Abstract. This study focuses on quantifying the conditional relationship between aerosol and convective precipitation properties of isolated deep convective clouds (DCCs) in the Houston-Galveston region, after adjusting for confounding effects. We leverage comprehensive ground-based observations from the TRacking Aerosol Convection interactions ExpeRiment (TRACER) to estimate aerosol effects on convective echo top height (ETH), intensity, and area separately. Our results show that greater aerosol number concentrations generally have a limited impact on these convective properties, showing relationships consistent with the possibility of both invigoration and suppression effects. Under certain conditions, where ultrafine particles are abundant, aerosols exhibit a positive effect on ETH, increasing it by about 1 km. However, it is inevitable to consider measurement uncertainties and the limitations of temporal and spatial resolution in the data, as these factors can further contribute to uncertainties in our estimates. In DCCs associated with sea breezes, the estimated aerosol effects on DCCs are found to be more pronounced. However, this heightened effect could be attributed to the exclusion of key confounders such as boundary layer updrafts in the analysis.

1 Introduction

Deep convective clouds (DCCs) play a crucial role in the Earth's water cycle, as they generate a significant amount of global precipitation (e.g., Tan et al., 2015; Feng et al., 2016), regulate the global energy cycle through latent heat release (e.g., Tao et al., 2010), and vertical mass transport (e.g., Wang et al., 2019; Gupta et al., 2024), thereby driving large-scale atmospheric circulations that impact climate sensitivity (e.g., Sanderson et al., 2008; Del Genio, 2012). Despite their significance for weather

and climate, accurately simulating DCCs in state-of-the-art numerical models remains challenging (e.g., Wang et al., 2020a; Prein et al., 2021; Wang et al., 2022b). Even fundamental convective characteristics such as updraft strength, cloud top height, and anvil mass detrainment, and the variations of these attributes over the diurnal cycle are difficult to simulate (e.g., Moncrieff, 2010; Bony et al., 2016). While field campaign data analyses have provided valuable insights into DCC processes (e.g., Polavarapu and Austin, 1979; Dye et al., 2000; Long et al., 2011; Chi et al., 2014; Barth et al., 2015; Jensen et al., 2016; Martin et al., 2017; Geerts et al., 2017; Varble et al., 2021; van den Heever et al., 2021; Jensen et al., 2022; Reid et al., 2023; Kollias et al., 2024), conventional model-observational validations mostly rely on bulk precipitation characteristics and/or sparse cloud dynamics observations from a small set of cases, thus offering only a limited understanding of the processes involved. Furthermore, case studies, by their nature, are confined to specific geographical regions, restricting model assessments to specific environmental forcing conditions (e.g., Prein et al., 2022; Ramos-Valle et al., 2023).

Aerosol–cloud interactions in DCCs, particularly the aerosol effects on convective dynamics, the focus of this study, are among the most complex and challenging processes to simulate accurately. This difficulty was evidenced in a recent model intercomparison project (MIP) conducted by the Deep Convective Cloud Working Group of the Aerosol, Cloud, Precipitation and Climate (ACPC) initiative. This MIP was the first of its kind to assess the range of DCC sensitivity to aerosol loading across a suite of state-of-the-art convective system resolving models (van den Heever et al., 2018). Analysis of this suite of simulations conducted by Marinescu et al. (2021) focused on aerosol-induced changes to the terms in the vertical velocity momentum equation under prescribed low and high number concentrations of cloud condensation nuclei (CCN) for a DCC case. This study showed substantial variability among the models in terms of the precipitation amount and updraft velocity and their sensitivity to aerosol loading. The significant differences among the various models highlight an urgent need to resolve the lack of convergence in aerosol-DCC interaction process representations within such high-resolution modeling frameworks.

Numerous studies have aimed to shed light on the complex nature of aerosol-DCC interactions, towards improving their representations in the models, sparking the description of several different underlying physical mechanisms (e.g., Andreae et al., 2004; Khain et al., 2005; van den Heever et al., 2006; Rosenfeld et al., 2008; Lebo and Seinfeld, 2011; Li et al., 2011; Fan et al., 2018; Nishant et al., 2019; Grabowski and Morrison, 2020; Abbott and Cronin, 2021). The leading mechanisms include: (1) "cold-phase" invigoration, where high aerosol number concentrations, acting as CCN, nucleate more cloud droplets delaying hydrometeor growth via reduced collision-coalescence, lofting more liquid water above the freezing level, enhancing the total latent heating associated with freezing, increasing the buoyancy of rising convective parcels and ultimately invigorating convective updrafts (e.g., Khain et al., 2005; van den Heever et al., 2006; Rosenfeld et al., 2008); (2) "warm-phase" invigoration, where high aerosol number concentrations nucleate more cloud droplets and reduce supersaturation with respect to liquid water, increasing latent heat release through additional condensation of water vapor, and invigorating convective updrafts (e.g., Lebo, 2018; Fan et al., 2018, 2020); and (3) "humidity-entrainment" invigoration, where high aerosol number concentrations increase the environmental humidity by producing clouds that detrain more condensed water into the surrounding air, leading to higher humidity that favors large-scale ascent and stronger convective updrafts (Abbott and Cronin, 2021). This wide range of plausible mechanisms highlights the need for constraining this important problem with current observations. The lack of clear

55 understanding further underscores the need for more robust and high-resolution observational data along with the development of advanced statistical methods and modeling frameworks that can better elucidate the complexity of aerosol-DCC interactions.

Despite a range of hypothetical mechanisms for aerosol-DCC invigoration, recent studies continue to challenge these theories, revealing a spectrum ranging from enervation to invigoration (e.g., Grabowski and Morrison, 2020; Igel and van den Heever, 2021; Dagan, 2022; Romps et al., 2023; Peters et al., 2023). From an observational perspective, this challenge arises, 60 in part, from a lack of key supporting observations of vertical velocity, hydrometeor microphysical properties, and water vapor supersaturation within the convective core regions of DCCs, all of which would assist to provide further clarity on aerosol-DCC interactions. Moreover, the thermodynamic and kinematic regimes under which these interactions may be significant remain unresolved. Quantifying aerosol impacts on DCCs is further complicated because small-scale perturbations in large-scale vertical velocity, relative humidity, and other meteorological factors, such as wind shear and atmospheric instability, can potentially 65 affect DCC intensity in a manner comparable to aerosol-induced changes (e.g., Fan et al., 2009; Storer et al., 2010; Grant and van den Heever, 2015; Lebo, 2018; Dagan et al., 2020; Park and van den Heever, 2022). Disentangling aerosol impacts on DCCs from those driven by meteorological factors is therefore difficult (e.g., Varble et al., 2023).

To accurately assess the relationships between aerosol and DCC properties, a variety of techniques and methods have been developed from both modeling and observational perspectives. On the modeling side, a range of statistical methods and modeling frameworks have been established, including the simple factor separation approach (van den Heever and Cotton, 2007; 70 Grant and van den Heever, 2014), more sophisticated statistical emulators (Lee et al., 2011; Johnson et al., 2015; Wellmann et al., 2018; Park and van den Heever, 2022), and the piggybacking approach (Grabowski, 2015). These techniques have achieved some success in separating aerosol effects from the impacts of other forcing factors on DCC development. Though individual modeling studies have quantified aerosol effects on DCCs, it is important to note that there remains significant 75 disagreement between these studies, even in the sign of the effects, largely due to variations in model configurations and the methods used to analyze them (Varble et al., 2023). From the observational side, achieving this separation remains a long-standing challenge. Many observational studies have used multivariable models or machine learning approaches to quantify the relationships between aerosol and DCC interactions (e.g., Li et al., 2011; Storer et al., 2014; Veals et al., 2022; Zang et al., 2023). However, it is important to emphasize that properly selecting and accounting for meteorological covariates or confounders is key to successfully estimating the changes in DCCs that are solely due to aerosol impacts. Furthermore, it is vital 80 to employ comprehensive, high-resolution observations of DCCs and aerosols to capture these intertwined physical processes and identify potential "fingerprints" of aerosol-DCC invigoration.

