14
15 **Abstract.** Tropospheric ozone over Southern Africa is particularly high and causes tremendous health risks and crop yield
16 losses. It has been previously attributed to the influence by biomass burning (BB), with a minor contribution from
17 anthropogenic emissions. However, due to the lack of measurements for ozone and its precursors, the modeled impacts of
18 BB and anthropogenic emissions on tropospheric ozone were not well evaluated in Southern Africa. In this study, we
19 combined the nested GEOS-Chem simulation with a horizontal resolution of $0.5^\circ \times 0.625^\circ$ with rare multiple observations
20 at the surface and from space to quantify tropospheric ozone and its main drivers in Southern Africa. Firstly, BB emissions
21 from current different inventories exhibit similar peaks in summer season but also have large uncertainties in Southern
22 Africa (e.g., uncertainty of a factor of 2-3 in emitted NO_x). The model-satellite comparison in fire season (July-August) in
23 2019 shows that using the widely used GFED4.1 inventory, the model tends to overestimate by 87% compared to OMI
24 NO_2 , while the QFED2 inventory can greatly reduce this model bias to only 34%. Consequently, the modeled tropospheric
25 column ozone (TCO) bias was reduced from 14% by GFED4.1 to 2.3% by QFED2; the simulated surface MDA8 ozone
26 was decreased from 74 ppb by GFED4.1 to only 56 ppb by QFED2. This suggests a highly overestimated role of BB
27 emissions in surface ozone if GFED4.1 inventory is adopted. The model-observation comparison at the surface shows that
28 the global CEDSv2 anthropogenic inventory tends to underestimate anthropogenic NO_x emissions in typical Southern
29 African cities by a factor of 2-10 and even misrepresented anthropogenic sources in some areas. That means that urban
30 ozone and $\text{PM}_{2.5}$ concentrations in Southern Africa may be strongly underestimated. For example, a ten-fold increase in
31 anthropogenic NO_x emissions can change ozone chemistry regime and increase $\text{PM}_{2.5}$ by up to $50 \mu\text{g m}^{-3}$ at the Luanda
32 city. Furthermore, we also find that the newly TROPOMI can already capture the urban NO_2 column hotspots over low-
33 emission regions like Southern Africa while this is unavailable from the OMI instrument, highlighting the critical role of

34 high-quality measurements in understanding atmospheric chemistry issues over Southern Africa. Our study presents a
35 quantitative understanding of the key emission sources and their impacts over Southern Africa that will be helpful not only
36 to formulate targeted pollution controls, but also to enhance the capability in predicting future air quality and climate
37 change, which would be beneficial for achieving a healthy, climate-friendly, and resilient development in Africa.

38
39 **Keywords:** biomass burning, tropospheric ozone, Southern Africa, urban emissions

40 1 Introduction

41 Tropospheric ozone (O_3) is an important trace gas in the atmosphere, posing multifaceted threats to public health, crop
42 yield, and global environment (Xu et al., 2018; Bourgeois et al., 2021). Complex photochemical oxidation of nitrogen
43 oxides ($NO_x = NO + NO_2$) and volatile organic compounds (VOCs) in the presence of sunlight is the main source of
44 tropospheric ozone (Wang et al., 2022). These two ozone precursors are emitted from both anthropogenic and natural
45 sources. Great efforts have been made to reduce anthropogenic emissions, but ozone pollution is still challenging in many
46 urban regions across the globe (Gaudel et al., 2020; Lyu et al., 2023). Globally, it was estimated that ~365,000 premature
47 deaths could be attributed to ozone pollution in 2019 (Murray et al., 2020). The urban population exposed to ozone was
48 increased at a trend of 0.8% per year from 2000 to 2019, and the largest increases of daily maximum 8-hour mean (MDA8)
49 ozone occurred in Africa and India (Sicard et al., 2023). However, due to the lack of comprehensive studies on
50 tropospheric ozone pollution in Southern Africa, it is urgent to explore the major source contributions driving ozone
51 pollution over these less-studied regions. A better understanding of the major emission sources is not only helpful to
52 formulate actionable targeted pollution controls and to reduce air pollution risks, but also important to predict future air
53 quality in developing regions under the rapid changing of emissions and climate change.

54
55 Biomass burning (BB) emissions emit large amounts of air pollutants that are important ozone precursors (Qin et al., 2024).
56 Africa is frequently exposed to intense BB (Vernooij et al., 2021), contributing to 70% of the global BB area and nearly
57 75% of global infant deaths attributed to BB pollutants (Jiang et al., 2020; Hickman et al., 2021). Exposure to air pollution
58 from BB has strong differences in socioeconomic levels (Yue et al., 2024), with the most heavily exposed populations
59 being in Southern Africa (Xu et al., 2023). Due to the complex climate types and unique lifestyles, BB in Africa during
60 June-August months is concentrated over Southern Africa (Meyer-Arnek et al., 2005; Williams et al., 2010), and this
61 “slash-and-burn” agricultural activity could lead to the very high ozone concentrations over Southern Africa. As shown in
62 **Figure S1**, surface ozone concentrations in Southern Africa were simulated exceeding 100 ppb in July, making it to be the
63 highest ozone level worldwide. This is consistent with the previous modeling findings that BB activities are the dominant
64 driver of tropospheric ozone in this region (V. Clarmann et al., 2007). At the city level, Rwanda with observed daily ozone

65 maximum of 70 ppb during the dry season (Dewitt et al., 2019) can be affected by the transport of BB from Northern and
66 Southern Africa. The high ozone is mainly driven by BB NO_x emissions; for example, the Southern African BB can increase
67 NO_x concentrations by a factor of 2-5 in July-August months (Hoelzemann, 2006). Although BB has a great impact on
68 ozone and its precursors in Southern Africa, there are few quantitative studies on this issue.

69
70 The popular way of quantifying the role of BB is to conduct chemical transport modeling, e.g., using the ECHAM5-MOZ
71 (Aghedo et al., 2007), GEOS-Chem (Wang et al., 2022; Marvin et al., 2021), and WRF-Chem (Yang et al., 2022). The
72 ECHAM5-MOZ model simulations show that BB can increase surface ozone by more than 50 ppb in Central Africa in
73 June-August during 1997-2001 (Aghedo et al., 2007). Williams et al. (2010) used the Tracer Model version 4 to simulate
74 June-August air pollution in 2006, and they showed that BB in Southern Africa is the largest source of carbon monoxide
75 and ozone precursor emissions in Africa. However, model assessment is highly dependent on BB emission inventories and
76 there is a lack of comparative studies of different BB inventories over the Southern Africa. This is because existing BB
77 emission inventories have large uncertainties in Africa (Petrenko et al., 2012; Shi et al., 2015). The most widely-used
78 inventory for global model simulations is the Global Fire Emissions Database (GFED) (Shi et al., 2020), and other BB
79 inventories include the Quick Fire Emissions Database (QFED), the Global Fire Assimilation System (GFAS), and the Fire
80 Inventory from NCAR (FINN). The uncertainties of a factor of 2-10 among these inventories source from estimated burned
81 area, emission factors, and vegetation type (Fu et al., 2022). Depending on how fire emissions are calculated, these
82 inventories can be divided into two categories: the fuel-based bottom-up estimation (e.g., GFED and FINN) (Pechony et
83 al., 2013; Nikonovas et al., 2017) and the satellite-derived top-down estimation (e.g., QFED and GFAS) (Nikonovas et al.,
84 2017). In addition, the injected height of BB emissions is also a key factor in determining the residence time of pollutants
85 in the atmosphere that would impact the spatiotemporal distribution of tropospheric ozone (Rémy et al., 2017). Therefore,
86 it is urgent to take advantage of observational constraints to evaluate the current BB inventories and quantify their impacts
87 on tropospheric ozone in Africa.

88
89 In addition to the effects of BB, tropospheric ozone can be also affected by anthropogenic emissions in Africa. Although
90 the intensity of anthropogenic emissions is relatively low in Africa, its impact at the urban scale cannot be ignored. With
91 the rapid urbanization (Lioussé et al., 2014), mean concentrations of surface SO₂, PM_{2.5}, and PM₁₀ in Luanda have exceeded
92 European Union human health protection limits (Campos et al., 2021). More importantly, anthropogenic emissions (e.g.,
93 black carbon) are projected to be comparable with BB emissions by 2030 in Africa (Lioussé et al., 2014). Projection studies
94 also pointed out that 50% of the population will be expected to live in cities by 2050 (Aucoin and Bello-Schünemann,
95 2016), resulting in a significant increase in the population exposure to ozone in Africa. With air pollution becoming a major
96 cause of premature deaths in Africa (Julien et al., 2018), urban air pollution will likely pose more challenges in the context

97 of increasing anthropogenic emissions (Roy, 2016; Marais and Wiedinmyer, 2016; Zhang et al., 2021). However, whether
98 the current anthropogenic emission inventories are reasonable in urban Southern Africa remains unclear.

