Abstract

Due to US regulations, concentrations of hygroscopic inorganic sulfate and nitrate have declined in recent years, leading to an increased importance in the hygroscopic nature of organic matter (OM). The hygroscopicity of OM is poorly characterized because only a fraction of the multitude of organic compounds in the atmosphere are readily measured and there is limited information on their hygroscopic behaviours. Hygroscopicity of aerosol is traditionally measured using Humidified Tandem Differential Mobility Analyzer (HTDMA) or Electrodynamic Balance (EDB). EDB measures water uptake by a single particle. For ambient and chamber studies, HTDMA measurements provide water uptake and particle size information but not chemical composition. To fill in this information gap, we have developed a novel methodology to assess the water uptake of particle collected on Teflon filters, thereby providing an opportunity to link the measured hygroscopicity with ambient particle composition. To test the method, hygroscopic measurements were conducted in the laboratory for ammonium sulfate, sodium chloride, glucose, and malonic acid, which were collected on 25mm Teflon filters using an aerosol generator and sampler. Constant humidity solutions (CHS) were employed to maintain the relative humidity (RH) at approximately 84%, 90%, and 97% in small chambers. Hygroscopic parameters, including the water-to-solute (W/S) ratio, molality, mass fraction solute (mfs), and growth factors (GF), were calculated from the measurements. The results obtained are consistent with those reported by the E-AIM model and previous studies utilizing HTDMA and EDB for these compounds, highlighting the accuracy of this new methodology. This new approach enables the hygroscopicity and chemical composition of individual filter samples to be assessed so that in complex mixtures such as chamber and ambient samples, the total water uptake can be parsed between the inorganic and organic components of the aerosol.

Keywords: Hygroscopicity, Organic Aerosol, Teflon Filters, Constant Humidity Solutions

Highlights

- This is the first study to assess the hygroscopicity of particles collected on Teflon filters.
- This study's methodology can evaluate water uptake at RH levels as high as ~97%.
- This methodology enables the investigation of composition-dependent hygroscopicity of particles.

1. Introduction

Atmospheric particles significantly degrade air quality by reducing visibility and posing health risks to humans (Gupta et al., 2022; Kohli et al., 2023; Qu et al., 2020). Additionally, they function as cloud condensation nuclei (CCN) or ice-nucleating particles (INPs), profoundly influencing cloud properties and consequently exerting a significant effect on Earth's radiation budget (Haseeb et al., 2024; Lee et al., 2008; Li et al., 2022; Mikhailov et al., 2021; Nadler et al., 2019; Reich et al., 2023; Sjogren et al., 2007; K. Wang et al., 2021; Zieger et al., 2017). Atmospheric aerosol consists of both organic and inorganic compounds with varying physicochemical properties, which further determine the CCN activity, reactivity, deposition, and optical properties (Padró et al., 2012; J. Wang et al., 2010). Historically, the hygroscopic (water-attracting) characteristics of CCN were primarily influenced by inorganic compounds such as nitrates, sulfates, and chlorides. However, with the implementation of emissions controls that have successfully reduced nitrogen and sulfur oxide emissions, the organic fraction of aerosol is assuming a more prominent role. Additionally, the organic fraction is considerably more complex than its inorganic counterpart, comprising thousands of individual compounds originating from diverse sources and reaction pathways, each possessing distinct physical and chemical properties (Boris et al., 2019; Jathar et al., 2016). This complexity often poses challenges to establishing a clear correlation between the organic fraction and hygroscopicity (Han et al., 2022).

The hygroscopicity of particles, which refers to their ability to absorb water, depends on both size and chemical composition (Luo et al., 2020; Zieger et al., 2017). The water activity of atmospheric particles, particularly the affinity of various solutes for water, plays a crucial role in governing several important factors. These include the “total mass concentration of airborne particles, their acidity, the extent of light scattering, their rates of aqueous phase chemical reactions, and their ability to act as cloud condensation nuclei (CCN)” (Saxena et al., 1995). To characterize these attributes of airborne particles, it is necessary to know the amount of water uptake as a function of particle composition and relative humidity (RH) (Saxena et al., 1995).

Various thermodynamic models are available for estimating hygroscopicity, including, ISORROPIA (Nenes et al., 1998), Aerosol Inorganic-Organic Mixtures Functional groups Activity Coefficients (AIOMFAC) (Zuend et al., 2010), Extended Aerosol Inorganic Model (E-AIM) (Clegg et al., 1998), Universal Quasi-Chemical Functional group Activity Coefficients (UNIFAC)

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

model (Fredenslund et al., 1975), and the University of Manchester System Properties (UManSysProp) (Topping et al., 2016). For the organics, they utilize group contribution methods to estimate the water activity of ambient species relevant to the atmosphere (Han et al., 2022). However, these models require further experimental data to validate them and refine their predictions (Han et al., 2022).

Previous studies have measured the hygroscopic growth of both inorganic and organic compounds relevant to the atmosphere. Techniques such as the Humidifier Tandem Differential Mobility Analyzer (HTDMA) (Boreddy et al., 2014; Laskina et al., 2015; Mikhailov et al., 2021) and the Electrodynamic Balance (EDB) (Chan et al., 1992, 2000; Cohen et al., 1987; Kohli et al., 2023; Peng et al., 2001; Steimer et al., 2015; Tang & Munkelwitz, 1991) have been utilized for this purpose. EDB measures the change in mass of individual charged particles of known composition, which are levitated in a gaseous atmosphere by means of an electric field created by imposing voltages on the electrodes (Cohen et al., 1987; Kohli et al., 2023). When the mass of a levitating particle undergoes evaporation or condensation due to a change in RH, it becomes proportional to the DC voltage required to balance the particle in a stationary position. The particle's mfs can then be determined by measuring the particle's balancing voltage with that of a reference state of known composition (Peng et al., 2001). However, EDB is limited to analyzing single particles and is not suitable for studying the water uptake of ambient samples. HTDMA measures the change in particle size distribution in response to varying humidity levels and can be used to measure ambient aerosol. By exposing aerosol particles to controlled humidity levels and measuring their sizes before and after exposure, HTDMA assesses the extent of hygroscopic growth as a function of particle size. This method measures the change in the diameter of the particles, from which parameters such as mass fraction of the solute (mfs) and solute molality are estimated. However, this method does not measure chemical composition of the particles and faces challenges in measuring RH conditions exceeding 90% (Marsh et al., 2019), an RH regime that can lead to very high water uptake. Therefore, there is a need to devise a laboratory technique capable of measuring composition-dependent water uptake of aerosol sampled on the Teflon filters.