This study presents a statistical investigation into the aerosol-DCC interactions using comprehensive ground-based observational datasets. The datasets were collected during the TRacking Aerosol Convection interactions ExpeRiment (TRACER; 85 Jensen et al., 2023) in Houston-Galveston, operated by the U.S. Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Facility (Mather and Voyles, 2013). We focus on DCCs occurring during the summer months in 2022 from June to September, the TRACER Intensive Operational Period (IOP). During the IOP, detailed measurements of cloud, aerosol and thermodynamic profiles are available and the synoptic conditions show less variation compared to other seasons. We employ a Self-Organizing Map (SOM) approach (Kohonen, 1990) to identify the major synoptic regimes conducive to the formation of

90 isolated DCCs. By performing our analysis on cases within the same synoptic regime, we minimize the impact of large-scale ascent on the convective properties (Wang et al., 2022a). Multiple linear regression (MLR) is then used to estimate the aerosol effects on DCC properties, with the inclusion of essential covariates in the analysis.

2 Instrumentation and Datasets

2.1 DCC properties

95 As the first step in the investigation, we employ a Lagrangian framework to detect the formation and propagation of DCC rainfall cores and quantify their convective characteristics throughout their lifecycle. The term "DCC rainfall cores" typically refers to the convective regions in DCCs with heavy rainfall rates at the surface with a maximum value exceeding 10 mm/hr (e.g., Wang et al., 2018; Zhang et al., 2021). The maximum height of these cores can serve as a proxy for the maximum updraft velocity, as it is related to the ability of convective updrafts to lift large hydrometeors to higher altitudes, signifying deeper con-
100 vective systems (e.g., Heymsfield et al., 2010; Liu and Zipser, 2013; Guo et al., 2018). Note that this simplified representation neglects impacts aerosols may have on cloud microphysical processes (e.g., collision-coalescence, riming), which will, in turn, affect radar reflectivity and, consequently, the DCC echo top height (ETH). Quantifying such influence is challenging in the absence of in-situ observations of the cloud microphysical and dynamical properties (e.g., hydrometeor phase/size distribution, updraft velocity). The reliance on this proxy also stems from the lack of direct measurements of convective vertical velocity
105 for DCCs investigated here, a significant limitation not only for this study but also for many previous observational studies. Nevertheless, using ETH as a proxy allows for comparison of our findings with prior studies, which is valuable for the scientific community and for providing modeling constraints on simulations of the aerosol-DCC interactions.

More specifically, we tracked the trajectory of DCC rainfall cores using TINT (TINT Is Not TITAN [Thunderstorm Identification, Tracking Analysis and Nowcasting; Dixon and Wiener, 1993), a convective cell tracking algorithm developed by
110 Raut et al. (2021). Building upon our prior research (Wang et al., 2024), we have effectively used this algorithm to analyze the level-II data (NOAA, 1991) from the S-band Doppler weather radar KHGX-Houston at 1-km horizontal resolution within a domain of $400 \text{ km} \times 400 \text{ km}$ centered around the radar location. As a result, we have generated a comprehensive tracked DCC rainfall core dataset for the TRACER IOP during the summer of 2022 (Wang et al., 2024).

In that study and the current one, DCC rainfall cores are defined using radar observations as contiguous areas where the
115 2-km radar reflectivity (Z) is greater than 10 dBZ, the lower limit for rain echo detection by NEXRAD radar systems, and the maximum 2-km Z value exceeds 40 dBZ (Anagnostou, 2004; Moroda et al., 2021). Note that different reflectivity thresholds varying from 30 to 40 dBZ have been selected for studying DCC convective cores in various climate conditions, depending on the objectives of the studies (e.g., Giangrande et al., 2023; Gupta et al., 2024). Additionally, these cores must exhibit a 30-dBZ ETH exceeding 5 km above ground level at some point during their lifetime to exclude shallow convective cells, aligning with
120 a similar definition used by Dixon and Wiener (1993). Further details regarding additional criteria for identifying and tracking these rainfall cores can be found in Texts S1 and S3 in the supporting information and in Wang et al. (2024). Note that using

fixed thresholds may potentially influence the selection of DCCs investigated in the study, particularly in conditions where DCCs contain fewer raindrops due to the presence of a large number of background aerosols.

The first identification of the DCC rainfall core using the tracking algorithm is designated as the initiation of surface rainfall associated with the DCC core. The tracking algorithm can no longer identify the core once the DCC ceases to produce moderate precipitation (maximum 2-km $Z < 40$ dBZ), marking the termination of the convective stage. In other words, the tracked lifetime of the cores excludes the early initiation stage of non-precipitating cumulus clouds, the dissipation stage of non-precipitating anvil clouds, and the lightly precipitating periods during either stage. Table 1 details the number of DCC rainfall cores tracked and considered when using different radii from the main TRACER site to identify DCCs.

The DCC intensity is quantified using the maximum 30-dBZ ETH of the tracked core as the primary indicator (e.g., Liu and Zipser, 2013; Guo et al., 2018). Additionally, some studies have used the maximum height of the 10-dBZ or 15-dBZ echo as proxies for cloud depth and convective updraft strength (e.g., Hu et al., 2019; Veals et al., 2022). Therefore, to test the sensitivity of the results to our assumed proxy, we also consider the maximum 15-dBZ ETH, calculated using the KHGX-Houston radar data, as a secondary indicator of convective intensity.

2.2 Meteorological variables

Meteorological conditions are crucial in shaping the formation and evolution of DCCs and may co-vary with aerosol properties, complicating the accurate quantification of aerosol-DCC interactions (e.g., Lee et al., 2008; Storer et al., 2010; Grant and van den Heever, 2015; Lebo, 2018; Dagan et al., 2020; Park and van den Heever, 2022; Zang et al., 2023; Varble et al., 2023). These meteorological variables or convective indices, influencing both aerosol activation and convective updraft strength, are termed "confounders" or "confounding variables" (Jesson et al., 2021).

The convective indices analyzed in this study include convective available potential energy (CAPE), lifting condensation level (LCL), level of neutral buoyancy (LNB), environmental lapse rate (ELR) between 3 km and the surface (ELR_3), ELR between 6 km and 3 km (ELR_6), low-level vertical wind shear from the surface to 5 km (LWS), and low-level mean relative humidity below 5 km (RH). These variables have been identified in previous studies as the most influential meteorological factors altering the impacts of aerosols on convective updrafts and precipitation because these factors regulate the kinematic and microphysical processes in DCCs and the kinematic-microphysical feedback (e.g., Khain et al., 2008; Khain, 2009; Nishant et al., 2019; Fan et al., 2009; Tao et al., 2012; Storer et al., 2010, 2014; Varble, 2018; Wang et al., 2020a; Veals et al., 2022; Sun et al., 2023; Masrour and Rezazadeh, 2023).