99

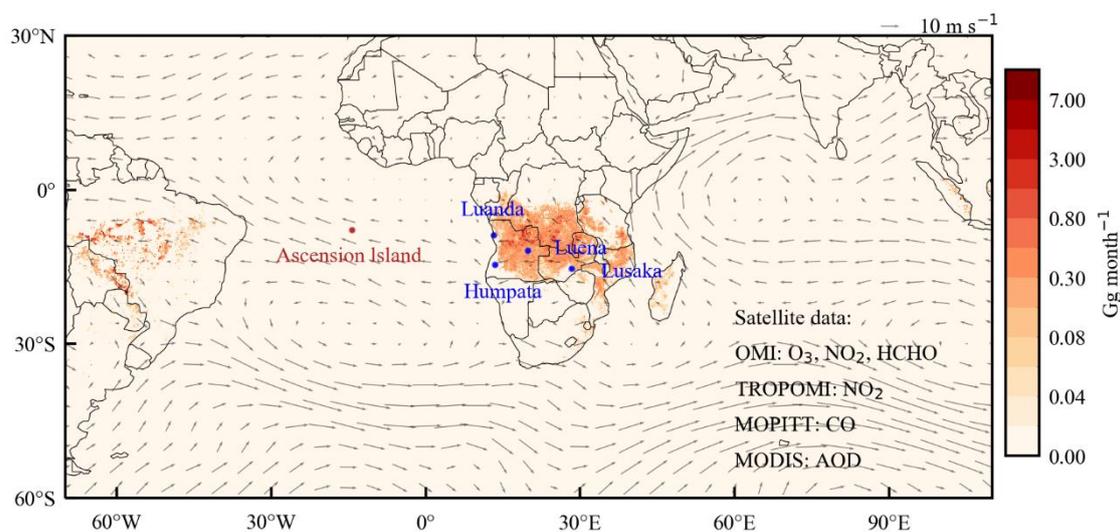

100 Lack of surface observations is a major challenge for assessment of emission inventories in Africa. About 66% of African
101 countries do not have regular air quality monitoring (Fajersztajn et al., 2014), particularly few in Southern Africa (Julien
102 et al., 2018). Recently, there are continuous surface measurements available at several major cities over Southern Africa
103 (**Figure 1**), together with the high-resolution satellite observations (e.g., TROPOMI), which could be very helpful to detect
104 urban air pollution in this region. With the worsening air pollution in Africa (Sicard et al., 2023), it is particularly timely
105 to take advantage of these valuable measurements to assess the key drivers of high tropospheric ozone in Southern Africa.

106

107 As abovementioned, there are notable uncertainties in the estimation of major emission sources over Southern Africa. The
108 assessing and predicting the impacts of emissions on air quality and health risks rely heavily on model simulations, and
109 these uncertainties in emission inventories can affect the development of effective control strategies. We therefore need to
110 utilize surface and satellite observations to gain a comprehensive understanding of the emission source contributions in
111 Southern Africa. This will help to develop effective mitigation measures to realize the Sustainable Development Goals for
112 having a healthy, climate-friendly, and resilient development in Africa.

113

114 Here we integrated the high-resolution GEOS-Chem model and newly-available measurements to estimate the impact of
115 biomass burning and anthropogenic emissions on tropospheric ozone over Southern Africa. The aim of this study is: 1) to
116 identify the best estimate of BB emissions and quantify their impacts on regional tropospheric ozone over Southern Africa,
117 and 2) to assess the representativeness of anthropogenic emission inventories in urban Southern Africa and their impacts
118 on urban ozone pollution. Observational data, model description and experimental setup are presented in Section 2. Section
119 3.1 shows the major emission sources and the high tropospheric ozone issue over Southern Africa. The estimated impacts
120 of biomass burning and anthropogenic emissions on tropospheric ozone are analysed in Sections 3.2 and 3.3, respectively.
121 Conclusions and discussion are given in Section 4.

122

123 **Figure 1.** The biomass burning NO_x emissions (shaded) and 850hpa wind fields. The BB NO_x emissions are for July-
124 August 2019 from the GFED4.1 inventory (unit: Gg month^{-1}). Blue dots represent the locations of surface observations and
125 red dot denotes the ozonesonde measurement; and satellite data used in this study are listed in the lower right corner.

126 2 Measurement data and model description

127 2.1 Surface measurements

128 **Figure 1** shows the locations of the four surface observation sites over Southern Africa. Hourly and daily real-time air
129 quality indexes (AQI) for NO_2 and $\text{PM}_{2.5}$ were obtained from the Worldwide Air Quality Index (<https://aqicn.org/station>).
130 The AQI can be converted to pollutant concentrations based on the website's AQI Calculator. There four sites record
131 continuous measurement data in the study area, namely: Humpata in Angola ($14^{\circ}95'S$, $13^{\circ}44'E$), Luanda in Angola ($8^{\circ}80'S$,
132 $13^{\circ}23'E$), Luena in Angola ($11^{\circ}76'S$, $19^{\circ}91'E$), and Lusaka in Zambia ($15^{\circ}41'S$, $28^{\circ}29'E$). The stations in Angola and
133 Zambia have been operating since mid-May 2023 and February 2022, respectively, and data for June-August 2023 were
134 selected for this study. To evaluate modeled ozone profiles, we adopted the Ascension Island's ozonesonde data from the
135 Southern Hemisphere Additional Ozone Sounding (SHADOWZ) network (<https://tropo.gsfc.nasa.gov/shadowz/>), which
136 measured ozone profile from 1998 (Thompson et al., 2000).

137 2.2 Satellite data

138 In order to investigate the model results driven by different BB emission inventories and the anthropogenic emission
139 inventories, multiple observations from the OMI (<https://disc.gsfc.nasa.gov/datasets/>), TROPOMI

140 (<https://www.earthdata.nasa.gov/sensors/tropomi>), MODIS (<https://ladsweb.modaps.eosdis.nasa.gov/search/>), and
141 MOPITT (<https://giovanni.gsfc.nasa.gov/giovanni/>) satellite instruments were used. Here, as listed in **Table S1**, we used
142 tropospheric ozone, NO₂, and HCHO observations from OMI with resolutions of 1° × 1.25°, 0.25° × 0.25°, and 0.05° ×
143 0.05°, respectively, as well as NO₂ observations from TROPOMI with a resolution of 0.125° × 0.125°. AOD and CO
144 observations with a resolution of 1° × 1° are from MODIS and MOPITT, respectively.

145 **2.3 Biomass burning emission inventories**

146 In this study, six BB emission inventories were compared: GFED4.1, GFED5, GFAS, QFED2, FINNv1.5, and FINNv2.5.
147 The GFED4.1 inventory provides dry matter emissions based on the area of BB and vegetation types from MODIS
148 observations (Marvin et al., 2021; Zhang et al., 2018). The GFED5 is an updated version of GFED4.1 and the GFED5
149 global burned area is 61 % higher than GFED4.1 (Chen et al., 2023). The GFAS inventory estimates the amount of dry
150 matter burning based on fire radiative power (FRP) (Vongruang et al., 2017). The QFED2 inventory is based on the FRP
151 method and draws on the cloud correction method developed in GFAS with the high spatiotemporal resolution. FINNv1.5
152 calculates dry matter combustion using fire hot spots (FHS) data to calculate the burned area, and FINNv2.5 builds on this
153 with extensive updates to the burned area, vegetation types, and chemicals emitted. In particular, FINNv2.5 adopted the
154 active fire detections from the Visible Infrared Imaging Radiation Suite (VIIRS) to better capture small fires, and used
155 multiple satellite products for daily fire emissions estimates (i.e., MODIS + VIIRS fire detections). The estimated BB NO_x
156 emissions from these inventories will be further discussed in Section 3.2.1.