This study's objective is to devise a methodology for assessing the water uptake of organic and inorganic aerosol collected on Teflon filters which are commonly used for gravimetric and chemical analysis. Our aim is to accurately estimate water adsorption by solute molecules that

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

commonly act as cloud condensation nuclei (CCN), which include atmospheric relevant inorganics such as ammonium sulfate and sodium chloride, as well as organics such as glucose, a sugar, and malonic acid, a dicarboxylic acid. We compare the results obtained to data from the literature to gain insights into the accuracy of the methodology developed. The novelty of this research lies in the development of method to determine the hygroscopicity of aerosol filter samples so that the chemical composition can be measured and to measure at high relative humidity, exceeding 90%, which is relevant to CCN and where most organic and inorganic compounds absorb considerable amounts of water.

2. Experimental observations

2.1. Relative Humidity Controlled Chamber

The initial step in developing this methodology involves maintaining RH throughout the entire water uptake measurement process. Constant humidity solutions (CHS) (Lide, 2004) offer a means to sustain specified RH levels within sealed chambers. In this study, our aim was to measure the water uptake of both organic and inorganic compounds across a range of high RH levels above 80%. Potassium chloride, barium chloride dihydrate, and potassium sulfate were selected for their capacity to maintain RH levels of approximately 84%, 90%, and 97%, respectively, in their saturated form. Prior to conducting the actual water uptake measurements, we placed these saturated solutions in 10-inch plastic and glass chambers for 24 hours to assess their practical efficacy. In addition, a real-time RH and temperature sensor (Rotronic HL-1D, with an accuracy of ±3.0% RH and $\pm 0.3^{0}$C) was placed inside the chambers. In the glass chambers, the RH reached the desired RH levels, but not so in the plastic chambers, likely due to the absorption by the plastic itself (Fig. 1). Wexler and Hasegawa (1954) specifically noted that chambers should be made of non-hygroscopic materials, preferably metal or glass, as otherwise, the time required to achieve RH equilibrium could be substantial, sometimes spanning days or weeks. Similar observations were made in our study.

Next, we used 4, 6, and 10-inch diameter glass chambers, to examine the consistency of RH levels across different chamber sizes. As expected, all these chambers reached their optimal RH depending on the saturated solutions used but there was a difference in time to equilibration. For instance, the initial time taken to reach the desired RH of ~97% (saturated K_2SO_4) for a 10-inch chamber was slightly longer compared to 4- and 6-inch chambers (Fig. 1). Based on these

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

observations, it is evident that RH equilibrium is influenced by the presence of hygroscopic materials, and the ratio of the solution's free surface area to the chamber volume. These findings affirm the appropriateness of CHS for conducting water uptake measurements using glass chambers of any size and that smaller sizes equilibrate more quickly.

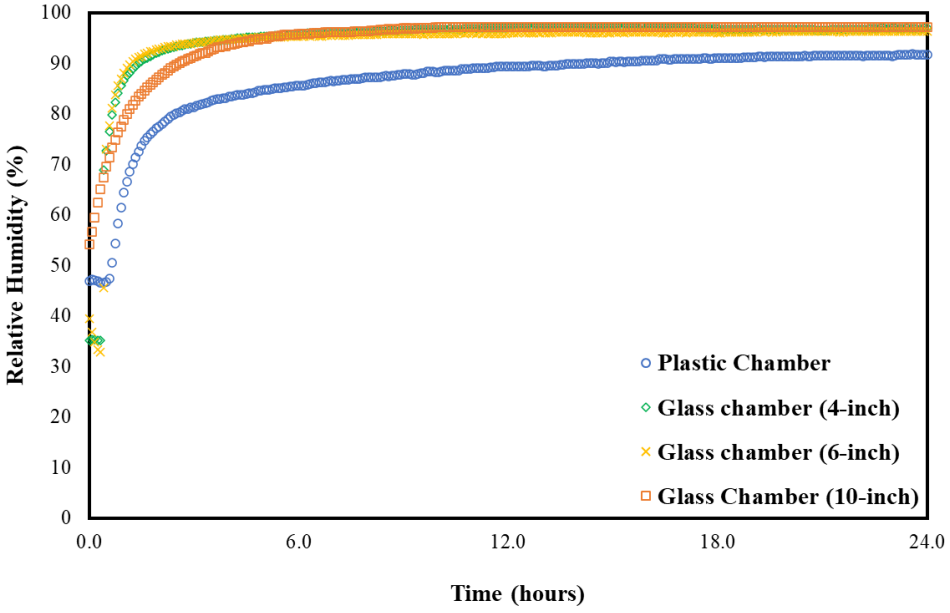

Figure 1. RH over 24-hours in the plastic (10-inch) and glass (4, 6, and 10-inch) chamber with saturated K_2SO_4 solution

2.1.1. Determining the RH (a_w) for the CHS

In the CRC Handbook (volume 85), (Lide, 2004) provided integer RH values for CHS at 25^0C. However, even a small variation in RH could substantially affect water uptake, particularly at higher RH levels, where the water uptake change per change in RH is very steep. The average temperature during these experiments ranged from 17.9^0C to 21.6^0C. To evaluate the effect of temperature variation on RH, the water activity over this range was calculated for each compound used to create CHS. The water activity is ~0.843 for saturated KCl and ~0.975 for saturated K_2SO_4, with no significant variation within the temperature range, according to Eq. (1) provided by Wexler & Seinfeld (1991),

$$\ln\frac{a_w(T)}{a_w(T_0)} = -\frac{M_w}{1000} m_s \frac{L_s}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) \quad (1)$$

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

where $a_w(T)$ is the water activity at temperature (T), $a_w(T_0)$ is the water activity at temperature (T_0, 298.15K), M_w is the molecular weight of water (18.01528 g/mol), m_s is the saturated molality of the compound used as CHS, R is the universal gas constant (8.314 kJ/kmol-K) and L_s is the latent heat of fusion for the salt from a saturated solution; it equals the difference between the standard heat of formation of the crystalline solid phase ($\Delta H_{f,c}$) and ($\Delta H_{f,aq}$), the standard heat of formation of the species in the aqueous solution at saturation molality. For $a_w(T_0)$, the values are 0.8426 for KCl and 0.975097 for K_2SO_4 (Kim & Seinfeld, 1995). The average saturated molality (m_s, in mol/kg) is 4.604 for KCl (Shearman & Menzis, 1937) and 0.636 for K_2SO_4 (Krumgalz, 2018). The latent heat of fusion (L_s, in kJ/mol) is -15.287 for KCl and -23.77 for K_2SO_4 (Kim & Seinfeld, 1995).

The water activity for saturated $BaCl_2.2H_2O$ was determined by extrapolating the water activities provided by (X. Wang et al., 2013) at temperatures of 5, 15, 25, and 35^0C (See Fig. S1). The average a_w for saturated $BaCl_2.2H_20$ during these experiments was ~0.908, ranging from 0.906 to 0.911 and for each experiment the variability in RH due to temperature fluctuations in the lab was negligible (less than 0.25%).