To quantify these convective indices, measurements from the ARM balloon-borne sounding system (SONDE) launched at the M1 site are used. Radiosondes were typically launched four times a day at approximately 0530, 1130, 1730, and 2330 UTC during the TRACER campaign, with additional launches at 1900, 2030 and 2200 UTC on enhanced operational days (as listed in Table S1, in the supporting information). These radiosondes provide in situ measurements of profiles of atmospheric thermodynamic state, wind speed, and wind direction. To address the sensitivity of the calculation of these variables to the choice of initial parcel conditions, three scenarios are considered. These scenarios involve lifting different air parcels to initiate a convective cloud: the surface-based parcel (*sfc*), the most unstable parcel (*mu*), and the mixed-layer parcel (*mix*). Detailed

information on these calculations can be found in Wang et al. (2020b). Note that, in the calculations, we assume that the parcel undergoes undiluted ascent in a pseudo-adiabatic process (neglecting hydrometeor loading).

Note that, in addition to the convective indices mentioned above, other factors such as entrainment rate (Abbott and Cronin, 2021; Peters et al., 2023) may also be important in regulating the aerosol-DCC interactions; however, no direct measurements of these quantities are available from TRACER. Therefore, these factors are not included in the analysis. The potential biases in the quantification of the aerosol effects due to these exclusions will be discussed in Section 4.6.

2.3 Surface aerosol measurements

The Aerosol Observing System (AOS; Uin et al., 2019) within the ARM mobile facility (AMF; Miller et al., 2016) was used for *in situ* aerosol measurements at the surface.

The dual-column CCN counter (Column A and Column B) was used to determine CCN number concentrations (N_{ccn}). This instrument measures the number and size of activated aerosol particles for each column at a specific supersaturation (SS) level. Particle size, after humidification, can be measured between 0.75-10 μm , and the range of particle number concentration measurement depends on the SS caused by the growth kinetics of activated particles. Column A has varying SS setpoints between 0% and 1% at a frequency of 1.5 hours, while Column B has a fixed SS setpoint of 0.35%. Due to the unavailability of Column B data at the time of the study, only Column A data were considered. The dataset used includes the number concentration of CCN at SS setpoints of 0.1%, 0.2%, 0.4%, 0.6%, 0.8%, and 1%, which are referred to as N_{ccn01} , N_{ccn02} , N_{ccn04} , N_{ccn06} , N_{ccn08} , and N_{ccn1} , respectively. Note that these measurements were bias-corrected based on a CCN closure study using methods developed by Petters and Kreidenweis (2007). As direct measurements of SS in convective cloud updrafts are not available (i.e., updraft SS is unknown), we consider all six parameters as potential predictors (individually) in the MLR model.

Moreover, the total aerosol number concentrations including ultrafine particles (< 100 nm in diameter) in the nucleation and Aitken mode along with larger, accumulation mode aerosols are considered. The total aerosol number concentrations have the potential to influence DCC evolution, assuming that these particles may be activated as CCN in DCC updrafts in which a range of SS values may be present (e.g., Politovich and Cooper, 1988; Benmoshe, 2010). These quantities were measured by the condensation particle counter (CPC) installed as part of the ARM AOS (Singh and Kuang, 2024). Two types of CPC instruments were used in the AOS: ultrafine CPC instruments (CPCU) and fine mode CPC instruments (CPCF). The CPCU counts aerosol particles with diameters ranging from 3 to 3,000 nm (N_{ufp}), while CPCF counts aerosol particles with diameters ranging from 10 to 3,000 nm (N_{cn}).

The N_{cn} and N_{ufp} were measured at a temporal resolution of 1 minute, N_{ccn} at various SSs had two measurements per hour, and radiosondes, used to derive meteorological parameters, were launched four to seven times per day. To synchronize the two datasets, we employ two commonly used methods from previous studies to explore the sensitivity of results to the averaging process. One approach entails averaging the aerosol properties over a 1-hour period following the launch of a radiosonde (post-sounding averaging; e.g., Veals et al., 2022). The second method involves utilizing a 1-hour period preceding the initial

identification of the rainfall cores, representing the aerosol conditions before the detection of precipitation at the surface (prior-
190 rain averaging).

Based on a t-test (Welch, 2005), the differences between the distributions of the aerosol properties derived using the post-sounding averaging and the prior-rain averaging are statistically insignificant. This is true for all aerosol properties considered in this study. In addition, the median values of the aerosol parameters from these two averaging methods are also comparable, with relative differences ranging from 2% (N_{ccn02}) to 23% (N_{ccn01}). Similar results are found when comparing the variability
195 of aerosol properties within the 1-hour averaging period, showing a consistent median value of the standard deviation for these parameters across all the DCC samples.

2.4 Pairing environmental variables with tracked DCCs

In the next step, we align environmental variables (aerosol and meteorology) with tracked DCC properties. This is achieved by identifying DCC rainfall cores that form within 6 hours after launching each sounding, within a maximum distance of 50 km
200 from the M1 site. The DCC tracking results are then averaged to represent the mean DCC properties for each corresponding sounding. More specifically, in terms of ETH, we identify the maximum ETH throughout a tracked DCC lifetime (one ETH for one DCC), then we average these ETHs to represent the mean ETH of these qualified DCCs. The specifics of the number of samples are detailed in Table 1.

The choice of a 6-hour time gap and a 50 km distance threshold as the upper limit represents a compromise between capturing
205 representative environmental conditions and maintaining a sufficient sample size. We do want to emphasize the possibility of substantial temporal and spatial variability in the thermodynamic conditions around the M1 site. Local phenomena such as sea breeze, bay breeze, urban effects, and other factors may complicate the extent to which the environmental measurements at the M1 site represent the actual air mass injected into the DCCs (e.g., Rapp et al., 2024; Wang et al., 2024).

To account for the heterogeneous and evolving nature of meteorological conditions that may impact DCC development, we
210 evaluate the spatial and temporal scales of meteorological influences on DCC rainfall core characteristics through sensitivity tests. These tests involve examining DCC rainfall cores initially identified within a radius of 20 km, 30 km, 40 km, and 50 km from the M1 site, considering two different groups of soundings: those launched within 4 hours and those within 6 hours before the initial identification of the DCC rainfall cores.

Given the temporal and spatial constraints of the current observations, the purpose of these tests is to strike the best possible
215 balance between accurately characterizing the initial conditions where DCCs are embedded with the available observations and maintaining a sample size that optimizes the performance of the subsequent analysis.

Note that various pairing methods have been used in prior observational studies on aerosol-DCC interaction with the goal of expanding the sample size. One approach involves searching for a sounding launch within a specific period preceding the identification of each tracked DCC within a defined domain (Veals et al., 2022). This increases the number of samples to be
220 equal to the number of tracked DCCs, in contrast to our original method where the number of samples is equivalent to the number of sounding launches. It is crucial to acknowledge that different DCCs may correspond to the same sounding profiles in the Veals et al. (2022) method, limiting the natural variability of the pre-convection environment across different cases.

Therefore, the subsequent analysis is exclusively conducted on datasets generated from the original method of using the mean properties of DCC rainfall cores tracked within 4 or 6 hours after the launch of each sounding.