157 **2.4 GEOS-Chem Model**

158 The atmospheric composition in Africa was simulated by using the nested version of the three-dimensional global chemical
159 transport model (GEOS-Chem, version 13.3.3; <http://acmg.seas.harvard.edu/geos/>), which was driven by the Modern-
160 Era Retrospective analysis for Research and Applications version 2 (MERRA-2) meteorological reanalysis dataset. The
161 model domain was for Africa (35°S - 30°N, 17°W - 50°E) with a horizontal resolution of 0.5° × 0.625° and a vertical
162 configuration of 47 layers. The chemical boundary conditions for the nested simulation are provided by the global GEOS-
163 Chem simulation with a horizontal resolution of 2° × 2.5°, which was updated every three hours. GEOS-Chem model
164 includes fully coupled ozone-NO_x-hydrocarbon-aerosols chemistry mechanisms. PM_{2.5} components include sulfate, nitrate,
165 ammonium, dust, sea salt, organic carbon (OC), and black carbon (BC) (Park et al., 2004).

166

167 In Africa, anthropogenic emissions are from the Community Emissions Data System (CEDS) (Hoesly et al., 2018) and
168 biogenic emissions are from the Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1 (Guenther
169 et al., 2012). We simulated hourly concentrations of ozone, NO₂, and other pollutants in Africa for 2019-2023 using the

170 nested GEOS-Chem model with a set of sensitivity simulations (**Table 1**). In order to investigate the effect of BB on
171 tropospheric ozone, we conducted three model experiments. Firstly, we used GFED4.1 and QFED2 to simulate the hourly
172 concentrations of ozone, NO₂, HCHO, and CO for July-August, 2017-2019 (Run_GFED and Run_QFED), respectively,
173 and validated the model results with satellite observations. Then, we conducted a sensitivity experiment by scaling down
174 the QFED NO_x emissions to be consistent with satellite NO₂ observation (Run_QFED_34%). We used two different BB
175 inventories and turned off aerosol chemistry to explore the effect of aerosols on ozone (Run_GFED_no-aerosol and
176 Run_QFED_no-aerosol). We also explored the effect of emission height on simulated tropospheric ozone by emitting BB
177 pollutants only within the PBL (Run_QFED_PBL).

178

179 After evaluating the BB emission inventories at the regional scale, we set up a series of experiments to explore the impact
180 of anthropogenic emissions on tropospheric ozone in Southern Africa. Firstly, we used the up-to-date QFED inventory to
181 simulate concentrations of NO₂ and PM_{2.5} in June-August 2023 (Run_QFED_2023) and compared them with five surface
182 air quality observations, and we also conducted model simulations for January-February 2020 (Run_QFED_2020) to
183 explore the effect of anthropogenic emissions on tropospheric ozone during the non-fire season. It is noted that we fixed
184 the anthropogenic emissions from CEDS at 2019 in all these simulations due to the lack of up-to-date anthropogenic
185 emission data. Based on the underestimation of surface NO₂ observations in the model, we explored the sensitivity of ozone
186 and PM_{2.5} concentrations to anthropogenic NO_x changes by a factor of 10 or 20 over the Southern Africa
187 (Run_QFED_Anth10NO_x and Run_QFED_Anth20NO_x); at the city scale, we explored the effects of perturbing
188 anthropogenic NO_x emissions in Luanda by a factor of ten for different sectors (i.e., power plant, industrial, and
189 transportation) (Run_QFED_Anth_10NO_x_Sector).

190

191 Finally, we conducted two sets of sensitivity simulations to attribute ozone to different emission sources, by turning off BB
192 emissions, natural emissions (i.e., biogenic VOC and soil NO_x), and anthropogenic emissions, respectively (**Table 1**). In
193 particular, we compared the ozone source attribution between the simulations by using the CEDS inventory and 10-fold
194 CEDS NO_x emission.

195

Table 1. GEOS-Chem model simulations

	Experiments	BB emissions	Anthropogenic emissions
Impacts of biomass burning (July-August 2017-2019)	Run_GFED	GFED4.1	CEDSv2
	Run_QFED	QFED2	CEDSv2
	Run_QFED_66%NO _x	34% reduction in QFED2 NO _x emissions	
	Run_GFED_no-aerosol	Aerosol chemistry was turned off	
	Run_QFED_no-aerosol		
	Run_QFED_PBL	100% emissions below the PBL*	
Impacts of anthropogenic emissions	Run_QFED_2023		CEDSv2
	Run_QFED_Anth10NO _x	QFED2 June-August 2023	10-fold NO _x emissions
	Run_QFED_Anth20NO _x		20-fold NO _x emissions
	Run_QFED_Anth_10NO _x _Sector		10-fold NO _x emissions of energy, industry, and transportation sectors, respectively
		Run_QFED_2020	QFED2 January-February 2020
Ozone source attribution (July-August 2019)	Run_QFED_noBB	BB emissions were turned off	
	Run_QFED_noNatI	BVOC and soil NO _x emissions were turned off	
	Run_QFED_noAnth	Anthropogenic emissions were turned off	
	Run_QFED_Anth10NO _x _noBB	BB emissions were turned off	
	Run_QFED_Anth10NO _x _noNatI	BVOC and soil NO _x emissions were turned off	
	Run_QFED_Anth10NO _x _noAnth	Anthropogenic emissions were turned off	

196

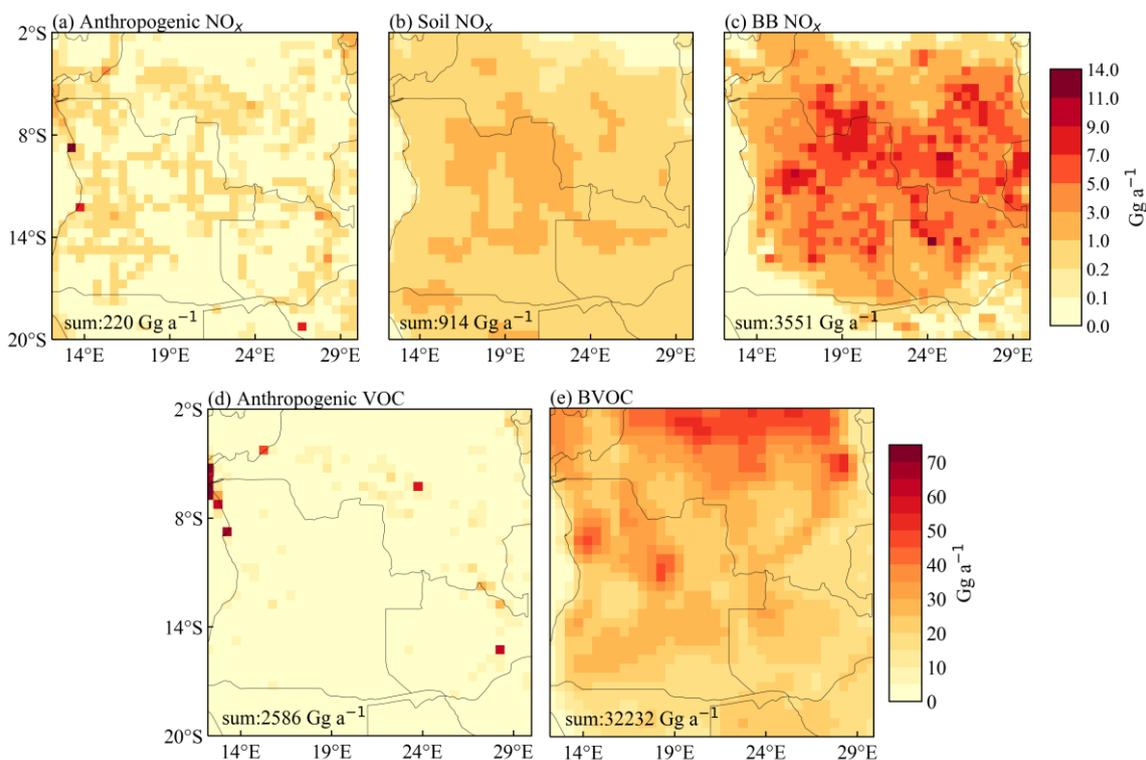

*The baseline simulation follows the vertical distribution of QFED2 emission (i.e., 65% emissions below the PBL and 35% emissions into the free atmosphere).