2.2. Laboratory sample collection

The laboratory particulate samples were produced utilizing a home-built aerosol generator and sampler, which consists of an atomizer (Aerosol generator 3076, TSI Inc., USA), a custom-built diffusion dryer, and an IMPROVE aerosol sampler operated at 22.8 L/min. The aerosol generator and sampler was used to generate and collect the known mass of each target compound onto 25 mm Teflon filters (MTL, USA). De-ionized water (~18.2 MΩ purity) was used to make solutions of each compound, for collecting blank filter samples in the aerosol generator and sampler system and to flush the system. Pure filtered air and chemical solutions were delivered to the atomizer to generate aerosol particles. Before collecting each compound, a 30-minute pre-flush with water was conducted to eliminate any residual material from the previous sample collection run. Subsequently, a water blank was collected onto the Teflon filter to identify any remaining contamination from prior samples. If contamination was identified, further cleaning was performed. Following this, each compound was collected on a Teflon filter using an IMPROVE aerosol sampler with sufficient mass to produce measurable water uptake in the sample above its deliquescence RH (Table 1). After completing these steps, the aerosol generator and sampler

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

underwent a 30-minute water flush to remove any deposited compounds, leaving it was contamination-free for subsequent runs. Pre-weights and post-weights of filters were recorded at least thrice on three separate days using a high-precision ultra-microbalance with a readability of 0.1µg (model XP2U, Mettler–Toledo, USA) before and after sample collection. Following sample collection on the aerosol generator and sampler and prior to post-weighing, the collected samples were placed in a dry desiccator for a minimum of 24 hours to remove any residual water. The difference in the post-weight and pre-weight gives the amount of compound collected on the filter.

Table 1. List of compounds collected using aerosol generator and sampler for water uptake measurements

Compound	Chemical Formula	Molecular Weight (g/mol)	Density (g/cc)	Deliquescence Relative Humidity (DRH) (%)[a]
Ammonium Sulfate	$(NH_4)_2(SO_4)$	132.14	1.77	78 − 82
Sodium Chloride	NaCl	58.44	2.16	73 −77
D-Glucose	$C_6H_{12}O_6$	180.156	1.56	90[b]
Malonic Acid	$C_3H_4O_4$	104.0615	1.619	65 − 76

[a]Peng et al., 2022; [b]Mochida & Kawamura (2004)

2.3. Water Uptake Measurements

After post-weighing, the dry particle-loaded filters (DS, post weighed filters with dry particles) were placed in sealed chambers at RHs of 84.3%, 90.8%, and 97.5%, and allowed to equilibrate for more than 24 hours. Subsequently, they were weighed to measure the water uptake by the solutes present on the filters. However, the weighing process did not proceed as expected; the filter weights were unstable on the balance, gradually decreasing until they reached their initial dry particle load weight (Fig. 2(a)). This indicated that the water taken up by compounds on the filter was evaporating during the weighing process, making it impossible to measure the water uptake at the chamber RH. Thus, there was a need for containment to prevent water loss during weighing.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

2.3.1. How can we minimize water loss?

To limit water loss during the wet weighing of the filter, different types of pouches were used to contain the filter and lock in the humidity, including plastic and antistatic zip lock bags. However, these proved to be ineffective due to electrostatic interference during weighing and hygroscopicity of the pouch material. Consequently, aluminum foil pouches were tested. Pouches (approximately 5cm × 3cm × 1 cm) were fabricated from these foils, with three sides sealed. The weights of these pouches were quite stable; therefore, they were tested further for possible use in the water uptake measurements.

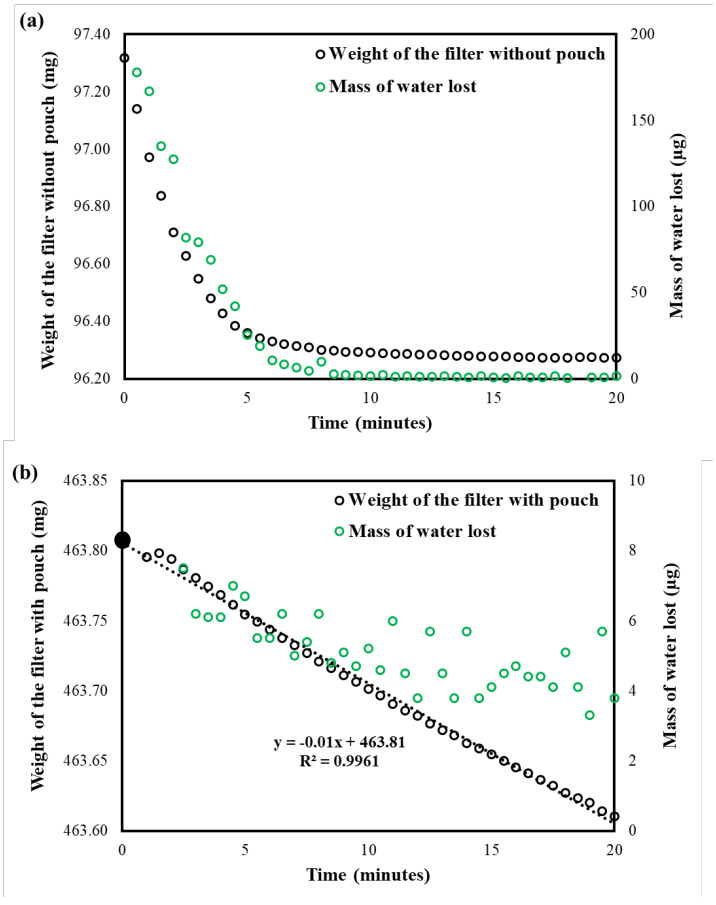

Figure 2. Weight of the filter and mass of water lost while weighing glucose from 97.5% RH: (a) without a pouch and (b) with a pouch. The dashed line represents the linear extrapolation of the observed filter weights to determine the actual wet filter weight (solid black circle) at the time the sample was taken from the chamber.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

A dry particle-loaded filter was placed in a pouch and then placed in the chambers at the specified RH for more than 24 hours, with the fourth side open to allow water vapor in the air to interact with the particles on the filter. After equilibration and upon opening the chamber lid, the pouches were sealed immediately, and the time was recorded. Subsequently, the samples were transferred to the balance, and gravimetric readings were taken. The weight of the wet loaded sample (WSP, mass of the pouch with solute sample at measured RH) was recorded every 30 seconds for 20 minutes (Fig 2b) to investigate how the wet weight of the filter with the pouch varied compared to that of the wet loaded filter without a pouch. The time taken for the sample transfer from the chamber to the first weight was also recorded.