225 3 Methodology

To assess the potential impacts of aerosols on DCC properties, an approach incorporating the use of SOM and MLR is used.

First, we use the SOM method (Section 3.1) to classify the synoptic weather regimes with the aim of singling out DCC cases occurring within the context of weak synoptic-scale forcing. This choice serves to mitigate the potential influence of large-scale ascent on the evolution of DCCs. In other words, we aim to exclude large-scale, dynamically-driven convective clouds, such as mesoscale convective systems, since the aerosol effect may be overwhelmed by meteorological forcing (Chakraborty et al., 2016; Storer et al., 2010). The characteristics of the synoptic regimes over the Houston-Galveston region, details of the SOM setup, training process, and further information on the SOM method can be found in Wang et al. (2022a).

Second, we determine the relationships between aerosol and DCC properties using the MLR model, and estimate the aerosol effects on DCCs based on the partial regression coefficient associated with the aerosol predictor. Note that we control for potential confounding variables, meaning that these variables are also included as independent variables besides aerosol properties. In the context of this study, these confounders refer to convective indices—such as CAPE—that may influence both aerosol number concentrations and DCC characteristics.

3.1 Minimizing the influence of variability in synoptic-scale forcing

In this subsection, we describe the first step in which we use an unsupervised machine learning technique, SOM, to categorize synoptic weather patterns in the Houston-Galveston area. The purpose of this step is to focus on DCC-aerosol relationships while minimizing the influence of synoptic-scale ascents such as those that are associated with strong synoptic-scale troughs and onshore winds.

In our prior studies (Wang et al., 2022a), we identified three main synoptic patterns in the Houston-Galveston region using the SOM approach, including a pre-trough, a post-trough, and an anticyclonic regime. The input data for the SOM analysis were 700-hPa geopotential height anomalies (recorded at 0000 UTC) from the European Centre for Medium-Range Weather Forecasts (ECMWF) Reanalysis version 5 (ERA5; Hersbach et al., 2020) during the summer months (June to September) of 2010 to 2022. Among these regimes, the anticyclonic regime is the most frequent, representing 49% of all days across the 13-year dataset, occurring predominantly in July and August. The corresponding regime for each day during the TRACER IOP can be found in Figure S1.

During the anticyclonic regime, a high-pressure system typically resides over the Houston-Galveston area as the Bermuda High has shifted toward the west. The region is positioned on the inner eastern edge of a ridge at 500 hPa, and on the inner western edge of an anticyclonic system at 850 hPa. This configuration creates a stable synoptic background characterized by large-scale subsidence over the study area, weak horizontal winds throughout the troposphere, and moderate column water vapor content (Wang et al., 2022a). These conditions are favorable for the formation of locally-forced, isolated DCCs with

255 minimal LWS and moderate low-level moistening (Wang et al., 2024). As such, this environment is conducive to studying the interactions between DCCs and aerosols. Conversely, the pre-trough and post-trough regimes are associated with large-scale trough intrusions and moisture transport from the Gulf of Mexico, which are more likely to promote organized convective clouds over the region that are primarily driven by large-scale dynamics (Wang et al., 2022a). Therefore, these specific cases are excluded from our study, aligning with our emphasis on evaluating aerosol impacts on locally-driven DCCs, which are
260 comparatively less influenced by the large-scale ascent.

3.2 Aerosol-ETH association

Given our potential predictors, namely aerosol or CCN number concentrations at various SS levels, we aim to identify the most relevant aerosol parameters, impacting the DCC ETH. In other words, the "valid" predictors are those that demonstrate a significant association with DCC ETH.

265 To achieve that, we evaluate the performance of a simple linear regression (SLR) model when attempting to predict DCC ETH using each aerosol parameter individually. The p -value of each SLR model is assessed, indicating the statistical significance of the associations between ETH and aerosol parameters.

Figure 1 illustrates the p -values resulting from each fitted model, with 30-dBZ ETH and 15-dBZ ETH as the dependent variable and each aerosol parameter (N_{ccn} at various SSs, N_{cn} , or N_{ufp}) as the predictor (derived from the two averaging
270 methods described above). A p -value below 0.05 signifies a statistically significant association between the predictor and dependent variables. The most notable feature from Figure 1 is that only a small fraction (20 out of 128, accounting for 16%) of the SLR models are statistically significant. This result suggests that, in the majority of scenarios, the CCN and aerosol number concentrations are not reliable influencers of changes in DCC ETH, suggesting limited impacts of aerosol loading on DCC ETH. Among the "valid" SLR models ($p < 0.05$), all of them use N_{cn} or N_{ufp} as the predictor variable. This implies
275 that aerosol loading potentially influences DCC ETH if smaller aerosol particles are considered in the analysis.

3.3 Identification of confounding variables

In this subsection, our primary objective is to identify a specific set of confounding variables from a range of convective indices introduced in Section 2.2. To achieve this, we assess the Pearson correlation coefficients (R) between 30-dBZ ETH/15-dBZ ETH and selected convective indices, as delineated in Table 2 and shown in Figure 2.

280 Positive R -values between 0.2 and 0.4 are evident when examining the relationship between LNB, $CAPE_{mu}$, LCL, or ELR_3 and 30-dBZ ETH. The positive association between $CAPE_{mu}$ and 30-dBZ ETH can primarily be attributed to the direct impact of CAPE on the maximum potential velocity of updrafts, independent of entrainment and hydrometer loading effects (Weisman and Klemp, 1984; Kirkpatrick et al., 2011). This relationship finds support in observations across diverse climate regions, including Darwin, Australia (Kumar et al., 2013), the Sierras de Córdoba mountain range (Veals et al., 2022), and the
285 central Amazon (Wang et al., 2019). This robust association is also present when using surface parcels but diminishes with mixed-layer parcels (Table S2, in the supporting information). Additionally, the LNB shows weak, positive correlation with both 30-dBZ ETH and 15-dBZ ETH, since it is highly correlated to CAPE (Figure 2).

Concerning LCL, its impact on 30-dBZ ETH can be explained by its previously demonstrated positive correlation with the width of updrafts at cloud base (McCaul and Cohen, 2002; Mulholland et al., 2021). In other words, a higher LCL tends to promote wider boundary-layer updrafts. These wider updrafts are more likely to evolve into expansive and deeper updraft cores within DCCs since they experience less dilution of buoyancy due to entrainment compared to narrower updraft cores. Consequently, this leads to a higher 30-dBZ ETH. Similarly, a steeper ELR₃ is closely linked to a higher LCL ($R = 0.9$, Figure 2), and subsequently, a higher 30-dBZ ETH. This steeper ELR₃ also corresponds to a "fatter" buoyancy profile (Zipser and LeMone, 1980), where CAPE is concentrated at lower levels. An air parcel accelerates more rapidly through these levels, reducing the exposure time for entrainment and other processes (Wang et al., 2020b). Therefore, a higher 30-dBZ ETH may be expected.

LWS is another essential factor governing DCC updraft intensity and regulating aerosol-DCC interactions, particularly in organized DCCs (e.g., Fan et al., 2009; Baidu et al., 2022). However, in the specific isolated DCC environment studied here, it has no association with 30-dBZ ETH, but does have a weak, negative correlation with 15-dBZ ETH. Therefore, LWS is excluded (included) as a confounding variable when the 30-dBZ ETH (15-dBZ ETH) is considered as the dependent variable in the next step.