197

198 3. Results and discussion

199 3.1 Emission sources and simulated high ozone over Southern Africa

200

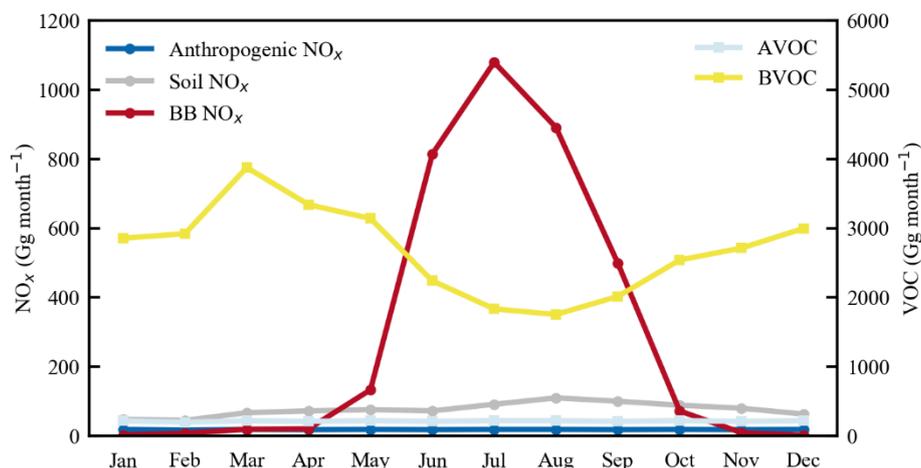

201 **Figure 2.** Spatial distributions of annual emissions of anthropogenic NO_x, soil NO_x, biomass burning NO_x, anthropogenic
202 VOC, and BVOC in 2019 (unit: Gg a⁻¹). Anthropogenic NO_x, VOC from CEDSv2 inventory, soil NO_x and BVOC from
203 Offline documents from GEOS-Chem official website, biomass burning NO_x from GFED4.1 inventory.

204

205 **Figure 2** shows the annual emissions of anthropogenic NO_x, soil NO_x, BB NO_x, as well as anthropogenic VOCs (AVOC)
206 and biogenic VOCs (BVOC) over Southern Africa in 2019, which were estimated at 220 Gg a⁻¹, 914 Gg a⁻¹, 3551 Gg a⁻¹,
207 2586 Gg a⁻¹, and 32,232 Gg a⁻¹, respectively. It should be noted that here BB NO_x emissions are from the GFED4.1
208 inventory. In terms of NO_x emissions, BB emission is the largest contributor and is about 16 times of NO_x emissions from
209 anthropogenic sources. The regions with high anthropogenic emissions are mainly Luanda, Kinshasa, and Lusaka which
210 are the capitals of Angola, the Democratic Republic of the Congo (DRC), and Zambia, respectively. High vegetation cover
211 in Southern African region leads to high BVOC emissions which are about 12 times of AVOC emissions. Seasonally,
212 **Figure 3** presents the monthly variations of ozone precursor emissions averaged over Southern Africa in 2019. The BVOC

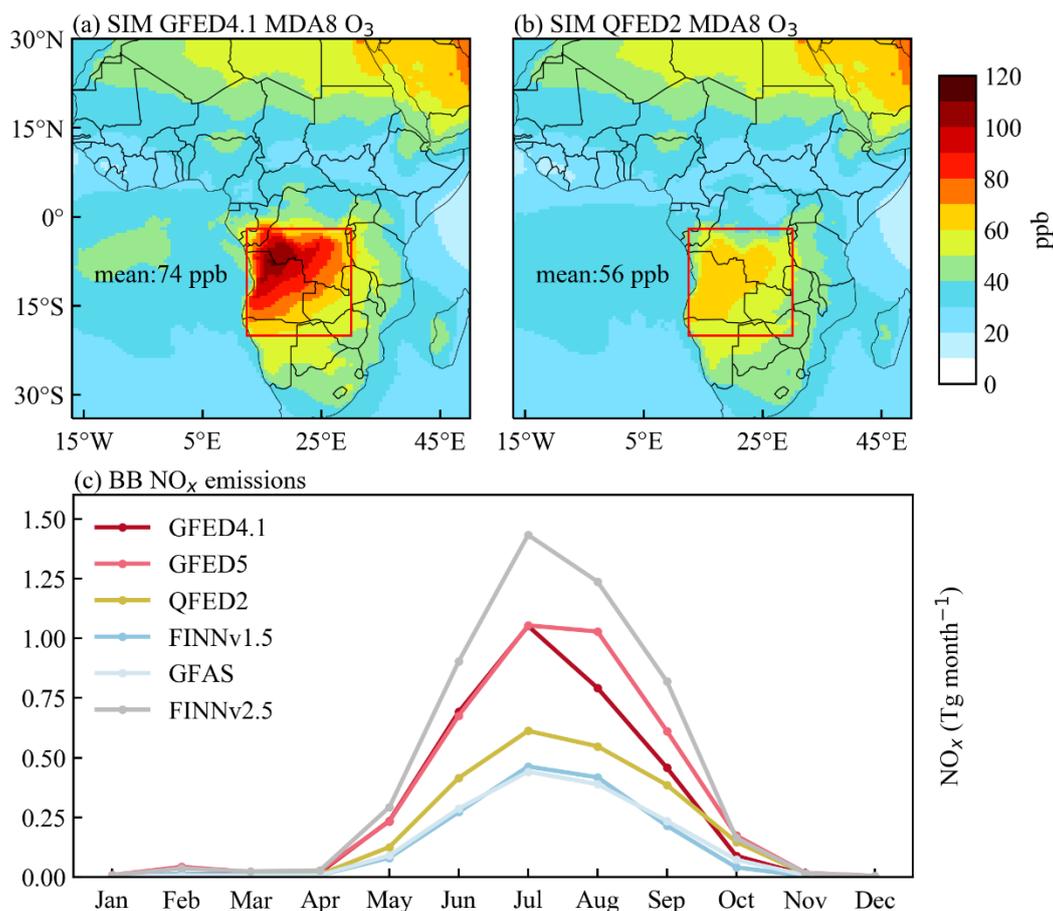

213 emission exhibits a strong seasonal pattern ranging from 2000 Gg month⁻¹ to 4000 Gg month⁻¹, and it peaks in March and
214 then decreases to the minimum in July-August. This seasonality is consistent with the seasonal variation in isoprene
215 emissions in Southern Africa in 2006 as reported by Williams et al. (2009). We can also see that NO_x from BB peaks during
216 June-August, which is consistent with the results of Boschetti and Roy (2008). Emissions of BB NO_x in January-April and
217 November-December were relatively small. The seasonal contrast in BB NO_x and BVOC emissions highlights the
218 importance of BB in the production of high summer tropospheric ozone in this region (Vieira et al., 2023).

219
220 **Figure 3.** Seasonal variations in anthropogenic NO_x (deep blue), soil NO_x (grey), biomass burning NO_x (red),
221 anthropogenic VOC (blue), and biogenic VOC (yellow) emissions in 2019 (unit: Gg month⁻¹). Anthropogenic NO_x, VOC
222 from CEDSv2 inventory, soil NO_x and BVOC from Offline documents from GEOS-Chem official website, biomass
223 burning NO_x from GFED4.1 inventory.

224
225 **Figure 4a** shows the simulated spatial distribution of MDA8 ozone in July-August of 2019 in Africa by using the GEOS-
226 Chem model with the GFED4.1 inventory (Run_GFED). The regional average of MDA8 ozone in Southern Africa is about
227 74 ppb and the maximum can be up to 120 ppb in northern Angola and southwest Congo. Dewitt et al. (2019) observed a
228 daily ozone maximum of 70 ppb during the dry season in Rwanda, which is adjacent to the DRC. Based on our simulation