Using a pouch to contain water loss while weighing proved to be effective. We observed a small, slow decrease that achieved steady-state (noisy due to being close to the uncertainty of the balance) after about 10 minutes in the wet weight of particulate filter with the pouch (fig 2(b)), compared to the large, rapid decrease without the pouch (fig. 2(a)). The initial increase in mass, followed by a linear decline required that the data be extrapolated from the linear region back to time zero to accurately determine the net water uptake by the solute on the filter (fig. 2(b), dotted line). These observations clearly suggest that the water loss from the filter can be nearly contained by using the pouch. Gold-coated aluminum foils were also tested and functioned similarly to regular aluminum foil (Fig. S2). Gold-coated foils were used in subsequent experiments because they come in separate sheets, making them easier to handle than rolled aluminum foil.

2.3.2. Why does the pouch weight initially increase and then decrease?

The initial weight gain of the pouch was perplexing, so we investigated by collecting wet weight of a pouch with a filter and pouch without a filter (Figure 3) every 30 seconds for over 20 minutes. The same interval and duration of weighing were applied for all filters and tests unless stated otherwise. This procedure was repeated for five days. The weight increase in the initial minutes of weighing was calculated using the measured data shown in Figure 3 and compared it to the calculated change in air mass between wet and dry air using the psychometric data to determine if dry air intrusion into the pouch was the cause of the weight gain.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

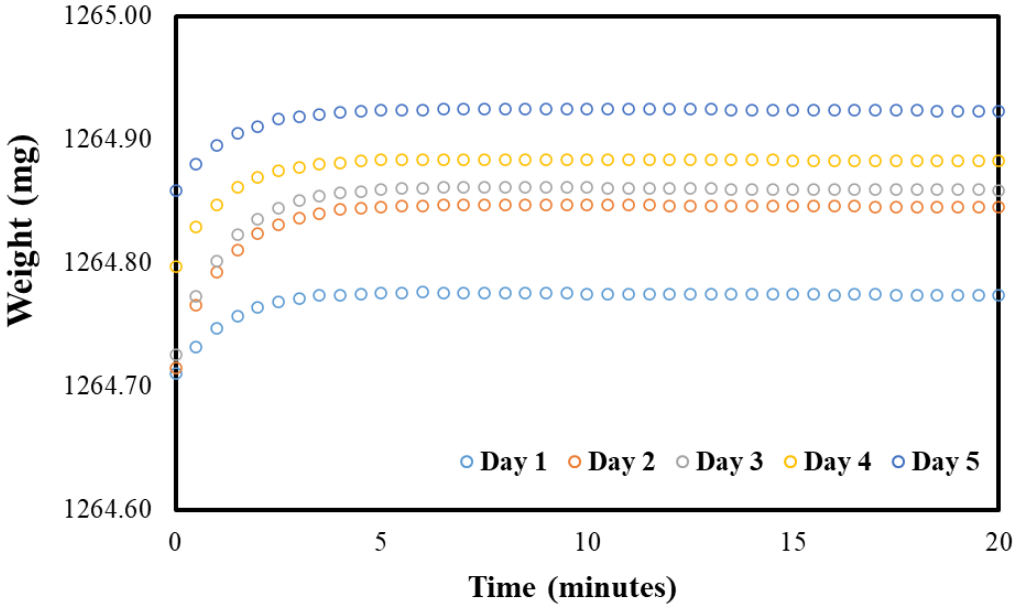

Figure 3. Variation in the weight of the pouch with a Teflon filter over time starting when the pouch is removed from the chamber (RH = 97.5%) and placed on the balance.

2.3.2.1. Measurements

The observed variation in the weight of the pouch (with a filter) over time during the transition from measured RHs to the weighing balance, set at room RH, is depicted in Fig. 3. Across all days and with or without a filter, the weight variation followed a similar pattern, increasing for the first few minutes and then stabilizing.

The change in air mass for each day was determined by calculating the weight difference between the initial time and the point at which the weighing reached a near-constant, as illustrated in Eq. (6).

$$m_i = m_z - m_0 \quad (6)$$

where, m_z is the weight of pouch at time 'z' where it becomes constant, and m_0 is the weight of pouch at zero time.

The average (±SD) increases in mass from zero time to the point where the pouch (with a filter) weight became relatively constant for 84.3%, 90.8%, and 97.5% RHs was 95 (±9) µg, 98 (±56) µg, and 97 (±34) µg, respectively.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

2.3.2.2. Theoretical calculations using the Psychometric Chart

The measured mass change was then compared to the calculated change in the mass of air from the chamber RHs to room RH from the specific volume (SV) using the psychometric chart (PC) (source: https://daytonashrae.org/psychrometrics/psychrometrics_si.html#start) at the known values of temperature and RHs. The assumption was made that the air inside the pouch was exchanged for room air within a few minutes. During this time, an increase in weight would be observed due to the displacement of less dense air (i.e. 97.5% RH) with denser air (~45% RH). The obtained SV from the PC was then inverted to determine the density (þ) of air at the respective RHs, as shown in Eq. (2) & (3),

$$þ_r = \frac{1}{SV_r} \quad (2)$$

$$þ_i = \frac{1}{SV_i} \quad (3)$$

where, $þ_i$ represents the air density at different RHs (i : 84.3%, 90.8%, and 97.5%), and SV_i is the specific volume at these RHs. $þ_r$ and SV_r represents the density and specific volume at room conditions (r).

The net change in air density (Δþ) from the measured relative humidities to room conditions is calculated using the Eq. (4),

$$Δþ = þ_r - þ_i \quad (4)$$

The variation in the mass of air (m_i) is calculated using the Eq. (5),

$$m_i = Δþ \times V_P \quad (5)$$

where, m_i is the change in the mass of air from the measured RHs (84.3%, 90.8%, and 97.5%) to the room RH and V_P is the volume of the aluminum pouch.

The calculated air density and mass obtained at high and room RHs using PC are presented in Table S1. At higher RHs, the density of air in the pouch was lower, due to the increased concentration of water molecules at higher RHs, which have a lower molecular weight (18 g/mol) compared to that of air (29 g/mol). The calculated average net mass gain (±SD) from high RHs of

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

84.3%, 90.8%, and 97.5% to room RHs) was 197 (±58) µg, 200 (±52) µg, and 255 (±54) µg, respectively.

The theoretical increase in the mass of air was higher than the measured values. This is attributed to the air in the pouch being at a lower RH than the chamber RH at the initial weigh due to the time it takes to move the pouch from the glass chambers to the balance and an incomplete exchange of high RH to room RH air.

2.3.3. Increasing weights of filter with pouch during repeated measurements over multiple days

While conducting water uptake measurements, we observed that the weight of the pouch with sampled filter was increasing from measurement to measurement even though the RH was not changing, leading to uncertainty in our water uptake measurements (Fig. 3). There was a consistent increase in the wet weight of the pouch with a filter for each consecutive day across all RHs (84.3%, 90.8%, and 97.5%), with average (±SD) increases of 13 (±10) µg, 17 (±9) µg, and 37 (±25) µg, respectively, as shown in Fig. 3 for 97.5% RH; results for 84.3% and 90.8% RH are shown in Figure S3. Similarly, for the pouch without a filter, there was increases in weight of 14 (±4) µg, 25 (±11) µg, and 44 (±7) µg, respectively (see Fig. S4).