Overall, LNB, CAPE, LCL, and ELR₃ exhibit weak to moderate R -values across various scenarios, making them suitable potential covariates for predicting 30-dBZ ETH alongside aerosol properties. However, high correlation is found between LNB and CAPE ($R = 0.9$, Figure 2) as higher values of CAPE indicate greater atmospheric instability, allowing air parcels to rise to higher altitudes, thus potentially higher LNB. Similarly, strong correlation is also exhibited between ELR₃ and LCL ($R = 0.9$, Figure 2), which can be attributed to their shared relationship with temperature variations in the lower atmosphere. To address multicollinearity concerns, only one variable from each pair is selected as a confounding variable, which can otherwise lead to increased variance in estimated coefficients within the MLR model. Further discussion on multicollinearity is presented in Text S4 of the supporting information.

Finally, CAPE and ELR₃ are chosen due to their higher R -values with 30-dBZ ETH compared to their counterparts. Following a similar logic, CAPE and LWS are selected as confounders when the 15-dBZ ETH is used as the dependent variable in the MLR model. Moreover, these selected confounding variables exhibit a stronger association with aerosol parameters compared to other convective indices (Figure 2). Similar findings are reported in previous studies by Varble (2018). Using the surface and mixed-layer parcel, a consistent conclusion is drawn (Figures S2 and S3).

3.4 MLR

The main step involves fitting an MLR model to our data. In our case, the MLR model includes the dependent variable, Y , which represents the 30-dBZ (15-dBZ) ETH, and the independent variable, X , which represents aerosol properties. We also include two additional variables, which are $A = \text{CAPE}$, $B = \text{ELR}_3$ for $Y = 30\text{-dBZ ETH}$ and $A = \text{CAPE}$, $B = \text{LWS}$ for $Y = 15\text{-dBZ ETH}$ to account for confounding effects.

Therefore, the MLR model can be expressed as follows:

$$Y = \beta_0 + \beta_1 X + \beta_2 A + \beta_3 B \quad (1)$$

Here, β_0 is the intercept, $\beta_1, \beta_2, \beta_3$ are the estimated regression coefficients.

Note that the aerosol properties, X , are transformed into a binary distribution (0 or 1) to first help address potential biases associated with the N_{ccn} measurements/calculations during TRACER. Cases with N_{ccn} at various SSs, N_{cn} , or N_{ufp} above the median value are categorized as polluted cases with a scaled value of 1, while cases below the median value are classified as clean cases with a scaled value of 0. Most importantly, this transformation facilitates the estimation of the average aerosol effects on DCCs, because in this case, β_1 represents the expected difference in Y between when $X = 1$ and $X = 0$, holding A and B constant. In other words, β_1 is the average effect (or group difference) of X on Y while adjusting for A and B . The unit of coefficient β_1 is the same as the unit of Y .

We run model diagnostics to ensure the validity, reliability, and interpretability of the fitted MLR model as well as ensuring the robustness of coefficients. This is achieved by examining the key assumptions (i.e., linearity, homoscedasticity, normality, independence, and multicollinearity) of the MLR models as described in Text S4 in the supporting information. Overall, all scenarios presented in Section 3.2 satisfy these assumptions. In addition, we also calculated the adjusted R^2 values, the 95% confidence intervals for each independent variable (Table S4 in the supporting information). The adjusted R^2 values are generally below 0.5 and rarely increase even when all the potential confounders discussed in Section 2.2 are included. This result indicates that other confounding variables, beyond those included or discussed here, likely exist but are not accounted for. These variables may not have been measured or discovered to have a relationship with the dependent variables which will be discussed in Section 4.6. Additionally, the small sample size may contribute to the low adjusted R^2 , as high variability in the dependent variable can artificially suppress the correlation.

4 Results

In this section, we first provide an overview of the characteristics of the DCC properties and their associated aerosol and meteorological conditions in the Houston-Galveston region. Then, we present the estimated aerosol effects on DCC properties and discuss potential uncertainties of the results.

4.1 DCC properties and their associated environmental conditions

In Figure 3, we illustrate the distributions of selected convective indices representative of the pre-convective conditions. During the selected DCC days, the influence of anticyclonic large-scale flow leads to moderate low-level moistening, resulting in medium-to-high low-level RH (mean RH values below 5 km) of approximately 70% (Figure 3o). This moistening causes air parcels to saturate quickly at lower levels when lifted, leading to a relatively low mean LCL of 1 km (Figures 3g-i), although this value is higher compared to the LCL values in more humid conditions, such as an oceanic environment with a mean low-level RH of 80% (Wang et al., 2020b). The LCL is in close proximity to the LFC, with a smaller median difference of

100 m when using the most-unstable parcel and a larger difference of 600 m when using a mixed-layer parcel (Figures 3j-l). Consequently, the convective inhibition (CIN_{mu}) is relatively low, with a median value of -0.7 J/kg (not shown).

Under these conditions, (adiabatically) lifted parcels can ascend to significant heights, even reaching the tropopause, with a mean LNB_{mu} of 14.6 km (Figure 3d). When considering mixed-layer parcels, the mean value of LNB_{mix} decreases to 13.9 km as expected (Figure 3f). This environment allows for the accumulation of significant $CAPE_{mu}$ throughout the troposphere, with a median value of approximately 3,407 J/kg (Figure 3a). There are only small changes in CAPE values when using the surface parcel in the calculation compared to $CAPE_{mu}$ (Figure 3b), which implies that the majority of the most-unstable parcels are from near surface levels. Under such circumstances, using surface aerosol measurements to represent the in-cloud aerosol properties may result in reduced uncertainty compared to applying the same assumption to study elevated DCCs. The LWS is relatively weak, with a mean value of 5.7 ms^{-1} (Figure 3n), compared to LWS values that support the initiation of organized convective systems (Baidu et al., 2022).

The distributions of convective properties associated with DCCs initiated under such meteorological conditions are illustrated in Figure 4. In this demonstration, the selected DCC cases are those identified within a 50 km radius from the ARM M1 site. The definitions of these properties can be found in Text S2 in the supporting information. These tracked DCC rainfall cores show intense rainfall rates, exhibiting a mean maximum 2-km Z of 54 dBZ (Figure 4a). The maximum 30-dBZ ETH for half of these cores extends above 7 km (Figure 4b). These cores are small in size, with their maximum area having a median value of approximately 52 km^2 during their lifetime (Figure 4c), confirming their more isolated nature. Most of these rainfall cores form in the afternoon hours with a peak in the number of cores initiating around 2000 UTC, corresponding to 1500 local time (Figure 4d). This observation confirms that these cases are predominantly locally driven under weak synoptic-forcing and influenced by surface heating and/or sea-breeze circulations (Wang et al., 2022a). It is therefore no surprise that these cores propagate at a relatively slow speed of 5 ms^{-1} (Figure 4e) and have a relatively short duration of less than an hour (51 min, Figure 4f). The influence of aerosol number concentrations on these locally-driven DCC rainfall cores is expected to be more discernible compared to DCCs with significant large-scale forcing, given the limited large-scale ascent and minimal convection organization in such cases.