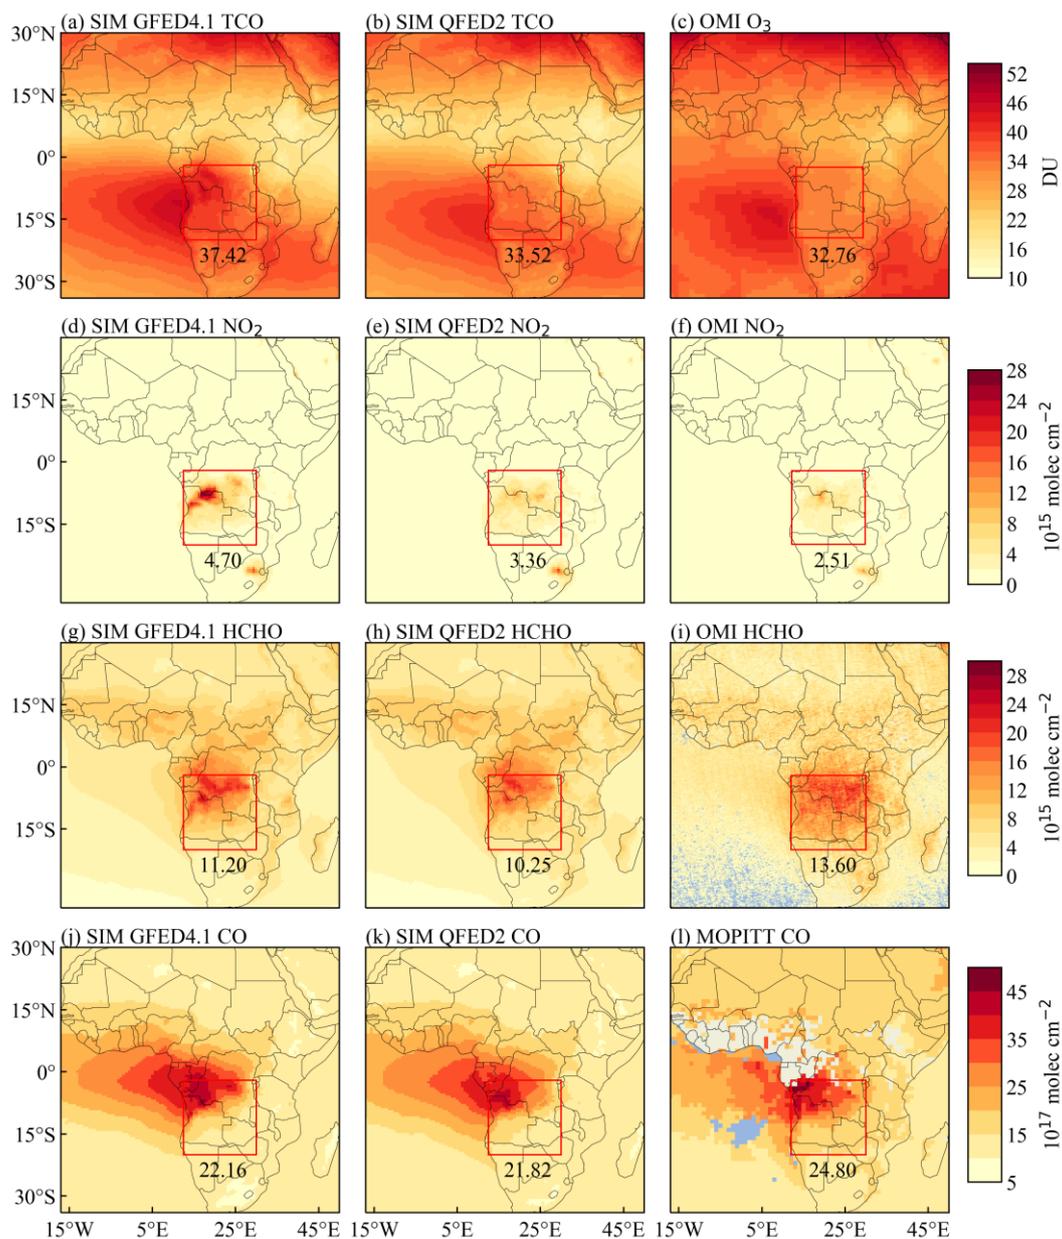

229

230 **Figure 4.** Differences in BB NO_x emissions and modeled surface ozone from different inventories. (a-b) Surface MDA8
231 ozone simulated by GEOS-Chem model for July-August 2019 by the GFED4.1 and QFED2 inventories, respectively. (c)
232 Monthly BB NO_x emissions in 2014 averaged over the Southern African region.

233

234 results, it can be found that the daily maximum ozone during the BB season is 86 ppb for Rwanda. This comparison
235 indicates an overestimation in the baseline simulation (Run_GFED). **Figure 5a** shows the spatial distribution of
236 simulated tropospheric column ozone concentrations (TCO), with maximum values of up to 50 DU mainly in northern
237 Angola and southwest Congo. Higher TCO levels are also seen over the Atlantic Ocean, which are mainly associated
238 with long-range transport (Williams et al., 2010; Meyer-Arnek et al., 2005). The above results confirm that BB
239 contributes greatly to high ozone concentrations during the fire season in Southern Africa. As such, a better understanding
240 of the high ozone over Southern Africa would depend on the accurate estimate of BB emissions.

241

242 **Figure 5.** The comparison of GEOS-Chem simulated (left and middle panels) and satellite-based (right panels) tropospheric
243 columns for ozone and its precursors. The simulated TCO, NO₂, HCHO, and CO columns in Africa for July-August 2019
244 were driven by the GFED4.1 and QFED2 inventories, respectively. For CO satellite data, only the July value was used due
245 to the large amount of missing measurement in August. The numbers in the figure are the mean values in the red boxed
246 area.

247 **3.2 Impacts of biomass burning (BB) on tropospheric ozone**

248 **3.2.1 Uncertainties in BB emission inventories**

249 Although the GEOS-Chem model has been widely employed for modeling tropospheric ozone globally (Balamurugan et
250 al., 2021; Li et al., 2023), its evaluation against measurements over Southern Africa is very limited. In order to accurately
251 evaluate the effects of BB emissions on tropospheric ozone, we need to take the uncertainties from different BB emissions
252 into account (Wiedinmyer et al., 2023).

253

254 **Figure 4c** shows the monthly emissions of BB NO_x in 2014 for the Southern Africa from the six emission inventories
255 (GFED4.1, GFED5, QFED2, GFAS, FINNv1.5, and FINNv2.5). All of the six BB inventories share the similar seasonality
256 in NO_x emissions, but there are large differences with a factor of 2-3 in estimated emission intensities, particularly in the
257 dry season. The inventory was divided into two groups based on the level of emissions, with the high emission groups
258 being FINNv2.5, GFED5, and GFED4.1. FINNv2.5 shows the highest BB NO_x emissions, which are 45% higher than
259 GFED4 emissions and 130% higher than QFED2 emissions, but Wiedinmyer et al. (2023) also suggests that FINNv2.5
260 probably tends to overestimate NO_x emissions in Africa. GFED5 is an updated version from GFED4.1, and their difference
261 in NO_x emissions is minimum in January-July and enlarged in August. The low emission groups are: QFED2, GFAS, and
262 FINNv1.5. GFAS and FINNv1.5 resemble in the estimated NO_x emissions but both of them are significantly lower than
263 the other inventories. This may be attributed to the underestimated burned area and emissions in FINNv1.5 (Wiedinmyer
264 et al., 2011). Therefore, in the following, we will use the GFED4.1 and QFED2 inventories to represent the high estimate
265 and low estimate of BB NO_x emissions for Southern Africa, respectively.

266 **3.2.2 Simulated tropospheric ozone with different BB emissions**

267 **Figures 4a-4b** show the simulated spatial distribution of MDA8 ozone in Africa during the fire season (July-August) in
268 2019 by using the GEOS-Chem model with the GFED4.1 and the QFED2 inventories, respectively. The simulated surface
269 MDA8 ozone by the GFED4.1 inventory is 74 ppb over Southern Africa, which is 32% higher than the value of 56 ppb by
270 the QFED2 inventory. The maximum value of MDA8 ozone by the GFED4.1 inventory can reach up to 120 ppb, but the
271 maximum value by the QFED2 inventory is only 70 ppb. This remarkable discrepancy suggests that the uncertainties of
272 surface ozone over Southern Africa are largely dependent on BB emissions. For the tropospheric ozone, **Figures 5a-5b**
273 show the simulated spatial distribution of TCO by using the GFED4.1 and QFED2 inventories. In contrast to surface ozone,
274 the regional average of TCO simulated by the GFED4.1 inventory is only 4 DU (11%) higher than that simulated by the
275 QFED2 inventory.

276 To evaluate whether the model performance in the vertical profile of tropospheric ozone in Africa, we compared the model

277 results with ozonesonde observations from Ascension Island, UK (7°96'S, 14°91'W) in **Figure 6**. As shown in **Figure 1**,
278 Ascension Island is located downwind of the high BB area, and ozone and its precursors from BB can be transported from
279 Southern Africa to the South Atlantic (Mari et al., 2008), leading to ozone enhancement in Ascension Island (Jenkins et al.,
280 2021). The ozone concentrations modeled by GEOS-Chem respond well to the ozonesonde observations in terms of vertical
281 distribution, and in particular the model captures the variation in observations with altitude well. The differences in ozone
282 concentrations due to the two BB inventories are small in vertical distribution, and are mainly concentrated below 1.5 km
283 with ozone concentrations differing by about 3 ppb. This is consistent with the results of small TCO differences in **Figures**
284 **5a-5b**. Compared to the ozonesonde observations, GEOS-Chem captures the ozone variations well regardless of which
285 inventory is used.

