerosol-convection correlations as expected~~, some of which had statistical significance.~~. Likewise, examining APR-3's $Z_{95,Ku}$, Pixels$_{Ku}$, and DFR yielded many positive correlations with aerosol concentration, including several with statistical significance. ~~While Pixels$_{Ku}$ was limited by a fairly small sample size in some cases, a trend of increasing Pixels$_{Ku}$ with increasing aerosol concentration could be seen in the scatterplots. The main feature of the $Z_{95,Ku}$ analysis was its relatively strong and statistically significant correlation with aerosol concentrations in environments with a low LCL, indicating a relatively high amount of low-level water vapor and supporting the idea raised in past studies that increased aerosol concentration may enhance convection within warm-phase regions. A standout result of the DFR analysis was~~Some of these strongest and most statistically significant correlations are potentially impactful and warrant exploration in future work. In particular, several noteworthy trends were observed when stratifying environments based on their temperature lapse rate or NCAPE$_{mod}$ which, among other environmental factors, suggests their importance to consider when examining aerosol-cloud effects. Some of the cases evaluated in more detail using scatterplots indicated the presence of a "Goldilocks" zone of medium aerosol concentration, suggesting that these medium values enhanced convection to a stronger degree than low or high aerosol concentrations in some cases, as ~~also observed in prior studies. Correlations between aerosol concentrations and the convective parameters occasionally became more highly positive and more statistically~~

~~significant, based on the associated p-value, as environmental conditions became more favorable for convection overall, which matches our hypotheses~~observed in prior studies, while higher aerosol concentrations were associated with stronger convection in other cases, which matches our hypotheses. Many trends were also consistent across the sensitivity tests we employed. However, the results generally remain inconclusive as a result of widespread cases for each aerosol-convective analysis where the correlations within many of the environmental bins were weak and/or had limited statistical significance. This results largely from limitations in the sample used and limitations in the methods used to examine these observed data. The inconclusive results also highlight the difficulties in separating aerosol effects from environmental influences when solely using observational data.

These results are important as they highlight some potentially impactful correlations between convective parameters and aerosol concentrations in the maritime tropics, including some instances where medium-to-high aerosol concentrations appeared supportive of convective invigoration~~.~~, while also demonstrating significant difficulties in separating environmental effects from aerosol effects. However, as noted throughout the manuscript, correlation does not necessarily indicate causation. Because of this, correlations highlighted in this study serve to identify potentially interesting and impactful trends that warrant a more in-depth exploration in future work, rather than providing solid definitive conclusions on their own. ~~Our results also stress the importance of considering environmental conditions alongside aerosol concentrations when evaluating impacts on convection.~~ Further, the correlation tables presented in this manuscript, including those in supplemental material, provide a wide range of information that is applicable to broader applications (e.g., a future study that might explore the impacts of low-level T_d or mid-level lapse rates on tropical convection).

Formatted: Font: Italic

Formatted: Font: Italic, Subscript

While many results were encouraging, several limitations must be considered. Dropsondes launched when the P-3 was above 500 hPa were relatively limited, reducing the sample size for all associated environmental parameters. Other limitations in the dataset, such as the P-3 avoiding the most intense convection during a given flight and environmental modification from nearby convection, impacted the results. There was some ambiguity regarding whether an increase in $Pixels_{Ku}$ was associated with a single updraft or multiple updrafts, which have different implications for convective intensity and prevalence. Lastly, while many correlations were strong and encouraging, they do not necessarily prove a cause-and-effect situation for their respective comparison, as previously discussed. Thus, it is not possible to say with certainty that increased aerosol concentrations enhanced convection in these CAMP^{2}Ex scenes solely based on the correlations presented in this study, but rather the data suggest the possibility for aerosol enhancement of convection and further analyses would increase confidence in these results.

