Text S1. Determination of primary and secondary organic carbon.

The concentrations of primary organic carbon (POC) and secondary organic carbon (SOC) are estimated by the EC-tracer method as follows,

$$\text{SOC} = \text{OC} - \text{EC} \times (\text{OC}/\text{EC})_{\min} \quad (\text{S1})$$

$$\text{POC} = \text{OC} - \text{SOC} \quad (\text{S2})$$

where $(\text{OC}/\text{EC})_{\min}$ is the minimum OC/EC ratio during the sampling period at each site.

Text S2. Calculation of light absorption parameters.

The light absorption coefficient (Abs_{λ} , Mm^{-1}) of WSOC at the wavelength λ is calculated as follows,

$$\text{Abs}_{\lambda} = (A_{\lambda} - A_{700}) \times \frac{V_1}{V_a \times L} \times \ln(10) \quad (\text{S3})$$

where V_1 (mL) is the volume of the water extracts, V_a (m^3) is the air volume corresponding to the extracted sample filter, and L is the optical path length (1 m in this study). A_{λ} is the absorbance at wavelength λ measured by the spectrophotometer. A_{700} is chosen to reduce the effects of baseline drift and $\ln(10)$ is used to convert the absorption coefficient from log base 10 to natural logarithm. In this study, Abs_{365} is chosen as a proxy for the absorbance of WS-BrC to exclude the interferences of other substances (e.g., nitrate, etc.) (Hecobian et al., 2010).

The mass absorption efficiency (MAE, $\text{m}^2 \cdot \text{g}^{-1}$) of WSOC is calculated as follows,

$$\text{MAE}_{\lambda} = \frac{\text{Abs}_{\lambda}}{C_{\text{WSOC}}} \quad (\text{S4})$$

where C_{WSOC} ($\mu\text{g} \cdot \text{m}^{-3}$) represents the mass concentration of WSOC.

The wavelength dependence of light absorption fits a power law as follows,

$$\text{Abs}_{\lambda} = K \times \lambda^{-\text{AAE}} \quad (\text{S5})$$

where K is a constant related to light absorption and AAE is the absorption Ångström exponent used to characterize the wavelength dependence of WSOC light absorption. In this study, AAE is fitted over the wavelengths of 330-400 nm.

The imaginary part (k) of the particle refractive index ($m = n + ik$) is an important parameter that evaluates the light-absorbing efficiency of aerosols. In this study, we calculate the k_{405} using equation S6 and used $\text{Log}_{10}(\text{MAE}_{405})$ vs. AAE to classify different light-absorbing BrC (Saleh, 2020). To unify and facilitate comparison, the MAE_{365} values reported in previous studies are converted to MAE_{405} by the following equations (Liu et al., 2013; Saleh, 2020),

$$k_{\lambda} = \frac{\text{MAE}_{\lambda} \times \lambda \times \rho}{4\pi} \quad (\text{S6})$$

$$k_{365} = k_{\lambda} \left(\frac{\lambda}{365} \right)^w \quad (\text{S7})$$

$$w = \text{AAE} - 1 \quad (\text{S8})$$

where ρ is particle density and assign as $1.5 \text{ g} \cdot \text{cm}^{-3}$ in this study.

55 Text S3. Estimation of direct radiative effect of water-soluble brown carbon.

Simple forcing efficiency (SFE) represents the energy added to the Earth-atmosphere system by a given mass of particles (Bond and Bergstrom, 2006). In this study, $dSFE(\lambda)/d\lambda$ ($W \cdot m^{-2} \cdot nm^{-1}$) and integrated SFE ($W \cdot g^{-1}$, 300-400 nm and 300-700 nm) are calculated by following equations to estimate the direct radiative forcing of water-soluble brown carbon (Chen and Bond, 2010),

$$60 \quad \frac{dSFE}{d\lambda} = -\frac{1}{4} \frac{dS(\lambda)}{d\lambda} \tau_{atm}^2(\lambda) (1 - F_c) [2(1 - \alpha_s)^2 \beta(\lambda) MAE(\lambda) - 4\alpha_s MAE(\lambda)] \quad (S9)$$

$$SFE = \int_{\lambda} \frac{dS(\lambda)}{d\lambda} \tau_{atm}^2(\lambda) (1 - F_c) \alpha_s MAE(\lambda) d\lambda \quad (S10)$$

where $dS(\lambda)/d\lambda$ is the solar irradiance ($W \cdot m^{-2} \cdot nm^{-1}$) obtained from the ASTM G173-03 reference spectra, τ_{atm} is the atmospheric transmission (0.79), F_c is the cloud fraction (0.6), α_s is the surface albedo (average 0.19), β is the backscatter fraction, MAE is the mass absorption efficiency of WSOC, respectively. It should be noted that only light absorption is considered and therefore
65 $\beta = 0$ in the calculation in this study.

Text S4. Light absorption spectra resolved by positive matrix factorization (PMF) model.

The positive matrix factorization (PMF) model is performed on the light absorption spectra of WSOC using the EPA PMF method (version 5.0). The rationale and detailed descriptions can be found in the PMF 5.0 Fundamentals and User Guide on the EPA website (<https://www.epa.gov/air-research/epa-positive-matrix-factorization-50-fundamentals-and-user-guide>). In
70 this study, absorbance data in the wavelength range of 250 to 400 nm (interval 5 nm) and corresponding uncertainties are included in the PMF analysis. The absorbance data below the method detection limit (MDL, 1.0 mAu in this study) are replaced by 1/2 MDL (Li et al., 2023b). The uncertainty (Unc) is calculated according to the following equations when the absorbance \leq MDL (equation S11) and the absorbance $>$ MDL (equation S12), respectively,

$$Unc = 5/6 \text{ MDL} \quad (S11)$$

$$75 \quad Unc = \sqrt{(\text{Error Fraction} \times \text{absorbance})^2 + (0.5 \times \text{MDL})^2} \quad (S12)$$

where the error fraction is set as 0.2 in this study.