To determine the cause of the mass increase, the following experiment was performed. After conducting water uptake measurements for five days, the pouches with blank filters were subsequently placed in a dry desiccator for a minimum of 24 hours and then weighed. This process was repeated for the next four days. The observed variations in the weights of the dried pouches are presented in Fig. 4 for 97.5% RH, and in Fig S3 for 84.3% and 90.8% RH. The weights of these pouches, measured across all RHs, remained fairly consistent, only varying by a few micrograms throughout the four days of measurement and did not exhibit a consistent trend in either increasing or decreasing weight. This suggests that after water adsorption onto the pouch, aluminum oxides are formed and remain stable at low RH. Considering these observations, it is prudent to account for water adsorption onto pouches when making water uptake measurements.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

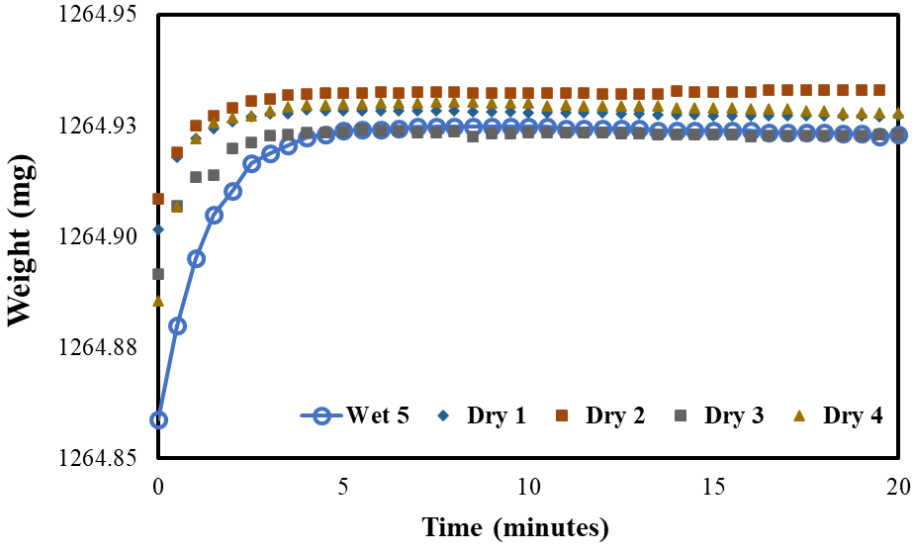

Figure 4. Variation in the dry weight of the pouch (with a filter) over time compared to the 5th day wet measurement (97.5% RH)

By including a measurement blank, consisting of a pouch with a blank filter, alongside the water uptake measurements using a pouch with a loaded filter, two issues are addressed: (i) water absorption on the pouch itself and (ii) small day to day fluctuations in the balance due to changes in meteorological and room conditions. The benefits of the measurement blank to account for water absorption on the pouch are illustrated with a filter loaded with sodium chloride and exposed to 84.3% RH for five days. Figure 5 illustrates the water uptake of sodium chloride with the pouch, the pouch with blank filter, and the net water uptake by sodium chloride, calculated as the difference between the water uptake of the pouch with sodium chloride and the pouch with blank filter. The water uptake of the pouch with sodium chloride filter increased day to day. However, by subtracting the water uptake from the pouch with blank filter, the water uptake by sodium chloride remained consistent day to day. Hence, to address pouch absorption, measurements were conducted simultaneously on pouches with blank filters at the specified RHs and on pouches with loaded filters; thus, for each compound, there were a total of six filters—three pouches with blanks, one at 84.3%, 90.8%, and 97.5%, and similarly, three loaded filters in pouches at the same RH.

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

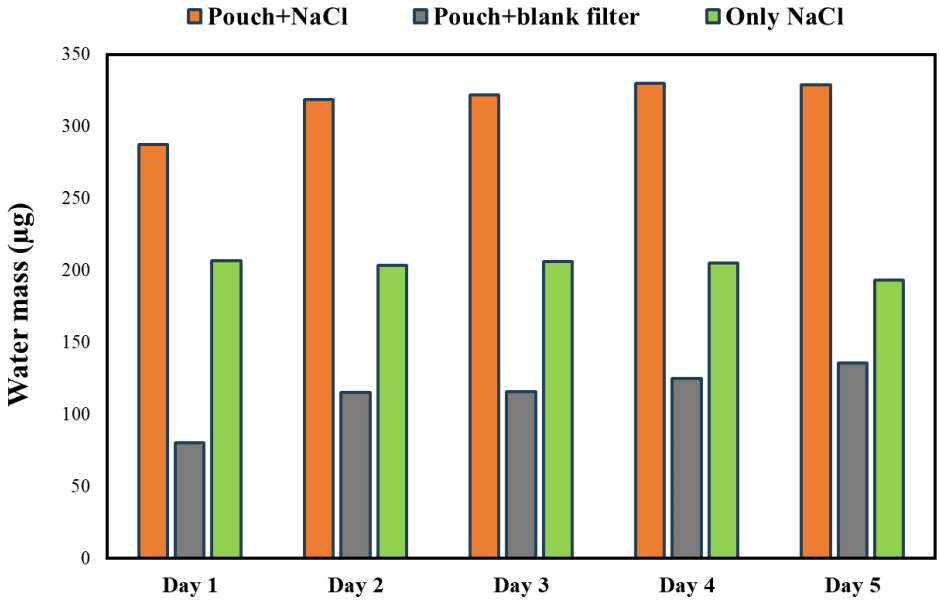

Figure 5. Water uptake by pouch with sodium chloride, pouch with blank filter, and only sodium chloride at 84.3% RH

2.4. Hygroscopic parameters estimation

Four parameters related to hygroscopicity are reported here: mass fraction of solute (mfs), molality, growth factor (GF). the water-to-solute ratio, which is the number of moles of water absorbed per mole of solute (compound). The calculations for these parameters are explained in the following sections.