Figure 5 illustrates the spatial distribution of DCC properties, showing a notable cluster along a line perpendicular to the coastline and northwest of the M1 site. This pattern can potentially be attributed to the interplay between sea breeze, bay breeze, and urban heat island-induced circulations, which may create a conducive environment for DCC initiation and/or collisions (Mejia et al., 2024). Such events appear to result in larger cell areas, as depicted in Figure 5c, and slightly longer lifetimes compared to cells located outside this zone (Figure 5f), consistent with findings by Hahn et al. (2024). Additionally, it is observed that these cells tend to initiate later in the day (Figure 5d), aligning with the timing of sea and bay breeze propagation and their convergence with urban heat island circulations in this region. Note that the spatiotemporal heterogeneity of these precipitation cores adds complexity to our study, as it relies on point measurements of environmental variables. While this approach is a practical solution given the absence of a comprehensive measurement network during TRACER, it highlights the need for long-term field campaigns with enhanced instrumentation to achieve better spatial coverage across regions with complex multiscale forcings.

Throughout the DCC days, the Houston-Galveston region experienced diverse aerosol number concentrations. As shown in Figure 6, the distribution of aerosol number concentrations spans a considerable range with a prominent peak at smaller number concentration bins. The mean values of these SS-determined distributions are significantly different according to results from a t-test, except for N_{ccn1} and N_{ccn08} . More specifically, this environment exhibits mean total aerosol number concentrations of 7,332 cm^{-3} for N_{cn} and 10,683 cm^{-3} for N_{ufp} during the study period (Figures 6g, h), showing high pollution levels. The most polluted instances occurred in mid-July (e.g., July 12, 13) and mid-August (e.g., August 10, 11, 17), exceeding the 95th percentile values of the distributions shown in Figure 6.

In addition, the Houston-Galveston region is found to have a unique combination of different aerosol species during the summer months (Figure S4), according to the aerosol composition measurements from the aerosol chemical speciation monitor (ACSM) at the M1 site. The predominant aerosol type measured is total organics, constituting 49% (2.24 $\mu g m^{-3}$) of the total aerosol mass concentration, followed by sulfate at 34% (1.54 $\mu g m^{-3}$), ammonium at 13% (0.61 $\mu g m^{-3}$), nitrate at 3% (0.14 $\mu g m^{-3}$), and chloride at < 1% (0.03 $\mu g m^{-3}$). This broad spectrum of aerosol species and their mass concentration is indicative of diverse emission sources, including both anthropogenic (e.g., from city, ships, refineries; Rivera et al., 2010; Wallace et al., 2018) and natural emissions (e.g., from agricultural activities, vegetation; Bean et al., 2016; Yoon et al., 2021) from nearby and/or distant locations.

4.2 Average aerosol effects on DCC ETH

Figure 7 illustrates the estimated average effect of aerosol number concentration on 30-dBZ ETH and 15-dBZ ETH, for all scenarios and varying distances (20 to 50 km) from the M1 site. The "valid" scenarios are indicated by the white hatch lines, representing cases with a relatively higher association between aerosol number concentration and ETH. The confounding meteorological variables are calculated using the most unstable parcel in this figure, and the post-sounding aerosol averaging method is used.

The findings reveal a positive average aerosol effect for N_{cn} and N_{ufp} with values ranging from 0.7 to 2.2 km. It implies that higher aerosol number concentration values correspond to an increase in 30-dBZ ETH within DCCs, thereby suggesting a deeper DCC in polluted conditions compared to that in clean conditions. We observe similar results when using 15-dBZ ETH as the dependent variable and when using different air parcels for calculating confounding variables, as illustrated in Table 3.

Interestingly, for the remaining scenarios, the estimated average aerosol effects are mostly negative (Figure 7), highlighting the potential for contradictory results when a different aerosol variable is used in the analysis. Even for the "valid" scenarios, the significance of the estimated aerosol effects is challenged by the inconsistent 95% confidence intervals for the coefficients of the aerosol variables in the fitted MLR models (Table S4). Specifically, the 95% confidence intervals for the aerosol variables sometimes cross 0, making it difficult to conclude that the aerosols have a clear and meaningful relationship with the ETH. This finding is consistent with the relatively small or minimal average aerosol effects observed for these scenarios in Figures 7 and 8. These aerosol effects could also be likely within the natural variability of these variables and the uncertainty range of the measurements or may be influenced by the sampling methods used.

In a separate test, we ran the MLR model without any confounders, and we found that the estimated mean aerosol effects on 30-dBZ ETH across all "value" scenarios increased by about 0.4 km. These results highlight the importance of controlling for confounders while quantifying aerosol impacts on convective properties.

We also conducted a sensitivity test to examine whether the diurnal cycle affects the estimated aerosol effects on ETH. The results indicate that the average aerosol effects are only around 0.1 km lower than those presented in Figure 7 for those "valid" scenarios, where the diurnal cycle was not controlled for. This suggests that the diurnal cycle has a limited influence on the aerosol effects on ETH under the specific environmental conditions of this study.

Note that the observational findings presented in this study do not unequivocally lend support to or negate the warm-phase invigoration pathway. The role of in-cloud SS is vital in determining the occurrence of warm-phase invigoration within DCCs (e.g., Romps et al., 2023). Unfortunately, direct *in situ* measurements of SS within convective updrafts remain unavailable, despite estimates using aircraft measurements for limited climate and vertical velocity regimes (e.g., Politovich and Cooper, 1988; Pinsky and Khain, 2002; Korolev and Mazin, 2003; Prabha et al., 2011; Romps et al., 2023).

Similarly, the presented aerosol effects do not conclusively confirm or reject the possibility of other hypothesized aerosol invigoration mechanisms (e.g., cold-phase, entrainment-humidity invigoration). As shown in Figure 4b, a substantial portion of the 30-dBZ ETH associated with the studied rainfall cores extends beyond 5 km. Consequently, the observed positive aerosol effects under specific conditions suggest potential evidence of cold-phase invigoration or partitioning between warm- and cold-phase invigoration. However, to fully support these invigoration mechanisms, we need to further assess the relative importance of additional latent heat release and hydrometeor loading (e.g., Igel and van den Heever, 2021). Testing for the presence of these mechanisms requires supporting measurements of hydrometeor and latent heating profiles in the convective updraft region, which were not available during the majority of the TRACER IOP. Moreover, while entrainment is found to alter aerosol-DCC interactions (e.g., Peters et al., 2023), the absence of direct measurements of convective vertical velocity presents a challenge in evaluating the significance of this process.

In summary, we quantify the average aerosol effects on ETH using observational data sets. However, to gain a comprehensive understanding of the plausible pathways driving aerosol-induced effects on ETH necessitates advanced instrumentation and specific field campaign designs, which are capable of capturing SS levels, vertical velocity within updrafts and understanding the intricate dynamics and microphysical processes occurring within DCCs.

4.3 Impacts of the sea-breeze circulations on aerosol-DCC interaction

The ARM M1 site is located close to Galveston Bay (6 km) and the Gulf of Mexico (50 km), frequently experiencing Bay- and Gulf-breeze circulations (simplified as sea-breeze circulations in the following text) during the summer months (Wang et al., 2024). Despite focusing on cases within the anticyclonic regime to exclude large-scale ascent contributions to the development of DCCs, sea-breeze fronts can still act as meso-scale forcing mechanisms, inducing upward motions within the boundary layer and influencing aerosol-DCC interactions.