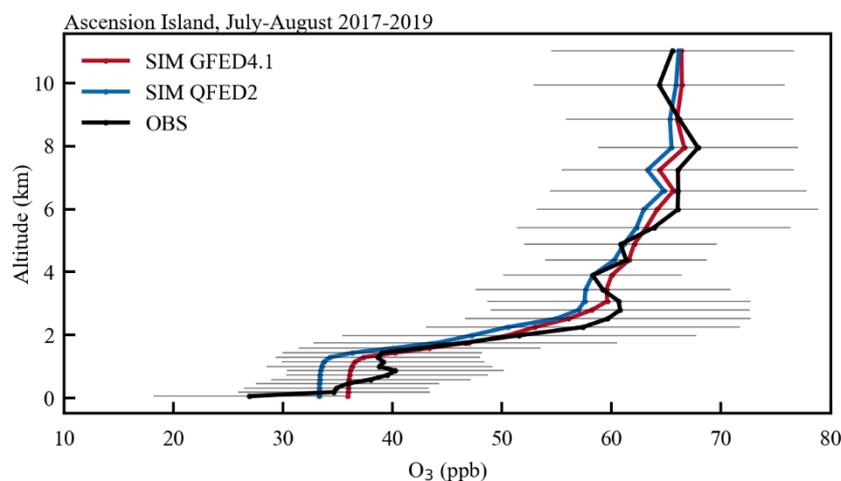

286

287 **3.2.3 Satellite constraints on BB emission estimates**

288 In order to evaluate the tropospheric ozone simulation in Africa region, in **Figure 5** we compared the simulated columns
289 with GFED4.1 and QFED2 inventories against satellite observations of TCO and ozone precursors (e.g., NO₂, CO, and
290 HCHO). The simulated TCO with GFED4.1 inventory shows high values of up to 50 DU near the fire source regions in
291 northern Angola and southern DRC, and in the downwind region over Atlantic Ocean. The OMI TCO has the regional
292 average of 37.4 DU, suggesting an overestimation of 14% in the GFED4.1 simulation relative to OMI. In contrast, the
293 simulated TCO with QFED2 inventory is strongly spatially consistent with the OMI satellite, with a slight overestimation
294 of 2.3%.

295

296 **Figures 5d-5e** show the simulated and observed tropospheric NO₂ columns. The GFED4.1 inventory simulation exhibits
297 high value of up to 28×10^{15} molecule cm⁻² near the BB source region, but there is a large overestimation of 87% with
298 respect to the OMI satellite data. Similar conclusions are also from Anderson et al. (2021) that the model using the GFED4.1
299 inventory can capture high NO₂ in Africa but the bias was as high as 100%. This is in agreement with previous studies that
300 model simulations trend to produce a high bias towards BB activities in Africa (Souri et al., 2024). However, the QFED2
301 inventory simulation can greatly reduce this high bias, with an overestimation of only 34%. In **Figure S2**, we also compared
302 model results with the TROPOMI satellite, and a similar high bias was also found in the modeled NO₂ columns. If we
303 further have QFED2 NO_x emissions reduced by 34%, as shown in **Figure S3**, it can effectively reduce the bias for NO₂
304 columns from 34% to 0.4% and reduce the overestimation of the TCO columns to 1.1%. This sensitivity simulation
305 demonstrates the importance role of BB NO_x emissions in tropospheric ozone production.

306

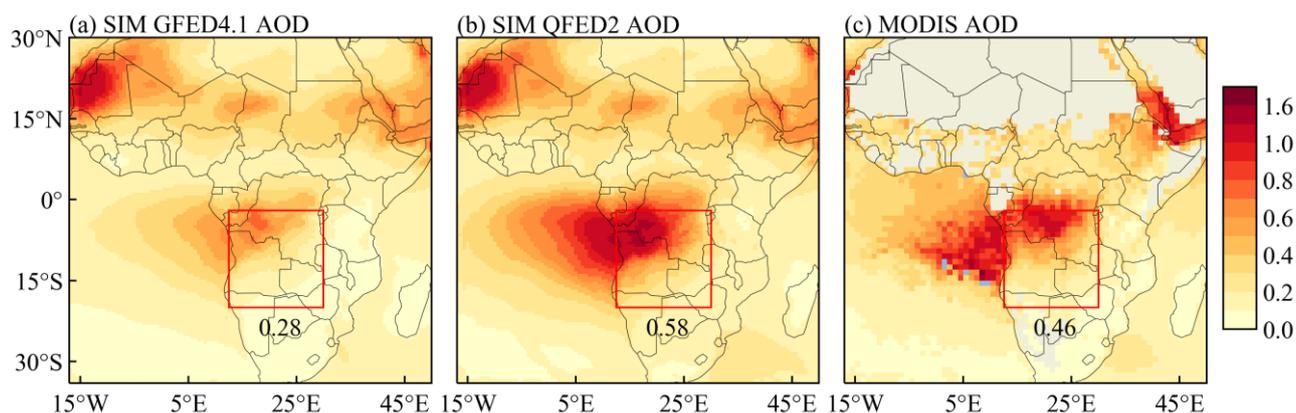

307 **Figure 6.** The comparison of GEOS-Chem simulated and measured vertical ozone distributions over the Ascension Island,
308 UK, for July-August 2017-2019. The model results by the GFED4.1 (red) and QFED2 (blue) inventories are both given.

309

310 **Figures 5g-5i** show the simulated and satellite-derived tropospheric HCHO columns. The HCHO column concentrations
311 simulated by GEOS-Chem are generally consistent with satellite observations, with high values of up to more than $20 \times$
312 10^{15} molecule cm^{-2} in northern Angola and southwest DRC. Simulated HCHO column concentrations between the
313 GFED4.1 and QFED2 inventories were consistent spatially, with only a difference of 1×10^{15} molecule cm^{-2} on a regional
314 basis. The levels and spatial distributions of HCHO are mainly influenced by BVOC and BB emissions. Firstly, the Congo
315 Basin, as one of the largest tropical rainforests, emits a large amount of BVOCs that can be oxidized to generate high values
316 of HCHO (Wells et al., 2020). It leads to the spatial distribution of HCHO similar to the distribution of BVOC sources.
317 Secondly, BB is found to be one of the main sources of HCHO in the African continent (Liu et al., 2020). Differences in
318 VOC and NO_x emissions between GFED4 and QFED inventories (Van Der Werf et al., 2017), e.g., BB VOC emissions in
319 GFED4.1 being two times of the QFED2 inventory in 2019, may account for the slightly different HCHO columns.

320

321 The simulated CO columns in **Figures 5j-5l** are spatially similar to MOPPIT retrievals, with high values in the downwind
322 regions of fire sources. The regional average of CO column concentrations simulated by GEOS-Chem is underestimated
323 by approximately 10% compared to MOPITT. Hoelzemann (2006) used a variety of BB emission inventories to drive the
324 MOZART model to simulate CO concentrations in Southern Africa in September-October 2000, and they showed that all
325 simulations exhibited an underestimation against the MOPITT CO. In addition, we also found that the simulated spatial
326 distribution of CO columns is similar with each other among different BB inventories, and their regional difference is only
327 1%. This suggests that neither HCHO nor CO is the main reason for the overestimation of ozone production.

328

329 **Figure 7.** The comparison of GEOS-Chem simulated AOD in Africa in July-August 2019 with the MODIS AOD. The
330 model results by the GFED4.1 (left) and QFED2 (middle) inventories are both given.

331

332 **Figure 7** shows the spatial distribution of modeled and satellite-based AOD. The simulation results by both inventories
333 can capture the spatial variability of MODSI AOD. But simulated regional mean AOD by the QFED2 inventory
334 overestimated MODIS AOD by 26%, while the GFED4.1 inventory underestimated MODIS AOD by 37%. Tian et al.
335 (2019) used GFED4 as an input to drive the GEOS-Chem model and also showed that the model tended to underestimate
336 the intensity and spatial distribution of AOD in the African region. The inconsistency between these two inventories may
337 be attributed to the discrepancy in carbonaceous aerosol emissions, since the OC and BC emissions from GFED4 are only
338 half of the QFED emissions (Chang et al., 2023). In addition, the difference between OC and BC in the biomass burning
339 emission inventories could affect ozone simulation through aerosol chemistry, and the results are shown in **Figure S4**.
340 After turning off aerosol chemistry alone in the model, regional surface ozone was increased by 10 ppb and TCO by 2 DU
341 using the GFED4.1, while using the QFED2 regional ozone was increased by 14 ppb and TCO by 4 DU. As such, the
342 lower level of aerosols in GFED4.1 may be a reason for the overestimation of simulated ozone concentrations.