2.4.1. Mass fraction solute (mfs)

The solute mass fraction is the fraction of solute relative to the total mass of the solution. The mass of solution in the case of hygroscopic particles is the sum of solute's mass and the mass of water absorbed by the solute at a given RH, as illustrated in Eq. (7):

$$\text{mfs} = \frac{\text{mass of solute (µg)}}{\text{mass of solute (µg)} + \text{mass of water uptaken by the solute (µg)}} \quad (7)$$

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

2.4.2. Molality (m)

Molality is the moles of solute dissolved in a certain mass of water, as illustrated in Eq. (8):

$$\text{Molality (m, mol/kg)}) = \frac{\text{no.of moles of solute}}{\text{mass of solvent (water absorbd by the solute)}} \quad (8)$$

2.4.3. Growth Factor

The growth factor (GF) of the dry particles at the measured RHs is estimated from the ratio of wet particle diameter to the dry particle diameter, as shown in Eq. (9):

$$GF_j = \frac{D_{w,j}}{D_{dry}} \quad (9)$$

where, $D_{w,j}$ is the diameter of the wet particle at RH, j and D_{dry} is the diameter of dry particle. The detailed calculations of GF at the respective RH are explained in Eq. (10) to Eq. (14):

$$\text{Volume of the dry solute, } V_{dry} = \frac{\text{mass of solute}}{\text{density of solute}} \quad (10)$$

$$\text{Volume of adsorbed water onto the solute, } V_{water} = \frac{\text{mass of water}}{\text{density of water}} \quad (11)$$

$$\text{Total volume of the wet particle, } V_{wet} = V_{dry} + V_{water} \quad (12)$$

$$\text{Average diameter of the wet particle, } D_{wet} = 2 \times \left(\frac{3V_{wet}}{4\Pi}\right)^{\left(\frac{1}{3}\right)} \quad (13)$$

$$\text{Average diameter of the dry particle, } D_{dry} = 2 \times \left(\frac{3V_{dry}}{4\Pi}\right)^{\left(\frac{1}{3}\right)} \quad (14)$$

2.4.4. Water-to-solute ratio

Equation 15 gives the water/solute (W/S) of the sample on the filter in terms of the measured quantities:

$$\frac{Water}{Solute} = \frac{(wet\ sample\ with\ pouch - dry\ sample\ with\ pouch) - (wet\ blank\ with\ pouch - dry\ blank\ with\ pouch)}{dry\ sample - dry\ blank} \times \frac{MW_s}{MW_W} \quad (15)$$

where, wet sample with pouch (WSP) is the mass of the pouch and sampled filter at high RH, dry sample with pouch (DSP) is the mass of the pouch with particles on the filter at dry conditions,

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

wet blank with pouch (WBP) is the mass of the pouch with blank filter at high RH, dry blank with pouch (DBP) is the mass of the pouch with blank filter at dry conditions, dry sample (DS) is the mass of the filter with particles on the filter at dry condition, and dry blank (DB) is the mass of the blank filter. MW_S and MW_W are the molecular weight of solute and water, respectively. All are in the units of milligrams (mg), except MW, mol/gm.

2.5. Uncertainty in the measured water-to-solute (W/S) ratio

The uncertainty of the measured water-to-solute ratio was determined using the partial derivatives of the input parameters employed in calculating the W/S ratio.

From Eq. (15), the W/S ratio can be written as

$$\frac{W}{S} = \frac{(WSP-DSP)-(WBP-DBP)}{DS-DB} \times \frac{MW_S}{MW_W} \quad (16)$$

The sensitivity of the W/S ratio to the input variables (X) were calculated using partial derivatives ($\frac{\partial(W/S)}{\partial(X)}$), as illustrated in Eq. (17) through (22):

$$\left|\frac{\partial(W/S)}{\partial(WSP)}\right| = \left|\frac{1}{DS-DB}\right| \quad (17)$$

$$\left|\frac{\partial(W/S)}{\partial(DSP)}\right| = \left|\frac{1}{DB-DS}\right| \quad (18)$$

$$\left|\frac{\partial(W/S)}{\partial(WBP)}\right| = \left|\frac{1}{DB-DS}\right| \quad (19)$$

$$\left|\frac{\partial(W/S)}{\partial(DBP)}\right| = \left|\frac{1}{DS-DB}\right| \quad (20)$$

$$\left|\frac{\partial(W/S)}{\partial(DS)}\right| = \left|\frac{-(WSP-DSP)+(WBP-DBP)}{(DS-DB)^2}\right| \quad (21)$$

$$\left|\frac{\partial(W/S)}{\partial(DB)}\right| = \left|\frac{(WSP-DSP)-(WBP-DBP)}{(DS-DB)^2}\right| \quad (22)$$

The uncertainty contribution δX of each input variable (X) to the measured W/S ratio was estimated using Eq. (23):

$$\delta X = \left|\frac{\partial(W/S)}{\partial X}\right| \times \sigma(X) \quad (23)$$

where, $\sigma(X)$ is the standard deviation of each input parameter (X).

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

The overall uncertainty in the measured W/S was calculated using Eq. (24):

$$\delta(\mathrm{W/S}) = \sum(\left|\frac{\partial(W/S)}{\partial(X)}\right| \times \sigma(X)) \quad (24)$$

The percentage uncertainty contribution by each input variable to total uncertainty in the W/S ratio was calculated using Eq. (25):

$$\frac{\delta(\mathrm{X})}{W/S} \times 100 \quad (25)$$

3. Results and Discussion

3.1. Derived hygroscopic parameters

Table 2 shows the hygroscopic parameters derived from the measurements, including water-to-solute (W/S) ratio, mfs, molality, and GF at the measured RHs for ammonium sulfate, sodium chloride, glucose, and malonic acid. The observed water uptake increased from 84.3% to 97.5% RH for all compounds. For example, the observed W/S ratio of sodium chloride i.e. moles of water absorbed per mole of sodium chloride was 14.62 at 84.3% RH, 19.8 at 90.8% RH and 86 at 97.5% RH. Similarly, for ammonium sulfate, glucose, and malonic acid, the W/S increased from an RH of 84.3% to 97.5% by factors of 5.0, 4.8, and 6.9, respectively. Conversely, the mfs and molality decreased with increasing RH for all the measured compounds. For example, the mfs of malonic acid was 0.47 at 84.3% RH, but only 0.11 at 97.5% RH. Similarly, the observed molality for malonic acid was 8.63 at 84.3% RH, which reduced to 1.25 at 97.5% RH.

455

456 In this study, the water uptake measurements for each compound at each specific RH were
457 repeated over five different days to investigate the repeatability of the determined hygroscopic
458 parameters. The variability (standard deviation) in the observed hygroscopic parameters, as shown
459 in Table 2, is small. For instance, the relative standard deviation (RSD, SD ÷ mean) of the growth
460 factor for malonic acid at all RHs was less than 0.5%. This observation clearly indicates that the
461 variability of measured hygroscopic parameters at the same RH for each compound between
462 different experiment days is minimal, highlighting the repeatability of this methodology. In
463 addition, to examine the reproducibility of this methodology, we repeated the water uptake
464 measurement for the malonic acid compound at 97.5% RH with different masses (48.8µg and
465 130.4 µg) and estimated the hygroscopic parameters. We observed insignificant differences
466 (~0.4%) in the water uptake parameters of malonic acid at 97.5% RH between the two experiments.
467 These observations indicate that the developed methodology can reproducibly assess the
468 hygroscopicity of particles collected on Teflon filters.