In this study, the sampling sites are classified into east China sites (QD, NJ, SH, TS) and outside east China sites (TJ, HD, XA, CD, CQ, HS) according to their distribution areas. Additionally, the absorption spectra have obvious regional characteristics, with the absorption spectra at outside east China sites showing obvious absorption peaks at 265 and 300 nm, while these
80 absorption peaks do not exist at east China sites (see Figure 5). PMF analysis is conducted on the absorbance datasets collected in two regions of China separately. Finally, four and three factors are resolved for east China sites and outside east China sites, respectively (see Figure S8).

Text S5. PARAFAC analysis and calculation of fluorescence parameters.

All the excitation emission matrices (EEMs) data are normalized by the water Raman peak area ($E_x = 350$ nm, $E_m = 385-410$ nm) and the data are ultimately presented in Raman units (RU) (Lawaetz and Stedmon, 2009). Parallel factor analysis (PARAFAC) with the non-negativity constraint of Raman normalized EEMs data is performed using the DOMFluor toolbox (v 1.7) in MATLAB R2020a to identify the potential fluorophores (Stedmon and Bro, 2008). Besides, fluorescent indices are calculated to provide source and structure information of atmospheric organic aerosols. The fluorescence index (FI), biological index (BIX) and humidification index (HIX) are determined according to the following equations (Wu et al., 2021), respectively.

$$FI = \frac{F(E_x = 370 \text{ nm}, E_m = 450 \text{ nm})}{F(E_x = 370 \text{ nm}, E_m = 500 \text{ nm})} \quad (\text{S13})$$

$$BIX = \frac{F(E_x = 310 \text{ nm}, E_m = 380 \text{ nm})}{F(E_x = 310 \text{ nm}, E_m = 430 \text{ nm})} \quad (\text{S14})$$

$$HIX = \frac{F(E_x = 255 \text{ nm}, E_m = 435-480 \text{ nm})}{F(E_x = 255 \text{ nm}, E_m = 300-345 \text{ nm})} \quad (\text{S15})$$

It should be noted that FI (BIX) refers to the ratio of emission intensity of 450 and 500 nm (380 and 430 nm) at $E_x = 370$ nm (310 nm), while HIX is calculated with the integrated intensity over the wavelength range of 435-480 nm and 300-345 nm at $E_x = 255$ nm. In this study, these fluorescent indices are calculated by the EFC software (v 1.2) (Bro, 1997; He and Hur, 2015; Murphy et al., 2010; Stedmon and Bro, 2008; Zepp et al., 2004).

Moreover, the total fluorescence volume (TFV; $\text{RU}\cdot\text{nm}^2$) and fluorescence volume (FV; $\text{RU}\cdot\text{nm}^2$) of each fluorophore are calculated by integrating the Raman normalized EEMs data in MATLAB R2020a.

100 **Text S6. Methods for extreme gradient boosting (XGBoost).**

The extreme gradient boosting (XGBoost) model is a gradient-boosting-based ensemble algorithm that improves traditional techniques with remarkable attributes, including efficiency, precision, stability, and scalability (Li et al., 2024). In this study, XGBoost is used to evaluate the contribution of conventional air pollutants (CO , SO_2 , O_3 , NO_2) and fluorescent components to the light absorption coefficient (Abs_{365}). The national air quality data comes from the real-time release platform of the China Environmental Monitoring Station for urban air quality nationwide (<https://quotsoft.net/air/>). To further quantify the contributions of the target factors, the SHAP algorithm is introduced, which evaluates the feature contributions based on the marginal contributions of individuals in cooperative games (Li et al., 2024). The main formulas as following,

$$f(x) = \varphi_0(f, x) + \sum_{i=1}^k \varphi_i(f, x) \quad (\text{S16})$$

$$\varphi_i(f, x) = \sum_{S \subseteq F \setminus \{i\}} \frac{|S|!(k-|S|-1)!}{k!} (f_x(S \cup \{i\}) - f_x(S)) \quad (\text{S17})$$

110 where $\varphi_0(f, x)$ denotes the expected value of the light absorption coefficient predicted by the model on the training set. k is the

number of factors influencing the model. $\phi_i(f, x)$ can be interpreted as the impact of the i -th factor on the prediction of the model when given an input x .

All operations are performed in Python 3.10 using Jupyter as an integrated coding environment. The following Python packages are used in this study: *scikit-learn* provides a standard interface for implementing machine learning algorithms, 115 *pandas* and *NumPy* for data analysis process, *BayesSearchCV* for parameter optimization, *matplotlib* for data visualization, and *SHAP* for sensitivity analysis (Li et al., 2024).

Table S1. Summary of the sampling information.

Sites	Location	Region	Sampling period	Sample size	Sampling duration	Sampler	Filter
Tianjin (TJ)	39.11°N, 117.19°E	north China	2019/11/29 to 2020/01/06	41	23.5 h	medium-volume (100 L min ⁻¹) sampler (TH-150A, Wuhan Tianhong, China)	QMA, Φ90 mm, (Whatman, USA)