Our recent study (Wang et al., 2024) indicates that at least 44% of the DCC rainfall cores analyzed here are associated with days that these circulations and boundaries are observed to cross the ARM M1 site. In that study, we identified sea-

breeze circulation days based on observations from NEXRAD, Geostationary Operational Environmental Satellites (GOES), and ARM surface meteorology data (e.g., wind fields, water vapor mixing ratio). Specifically, 64 sea-breeze circulation cases were identified during the TRACER IOP. As shown in Table 1, 38 rainfall cores, with a sounding launch within 6 hours prior to rainfall initiation, were tracked during these days within 50 km of the ARM M1 site in this study.

We applied the MLR model to DCCs that are associated with sea-breeze circulations, maintaining the same confounding variables since they showed moderate correlations with both ETH and aerosol variables (R values ranging from 0.4 to 0.5). Figure 8 illustrates the average aerosol effects on 30 dBZ ETH, which is around 1.4 km for these "valid" cases. It is higher than estimates for scenarios including all cases. This enhanced effect could be due to the potential exclusion of confounding variables that are not major contributors to non-sea-breeze cases. One important variable could be boundary layer updrafts, which consistently increase at the leading edge of sea-breeze fronts as observed from the Doppler Lidar measurements (Wang et al., 2024). Since this observation is only available at the ARM M1 site and not for each tracked rainfall core, it is challenging to include this confounding variable. The exclusion of this confounding variable may lead to an overestimation of the aerosol effects on ETH as discussed in the previous section.

Interestingly, we found more "valid" models (19) for the sea-breeze cases compared to scenarios including all cases. This suggests that the aerosol influence is a robust signal here, even though the extension of the ETH is not more than 15%. This robustness may be due to the coherent separation of clean versus polluted cases when using different exposure variables. This is supported by the observations that the DCC environment is much cleaner after the passage of sea-breeze fronts.

4.4 Average aerosol effects on precipitation intensity and area

In this subsection, we extend our investigation to estimate the impacts of aerosols on precipitation intensity and area. Precipitation intensity is assessed using the maximum 2-km radar reflectivity, while precipitation area is evaluated based on the maximum area with 2-km $Z > 30$ dBZ of the tracked precipitation core throughout the cell life cycle. All steps in our methodology remain the same for these applications, except the dependent variable is either maximum radar reflectivity or precipitation core area instead of ETH. The confounding variable considered in this analysis is only CAPE, as it is the only one that shows a correlation coefficient higher than 0.3 with both ETH and aerosol properties.

Figure 9 presents the aerosol effects on the core area for different potential exposure variables. Only one model is "valid", which corresponds to the scenario with DCCs identified within 30 km of the M1 site using N_{ccn} measured at SS of 0.8%. This finding implies that, only on rare occasions, aerosol number concentration impacts the precipitation core area expansion by approximately 39 km^2 . Given the fact that this area expansion is only observed in limited scenarios, it is less conclusive compared to the effects of aerosols on DCC ETH.

Regarding the aerosol effects on precipitation intensity, Figure 10 shows ten effective models, significantly more than those considering core area as the dependent variable. Although the mean aerosol effect across all "valid" scenarios is positive, the magnitude is around 2 dBZ, which falls within the uncertainty range of the NEXRAD radar (3 dBZ; Gou, 2003; Ryzhkov et al., 2005). Therefore, we cannot conclusively determine that aerosol loading results in heavier precipitation for the DCC cases evaluated in this study.

4.5 Sensitivity of the aerosol effect estimation

We explore the robustness of aerosol effect estimates by examining various factors that could influence the calculations. These factors include the data averaging period for aerosol measurements and the time gap between environmental measurements and DCC rainfall initiation (e.g., Nelson et al., 2021; Fast et al., 2024).

When using the prior-rain method for the aerosol averaging process, as shown in Figures 1b, d, we observe that the effective aerosol properties remain consistent with those obtained using the post-sounding method (Figures 1a, c), involving N_{cn} and N_{ufp} . The mean positive aerosol effects on 30-dBZ ETH and 15-dBZ ETH when using N_{cn} and N_{ufp} aligns closely with the results obtained using the post-sounding aerosol averaging method (Table 3). These findings suggest that our results have minimal sensitivity to the data averaging period for the measured aerosol properties used in this study.

Regarding the influence of the time gap between measurements of DCC and environmental properties on the estimation of the average aerosol effect, we exclude the cases when the nearest soundings were launched more than 4 hours before the initiation of DCC rainfall cores. As shown in Table 3, the mean aerosol effect on 30-dBZ ETH/15-dBZ ETH across all "valid" scenarios are very similar to results using 6-hour soundings.

The shorter the time difference, in theory, the more accurately the sounding measurement should represent the environment in which the DCCs are embedded. Therefore, these results reinforce the conclusion from previous sections, suggesting that aerosol invigoration is, for the most part, constrained, and requires all aerosol particles to be activated in convective updrafts if it is to be effective. However, the number of samples is reduced by approximately 20% when limiting our analysis to 4-hour soundings. Additionally, the percentage of cases heavily influenced by sea-breeze circulations also changes. These changes could all potentially impact the estimated aerosol effects.

In summary, the assessment of aerosol effects appears independent of the timing of environmental measurements relative to the initiation of DCCs and the accuracy with which these measurements reflect the air ingested into the DCC updraft cores. Nonetheless, the collective findings indicate a restricted impact of aerosols on DCCs across all sensitivity tests conducted.

4.6 Potential uncertainties

In this study, we have accounted for important confounders that could influence the aerosol-DCC interactions according to previous studies and also our evaluations, but there may still be some confounders that we did not observe or discover that could impact our results. For example, Peters et al. (2023) discovered that entrainment rate influences whether aerosols have an impact on DCCs. Additionally, the size of the updraft core in the boundary layer prior to the cloud formation is identified as a significant factor influencing the intensity of the subsequently developed DCCs (e.g., Morrison, 2017; Mulholland et al., 2021; Takahashi et al., 2023). However, direct measurements of these quantities were not available during TRACER and most other field campaigns aimed at observing the characteristics of deep convection. The lack of confounders may possibly cause an overestimation of aerosol effects.

In the absence of in-situ observations of cloud microphysical properties, the current analysis cannot account for any "direct" effects of aerosols on ETH or cloud depth through microphysical processes. Neither does the study investigate the microphys-

520 ical pathways through which aerosols may cause the changes in ETH. Such examinations require in-situ observations and/or high-resolution model simulations, which forms a key limitation of any study aiming to explore aerosol-DCC interactions using remote sensing retrievals alone.

5 Conclusions

This study explores the aerosol effects on the rainfall core properties of DCCs, aiming to provide evidence of aerosol invig-
525 oration or enervation. Leveraging the extensive observational dataset collected during the TRACER IOP (Jun. - Sep.) in the Houston-Galveston region, characterized by a diverse aerosol environment, we focus on examining isolated DCCs observed during this period in the anticyclonic regime.

To identify suitable DCCs for investigation, we establish a three-step approach.

First, we exclude synoptic-scale system-driven cases by applying a regime classification of synoptic weather patterns using
530 the SOM method. This step allows us to focus on locally driven cases under anticyclonic regimes, which are found to be more conducive to aerosol interactions in previous studies. The selected period is characterized by low LWS, limited large-scale uplift, and moderate humidity conditions, favoring predominantly isolated DCCs driven by local factors.