Given the ~~encouraging~~intriguing nature of ~~many~~some comparisons in this study, while also considering the above limitations, future work would greatly benefit these science questions. Future efforts could look at addressing the limitations above, such as using an advanced Z_H attenuation-correction method~~,~~ and distinguishing areas where $Pixels_{Ku}$ were adjacent or separated~~, and employing~~. Employing other datasets from the P-3 and Learjet-35 aircraft, in addition to incorporating numerical simulations, may increase the reliability of the strongest correlations observed.

~~Peak 30-dBZ Z_H contour height in a storm should be considered given its direct relation~~While our study sought to ~~updraft magnitude (e.g., emphasize data from the P-3 aircraft, other~~~~Straka et al., 2000; Amiot et al., 2019). Other~~ remote-sensing data (e.g., satellite) may help with assessing nearby convection just outside of the P-3 observation range. Other convective metrics could supplement those selected for this study, such as peak 30-dBZ Z_H contour height in a storm given its direct relation to updraft magnitude (e.g., Straka et al., 2000; Amiot et al., 2019). ~~Additional~~Likewise, additional environmental parameters, such as wet-bulb potential temperature profiles (Williams and Renno, 1993), would be useful to examine. ~~Other~~We focused on aerosol concentrations given their significant influence on cloud particle size distributions (all else being equal), but other aerosol properties (e.g., type, composition, and hygroscopicity) and their vertical location/distribution may also be helpful to consider~~. Examining~~, as would direct computation of updraft vertical velocity. Lastly, as one of the main takeaways from this manuscript, examining some of the most-significant convective-aerosol correlations in greater detail would ~~also~~ be of significant benefit~~, as would separating the scenes according to the type of convection observed (e.g., shallow versus congestus).~~.

Data availability

The AMPR, APR-3, AVAPS, and HSRL2 data are available on the NASA Langley Research Center's Airborne Science Data for Atmospheric Composition repository at https://www-air.larc.nasa.gov/cgi-bin/ArcView/camp2ex, cited herein as Aknan and Chen (2020). ~~The objective~~Objective selections of threshold values for environmental stratification were performed using Python's NumPy nanpercentile function~~ (Harris et al.,~~, and the random data sampling during the bootstrapping approach was accomplished using Python's NumPy random.choice function (Harris et al., 2020). Pearson correlation coefficients and p-values were calculated using Python's SciPy pearsonr function (Virtanen et al., 2020). Several of the environmental parameters were calculated using Python's MetPy package (May et al., 2022), including the mixed_layer_cape_cin function for $CAPE_{mod}$, the calc.lcl function for LCL altitude, and SkewT function for producing the dropsonde image in Fig. 1.

Author contributions

CGA performed all primary analyses and wrote the manuscript with feedback and contributions from all co-authors. TJL supervised the study, served as AMPR Principal Investigator (PI), and assisted with refining the methods and interpreting results. CGA and TJL processed the AMPR data. SCvdH ~~and RAF~~ served as PI for AVAPS~~ and~~, while RAF and CAH served as co-PIs for HSRL2~~, respectively~~. OOS processed the APR-3 data. SCvdH, RAF, OOS, LDC, SAC, and JRM assisted with refining the methods and interpreting results. SWF and GAS processed the AVAPS data. ~~CAH processed the HSRL2 data.~~ ST served as APR-3 PI.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

We are grateful to Hal Maring for financial support throughout the CAMP^{2}Ex deployment and data analyses, and to Jeff Reid for managing the CAMP^{2}Ex mission. We would also like to thank Wojciech Grabowski and ~~one~~an anonymous reviewer for their insightful comments and suggestions that helped improve this manuscript.

Financial support

CGA acknowledges funding from NASA Marshall Space Flight Center through Cooperative Agreement 80MSFC22M0001 with The University of Alabama in Huntsville. CGA's research was further supported by an appointment to the NASA Postdoctoral Program at NASA Marshall Space Flight Center, administered by Oak Ridge Associated Universities under contract with NASA, through contract 80HQTR21CA005.