Preprint. Discussion started: 9 August 2024

In our study, we recorded the wet weight every 30 seconds over 20 minutes to estimate the hygroscopic parameters. However, we evaluated if this length of time was necessary by calculating the GFs for each compound at the measured RHs for 5, 10, and 15-minute intervals and compared them with the GFs using the 20-minutes interval, shown in Figure S5. There was no significant difference between the GFs estimated using the 5, 10, 15 and 20-minute intervals. For future studies, it is unnecessary to take wet weighing for 20 minutes; and taking wet weights every 30 seconds over a 5-minute period is sufficient to determine hygroscopic parameters.

3.2. Comparison of estimated hygroscopic parameters with previous studies

Most of the prior studies reported the water uptake in terms of GFs with few reported in terms of mfs and molality so we will focus our comparisons on GF measurements. The estimated average GFs for each compound at the measured RHs were compared with previous studies, depicted in Fig. 6. These studies used techniques such as HTDMA and EDB to derive GF. These studies typically examined RH levels of 90% or lower, except for Mikhailov et al., (2024), who estimated GFs for ammonium sulfate and glucose at RH levels up to 99.9%. Additionally, the estimated GFs for compounds were compared with values provided by the thermodynamic model, E-AIM (http://www.aim.env.uea.ac.uk/aim/aim.php), which has been widely used to assess the water uptake of inorganic compounds for over three decades. The estimated GF for sodium chloride of 2.23 at 84.3% RH was similar to values reported in previous studies (M. Cheng & Kuwata, 2023; Hu et al., 2010; Peng et al., 2016), which ranged from 2–2.22. Similarly, at 90.8% RH, the observed GF for sodium chloride of 2.45 was close to previous findings (M. Cheng & Kuwata, 2023; Peng et al., 2016; Zieger et al., 2017), which ranged from 2.20–2.40. For ammonium sulfate, the observed GFs at 84.3%, 90.8, and 97.5% RH were 1.47, 1.7, 2.29, respectively, which are similar to those of previous studies (Bouzidi et al., 2020; M. Cheng & Kuwata, 2023; Choi & Chan, 2002; Cruz & Pandis, 2000; Denjean et al., 2014; Hämeri et al., 2002; Hu et al., 2010; Koehler et al., 2006; Liu et al., 2016; Mikhailov et al., 2024; Prenni et al., 2001; Sjogren et al., 2007), which were 1.49–1.60, 1.70–1.79, and 2.3, respectively. Likewise, for glucose, at 84.3%, 90.8%, and 97.5% RH, the observed GFs fell within the ranges reported in earlier studies (Lei et al., 2023; Mikhailov et al., 2024; Mochida & Kawamura, 2004), which were 1.2–1.5, 1.3–1.65, and 1.8 respectively. For malonic acid, the observed GFs at 84.3% and 90.8% RH were consistent with the ranges found in previous studies (Bouzidi et al., 2020; Peng et al., 2001; Pope et al., 2010;

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

Prenni et al., 2001). The measured GF for ammonium sulfate and sodium chloride at all RH levels agreed well with the E-AIM model values, except at 97.5% RH. The observed GF for ammonium sulfate at 97.5% in this study was slightly lower than the value reported by E-AIM, differing by a factor of 1.11. For sodium chloride, it was higher by a factor of 1.12. Changes in water uptake near saturation RH are steep, and even slight variations in RH can significantly affect the GF. This likely explains the slight differences between this study and the E-AIM at 97.5% RH.

This study's observed average mfs of malonic acid for 84.3%, 90.8%, and 97.5% RH was 0.47, 0.35, and 0.11, respectively, which are similar to those of previous studies (0.475, 0.37–0.38, and 0.11, respectively) as reported by Koehler et al. (2006) and Maffia & Meirelles (2001). In the same way, for other compounds, the observed mfs are closely matched with those of previous studies (ammonium sulfate: 0.37–0.42, 0.3–0.32, and 0.1–0.12 (Chan et al., 1992; Kim et al., 1994; Kreidenweis et al., 2005; Mikhailov et al., 2024); glucose: 0.60, 0.44–0.46, 0.25 (Mikhailov et al., 2024; Peng et al., 2001); sodium chloride: 0.175, 0.04 (Kreidenweis et al., 2005)). Few studies have reported water uptake in terms of molality, and the observed molality for all the compounds in this study were close to the range of those reported in previous studies (Ammonium sulfate: ~4–6.5, 3–3.2, and 1 (Y. Cheng et al., 2015; Mikhailov et al., 2024; Zamora & Jacobson, 2013), Glucose: ~5.25–8, 4.7, and 1 (Lei et al., 2023; Mikhailov et al., 2024; Zamora et al., 2011), Malonic acid: ~8.5, 5.7, and 1.25 (Lee & Hildemann, 2013)), and sodium chloride: ~4.25, 2.2, and 0.75 (Zamora & Jacobson, 2013)).

Preprint. Discussion started: 9 August 2024

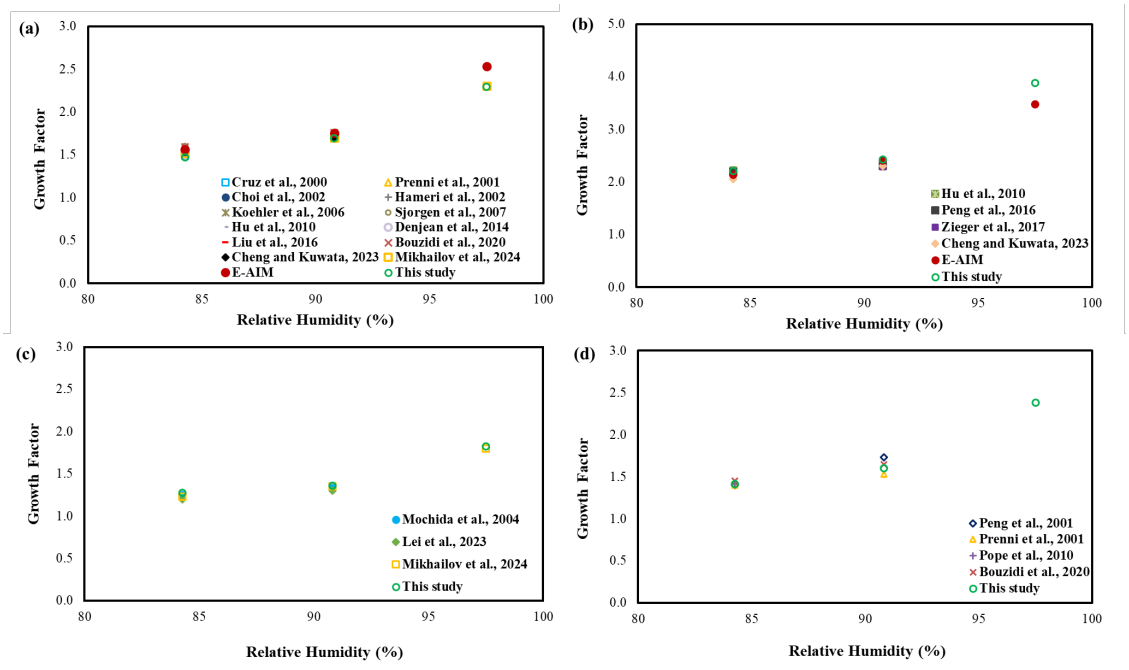

Figure 6. Comparison of estimated growth factor for (a) Ammonium sulfate, (b) sodium chloride, (c) Glucose, and (d) Malonic acid with previous studies

The above comparisons validates the accuracy and reliability of the methodology used in this study. Therefore, the water uptake of particles collected on Teflon filters can be effectively assessed using the developed methodology.