Second, we track DCC cases initiated within a certain distance from the M1 site using a Lagrangian framework based on NEXRAD data. This tracking process helps determine the properties of the DCC rainfall cores, which are identified as small
535 in size (74 km^2 on average), slow propagating (5 ms^{-1} on average), and short-lived (51 min on average), with predominantly afternoon initiation likely influenced by surface heating flux and/or sea-breeze circulations. In particular, 44% of the DCC cells tracked occurred on sea-breeze days.

Finally, we use MLR to assess the average effect of aerosols on identified DCCs. In the model, we also include convective indices that covary with aerosol and DCC, (CAPE and ELR₃ for 30-dBZ ETH, CAPE and LWS for 15-dBZ ETH) to account
540 for confounding effects.

The major findings include:

1. We observed a range of average aerosol effects on DCC ETH, spanning from negative to positive values. In a small subset of models where aerosols were more strongly linked to ETH, we detected a positive average aerosol effect. These findings highlight the substantial uncertainty in the sign of aerosol impacts. Only under specific conditions might a more
545 polluted environment lead to stronger convection compared to cleaner conditions, assuming all other factors remain equal. However, the in-cloud SS remains unobserved, and thus the activation of aerosol particles is uncertain.
2. When assessing the impacts of sea-breeze circulations on aerosol-DCC interactions, we found more positive and stronger aerosol effects on 30-dBZ ETH compared to the all-case scenario. This discrepancy could be due to the absence of major confounding variables (e.g., boundary layer dynamics) in the MLR model.
- 550 3. We also investigate the impact of aerosol loading on precipitation core area. Most models indicated positive average aerosol effects, suggesting an expansion of cell area in polluted cases. However, as only one model is deemed "valid,"

the robustness of this result needs further assessment. Moreover, regarding the influence of aerosols on maximum rainfall intensity, the observed effects fall within the range of radar measurement uncertainty.

- 555 4. The sensitivity analysis reveals minimal dependency on the choice of the proxy for updraft intensity, the temporal and spatial gaps between measurements of aerosol and DCC properties, the aerosol averaging period, and the types of originating air parcels used in calculating CAPE. In other words, these tests all show comparable aerosol effects on 30-dBZ ETH.

Figure 1. Simple linear regression model p -value for each aerosol number concentration as a predictor respectively for different aerosol averaging periods. Different colors represent different maximum distances between aerosol and DCC measurements (km in radius from the M1 site). The horizontal line indicates $p = 0.05$ and the white hatch lines indicate "valid" models ($p < 0.05$). Note that for some models, the p -value is zero which is not visible on the plot.

Figure 2. Correlation matrix between the meteorological variables and aerosol number concentrations for DCC cases identified within a radius of 50 km from the M1 site. The correlation matrix is a table showing Pearson R -values between sets of variables. The meteorological variables are calculated using ARM soundings when assuming the most-unstable parcel would rise to form a convection. The black hatch lines indicate non-significant R -values.

Figure 3. Histograms with density kernel estimation (solid lines) of meteorological variables from the ARM soundings launched prior to DCC cases identified within a radius of 50 km from the M1 site. The bin size is defined by the difference between the maximum and minimum values of each variable divided by the number of bins, which is fixed at 10 for each subplot.

Figure 4. Histograms with density kernel estimation (solid lines) of the maximum 2-km radar reflectivity, 30-dBZ ETH, and 30-dBZ rainfall core area along with initiation time, mean propagation speed, lifetime for each DCC rainfall core identified within a radius of 50 km from the M1 site. The binwidth is set to 2 dBZ for (a), 1 km for (b), 20 km² for (c), 2 hrs for (d), 0.5 m/s for (e), and 10 min for (f).

Figure 5. Dots indicate locations where the cell ETHs are maximized on maps for cells initiated within 50 km of the M1 site. The colors in these subplots indicate cell properties as shown in Figure 4.

Figure 6. Histograms with density kernel estimation (solid lines) of CCN number concentrations measured at different SS levels and total aerosol number concentrations for DCC cases identified within a radius of 50 km from the M1 site. The binwidth is set to 500 cm^{-3} for (a)-(d), 200 cm^{-3} for (e), 20 cm^{-3} for (f), $1,000 \text{ cm}^{-3}$ for (g), and $2,000 \text{ cm}^{-3}$ for (h).

Figure 7. Average aerosol effects on (a) 30-dBZ ETH and (b) 15-dBZ ETH estimated for each potential exposure variable. Different colors represent different maximum distances between measurements of environmental variables and DCC properties. The meteorological variables are calculated using ARM soundings (6-hr) when assuming the most-unstable parcel would rise to form a convection. The white hatch lines indicate "valid" results.

Figure 8. Average aerosol effects on 30-dBZ ETH estimated for each potential exposure variable after controlling for confounders (ELR_3 and CAPE) for DCCs identified during sea-breeze days only. The post-sounding aerosol averaging period is considered. Different colors represent different maximum distances between measurements of environments and DCCs. The meteorological variables are calculated using ARM soundings (6-hr) when assuming the most-unstable parcel would rise to form a convection. The white hatch lines indicate "valid" results.

Figure 9. Same as Figure 7a but for cell area as dependent variable and CAPE as confounding variable.

Figure 10. Same as Figure 7a but using maximum reflectivity as dependent variable and CAPE as confounding variable.

Table 1. Number of DCC cases tracked in 2022 from June to September when considering different radii to the M1 site and under different scenarios.

Distance to M1	6-hr soundings	4-hr soundings	Sea-breeze days, 6-hr soundings
20 km	43	29	12
30 km	61	46	22
40 km	70	54	29
50 km	86	70	38

Table 2. Pearson correlation coefficients (R -values) between convective indices and DCC ETH. The most-unstable parcel is used in the calculations of the convective indices. DCCs were identified within different distances, ranging from 20 to 50 km, from the ARM M1 site. Only the R -values that pass the significance tests are included.

Distance to M1	LNB	CAPE	LCL	LFC	ELR ₃	ELR ₆	LWS	RH
<i>Outcome variable: 30-dBZ ETH</i>								
20 km	×	×	×	×	×	×	×	×
30 km	×	×	×	×	0.3	×	×	×
40 km	×	0.3	0.2	×	0.3	×	×	×
50 km	0.2	0.2	0.3	×	0.4	×	×	×
<i>Outcome variable: 15-dBZ ETH</i>								
20 km	×	×	×	×	×	×	-0.3	×
30 km	×	×	×	×	×	×	×	×
40 km	×	×	×	×	×	×	×	×
50 km	0.2	0.3	×	×	×	×	×	×

Table 3. Average aerosol effects on ETH [km] using different confounders and dependent variables when using N_{cn} and N_{ufp} as independent variables.

Confounders	CAPE _{mu} , ELR ₃	CAPE _{sf} , ELR ₃	CAPE _{mix} , ELR ₃
<i>6-hr soundings, post-sounding averaging</i>			
30-dBZ ETH	1.0	1.0	1.0
15-dBZ ETH	0.8	0.7	0.8
<i>6-hr soundings, prior-rain averaging</i>			
30-dBZ ETH	1.1	1.1	1.1
15-dBZ ETH	1.4	0.8	0.8
<i>4-hr soundings, post-sounding averaging</i>			
30-dBZ ETH	1.2	1.2	1.2
15-dBZ ETH	1.2	1.2	1.3
<i>4-hr soundings, prior-rain averaging</i>			
30-dBZ ETH	1.2	1.2	1.2
15-dBZ ETH	1.1	1.1	1.2