3.3. Estimated uncertainties in the W/S ratio

The estimated uncertainties in the W/S ratio using this study's methodology are depicted in Fig. 7. Overall, the uncertainty for almost all the measured compounds at measured RHs was below 10%, except for sodium chloride at 84.3% and 90.8%, which had uncertainties of 12% and 15%, respectively. WSP and WBP contributed the most to the overall W/S uncertainty, followed by DSP and DBP, with DS and DB contributing the least for all the measured compounds, except sodium chloride. For sodium chloride, consistent water uptake was observed across all five measured days, as exemplified by the net water uptake at 84% RH, shown in Fig. 5. However, for sodium chloride, the major uncertainty was associated with DS, unlike other compounds. A plausible reason for this discrepancy is the smaller mass of sodium chloride (45, 39.5, and 27.8µg

https://doi.org/10.5194/egusphere-2024-2482
Preprint. Discussion started: 9 August 2024

for 84.3, 90.8, and 97.5% RHs, respectively) compared to other compounds which averaged 122, 274 and 88 ug for ammonium sulfate, glucose, and malonic acid, respectively for all three RHs The lower mass increases uncertainty due to the limitations in the precision of the balance.. For sodium chloride at 97.5%, water uptake was more than 3 times higher than at 84.3 and 90.8% RH resulting in lower uncertainty at 97.5%. This discrepancy is inherent in the W/S ratio calculation, as the mass of solute is in the denominator. Nevertheless, it is important to note that this uncertainty is not inherent in the developed methodology but rather caused by the lower mass used for sodium chloride in the water uptake measurements. To reduce this uncertainty, based on our observations, we recommend using a larger mass: at least 50µg for hygroscopic compounds like sodium chloride, 100µg for medium hygroscopic compounds like glucose, and more than 200µg for less hygroscopic compounds.

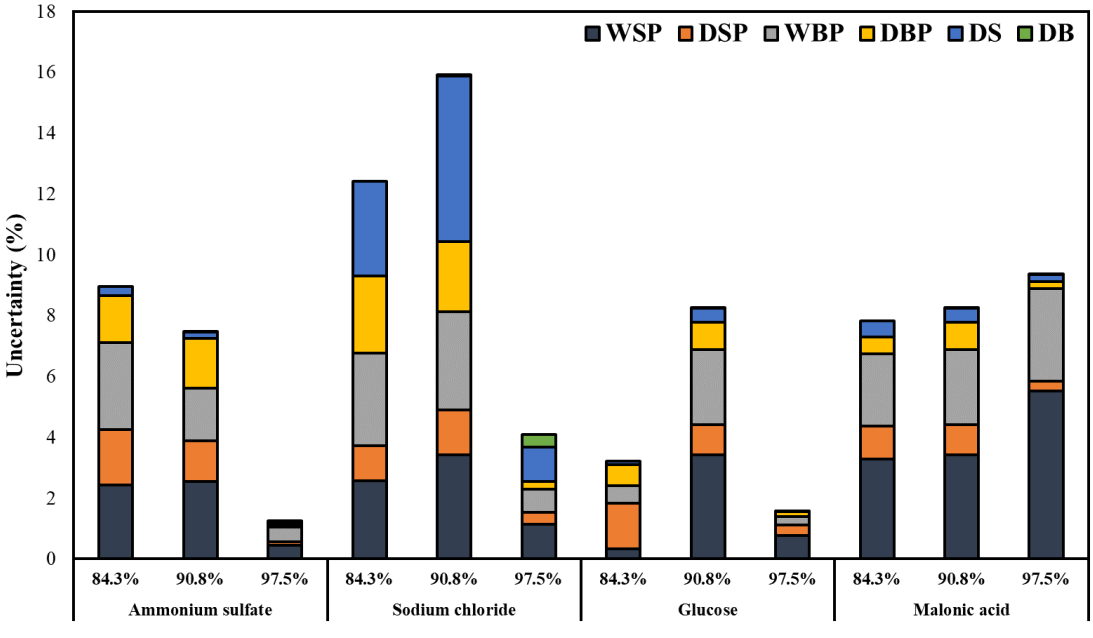

Figure 7. Estimated uncertainties in the measured water-to-solute ratio at different RHs.

Preprint. Discussion started: 9 August 2024

4. Conclusion

In this study, we developed a novel methodology to assess the water uptake of particulate samples collected on Teflon filters. By using filter samples, the chemical composition of ambient or chamber samples can be measured as well as water uptake, something neither HTDMA nor EDB can do for complex mixtures. The advantage of this method is that it enables hygroscopicity to be related to chemical composition. Additionally, this method can used to measure water uptake above 90% RH, which is typically not done with HTDMA measurements.

Constant humidity solutions were employed to maintain specific RH and enable measurements as high as ~97%. Hygroscopic parameters, including the W/S ratio, GF, molality, and the mfs, were estimated from water uptake measurements for ammonium sulfate, sodium chloride, glucose, and malonic acid at RH levels of 84.3%, 90.8%, and 97.5%. As expected, the water uptake increased with higher RH for all compounds. The observed GFs in this study were consistent with those reported in previous studies for all the measured compounds at the examined RH levels, and similar to modelled values for the inorganics highlighting the accuracy of this method. The overall uncertainty in the observed W/S ratio was less than 10% for most of the compound/RH combinations measured, further highlighting robustness and precision of this new method.

Author Contributions

ASW and AMD conceived of the project. NR developed the water uptake methodology, performed the laboratory work and data analysis, created the figures and tables, and wrote and edited the manuscript. ASW and AMD provided leadership for the project, including mentoring and supervising NR in the laboratory work, methodology development and data analysis, and reviewed and edited the manuscript.

Competing interests

The contact author has declared that none of the authors has any competing interests.

Acknowledgements

We would like to thank the Department of Energy (DOE), USA, for funding this project (grant no. DE-SC0023087). We also acknowledge the support of undergraduate students Lucas Wang and Alexander Velasco in the laboratory measurements.