343

344 In conclusion, the widely-used GFED4.1 inventory has a large bias in simulating tropospheric ozone in Southern Africa,
345 and the QFED2 inventory exhibit much more consistent with satellite observations. This bias is mainly due to the
346 overestimation of NO_x emissions in Southern Africa in GFED4.1. Firstly, NO_x emissions in GFED4.1 are 38% higher than
347 in QFED2 in Southern Africa. Secondly, the modeled NO_2 column in GFED4.1 shows a high bias compared to QFED2
348 and satellite observations, while the modeled HCHO and CO columns are generally consistent between GFED4.1 and
349 QFED2 inventories. Thus, we conclude that the overestimation of ozone in Southern Africa simulated with GFED4.1 is
350 due mainly to the overestimation of NO_x and the lower aerosol levels in GFED4.1 may be a minor reason for the
351 overestimation of modeled ozone concentrations. We will use the QFED2 inventory for BB emissions in the following

352 analysis.

353 **3.2.4 Role of BB emission heights in ozone simulation**

354 The representativeness of BB emission injection heights is also an important factor that can impact ozone simulations
355 (Rémy et al., 2017). We conducted a sensitivity experiment using the QFED2 inventory and allowed all BB emissions
356 emitting below the PBL. As shown in **Figure 8**, the impact of this vertical partitioning on surface ozone varies regionally.
357 At the surface, the changes of MDA8 ozone were within ± 2.4 ppb and the BB source areas showed a decreased ozone. For
358 TCO, the simulated mean values with this vertical partitioning were 0.2 DU higher than those without vertical partitioning,
359 but the magnitude of this effect is smaller than the TCO changes (~ 4 DU) caused by the difference in BB NO_x emissions
360 between GFED4.1 and QFED2 inventories. Thus, our simulations demonstrate that the configuration of BB emission height
361 has a limited effect on surface ozone level but a moderate influence on TCO columns in this region.

362

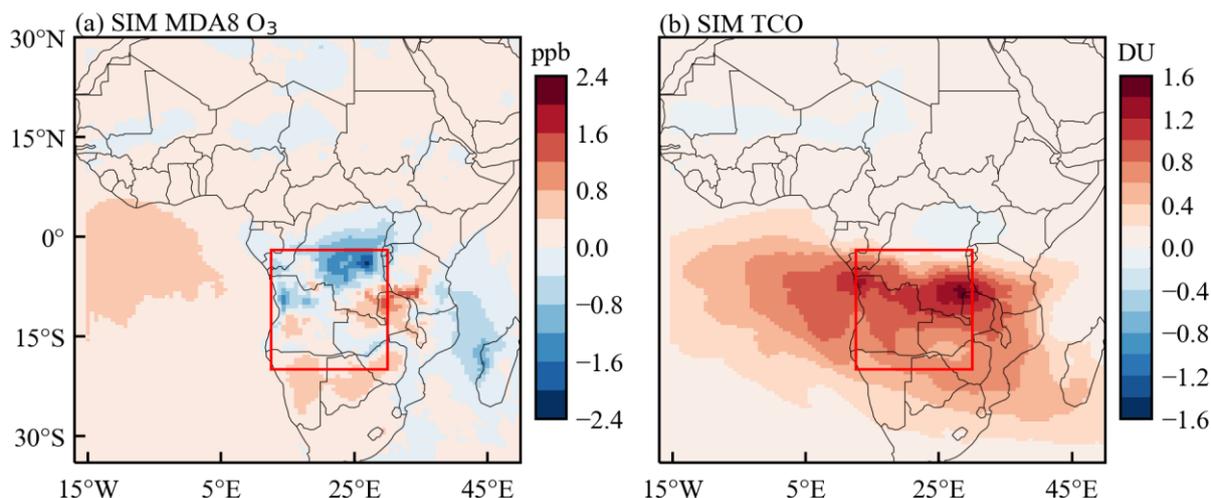

363 **3.3 Impacts of anthropogenic emissions on tropospheric ozone**

364 **3.3.1 Uncertainties in anthropogenic emission inventories**

365 Uncertainties may exist in anthropogenic emissions from regional scale to urban cities in Southern Africa. For example, in
366 **Table 2** we compared the differences in NO_x emissions between two widely-used global inventories: CEDSv2 and HTAPv3.
367 Whether in Southern Africa or Luanda, there is a missing seasonality in NO_x emissions in CEDSv2, whereas NO_x
368 emissions in HTAPv3 are much higher in January-February than in other months. Over the Southern Africa, monthly
369 NO_x emissions in the CEDSv2 are about 30% lower than the HTAPv3 in January-February. For Luanda, the CEDSv2
370 inventory is 87% lower than HTAPv3 in January-February 2018 and 20-50% lower in the other months. In addition, the
371 validation of anthropogenic emission in global inventories was barely evaluated in this region and we will take advantage
372 of recently available surface measurements and satellite retrievals to fill this gap.

373 **3.3.2 Model evaluation against surface measurements of NO_2 and $\text{PM}_{2.5}$**

374 Currently, there are very few surface observations in Southern Africa. However, in the study, there are three cities (Humpata,
375 Luanda, and Luena) that have continuous surface measurements of NO_2 during the period of June-August 2023, and four
376 cities (Humpata, Luanda, Luena, and Lusaka) with surface measurements of $\text{PM}_{2.5}$. These measurements are critical to
377 understand the hotspots of urban anthropogenic emissions as indicated in **Figure 2a**. Luanda is the capital of Angola with
378 dense population, and the median surface NO_2 concentrations observed at this station ranged from 10 ppb to 30 ppb. The

379

380 **Figure 8.** Effects of vertical partitioning of model BB emissions in surface MDA8 ozone and tropospheric ozone columns.
 381 The baseline simulation follows the vertical distribution of QFED2 emission (i.e., 65% emissions below the PBL and 35%
 382 emissions into the free atmosphere), and the sensitivity simulation allows 100% BB emissions emitted below the PBL.
 383 Here the plots are the differences between the baseline simulation (Run_QFED) and sensitivity simulation
 384 (Run_QFED_PBL).

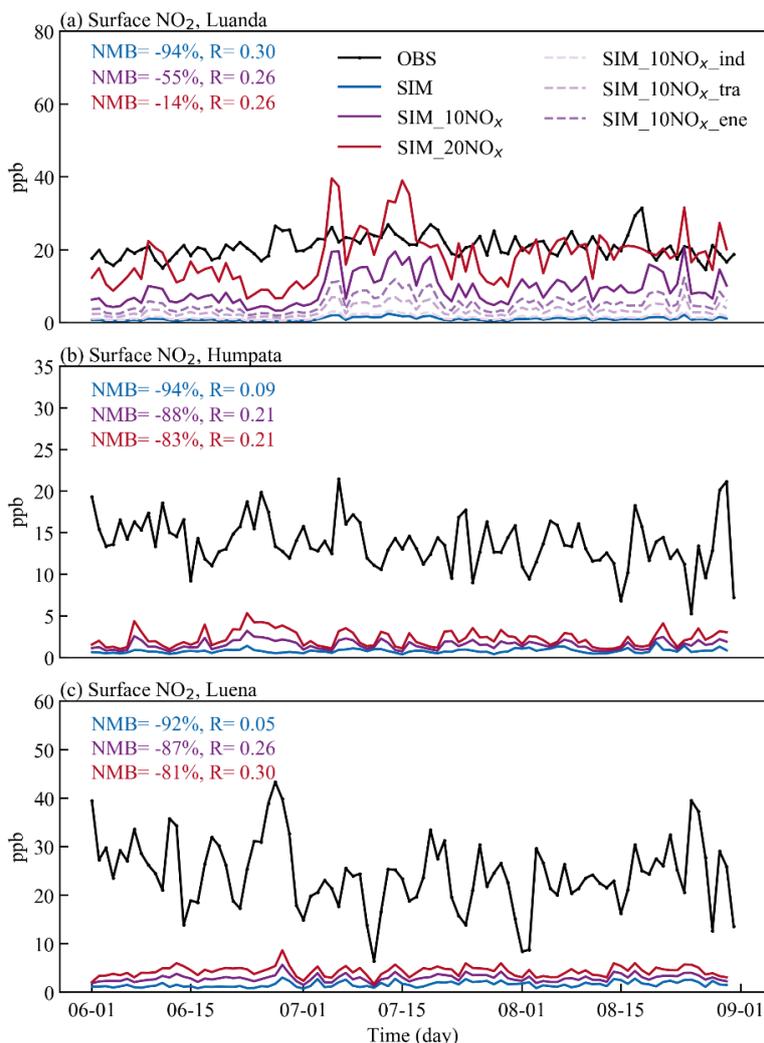

385

386 **Table 2.** Monthly anthropogenic NO_x emissions in Southern Africa and Luanda (unit: Gg month⁻¹).

		Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.
Southern Africa	CEDSv2	18.2	16.5	18.2	17.6	18.2	17.6	18.2	18.2	17.6	18.2	17.6	18.2

387

388 Humpata station is located at Universidade Privada de Angola, where the observed NO₂ concentrations ranged from 5 ppb
 389 to 25 ppb, with large day-to-day variations of up to 20 ppb. The Luena station is located in a residential area of Luena,
 390 where the observed NO₂ concentrations were much higher than those of the previous two stations, with a maximum of 50
 391 ppb. **Figure 9** shows the comparison of the observed and simulated daily surface NO₂ concentrations in Luanda, Humpata,
 392 and Luena, respectively. Compared with the observed values, the modeled NO₂ concentrations for all three cities are much

393

394 **Figure 9.** Time series of simulated and observed daily median surface NO₂ concentrations in Southern African cities
395 (Luanda, Humpata, Luena) in June-August 2023. The model was driven by the QFED2 inventory and fixed CEDSv2
396 inventory in 2019. The "SIM" denotes the baseline simulation (Run_QFED_2023), and "SIM_10NO_x", and "SIM_20NO_x"
397 denote the 10-fold and 20-fold increase in NO_x emissions from CEDSv2. The dashed lines indicate a 10-fold increase in
398 NO_x emissions from the energy (ene), industry (ind) and transportation (tra) sectors, respectively, in the CEDSv2 inventory.
399

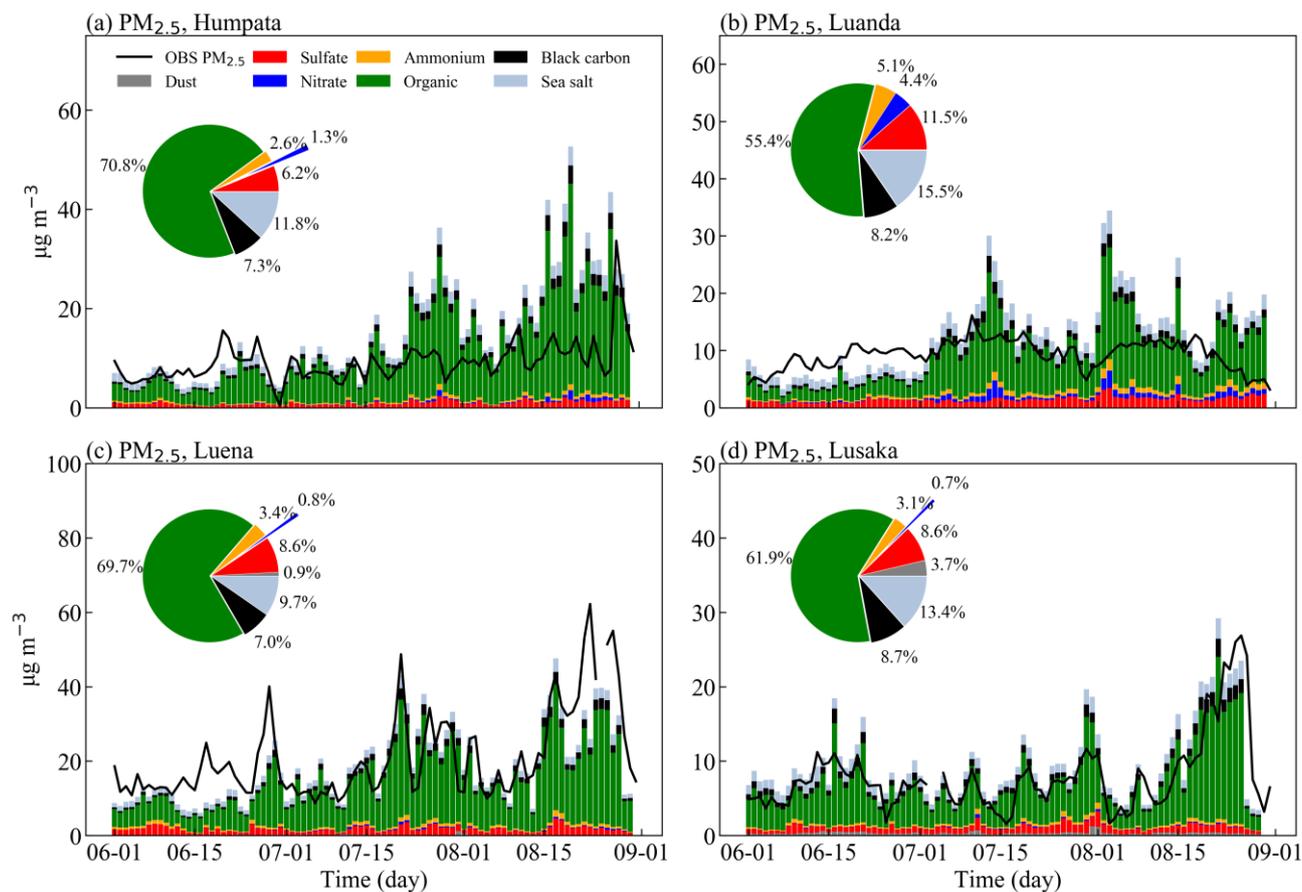

400 lower than the observed values, underestimated by 90%. There is also a large underestimation of surface NO₂ in Luanda
401 compared to the observations from Campos et al. (2021). This indicates that urban NO_x emissions in our model are highly
402 underestimated in Southern Africa.

403 To test the sensitivity of simulated NO_2 concentration to urban emissions, we increased the NO_x emissions in the CEDSv2
404 inventory by a factor of 10, and the model results are shown in **Figure 9**. In Luanda, the Normalized Mean Bias (NMB) of
405 simulated NO_2 concentrations will be decreased from -94% in the baseline simulation to -55%, while the changes of NO_2
406 in Humpata and Luena are very limited with an improvement of the NMB of only 5%. Even if when NO_x emission is scaled
407 up by a factor of 20, the simulated NO_2 concentrations in Humpata and Luena are increased by only 11-21%. For Luanda,
408 there is a NMB of -50% in modeled surface NO_2 with 10-fold NO_x emissions, and previous studies have shown that the
409 GEOS-Chem model tends to underestimate observed surface NO_2 concentration by above 50% in urban air (Silvern et al.,
410 2019), which may suggest that the upper limit of the underestimation in NO_x emissions from CEDSv2 inventory in Luanda
411 is a factor of 10. But for Humpata and Luena, the CEDSv2 inventory is not capable to correctly estimate the anthropogenic
412 sources, leading to the small sensitivity of simulated NO_2 concentration to perturbed urban emissions.

413
414 Although this study focused on ozone simulation, the comparison of model results against the valuable $\text{PM}_{2.5}$ measurements
415 will be also meaningful to understand urban emissions in this region. **Figure 10** shows the time series of observed and
416 simulated $\text{PM}_{2.5}$ concentrations in June-August 2023. The $\text{PM}_{2.5}$ concentrations observed at both the Humpata and Luanda
417 sites were around $10 \mu\text{g m}^{-3}$. The $\text{PM}_{2.5}$ concentrations at the Luena site were slightly higher compared to the other two
418 sites, with median concentrations ranging from $10 \mu\text{g m}^{-3}$ to $70 \mu\text{g m}^{-3}$. Lusaka is the capital of Zambia and the observed
419 site is located within the urban area of Lusaka, where $\text{PM}_{2.5}$ concentrations were about $10 \mu\text{g m}^{-3}$ in June-July and then
420 suddenly increased to about $20 \mu\text{g m}^{-3}$ in August. **Figure S5** shows the comparison of simulated and observed $\text{PM}_{2.5}$
421 concentrations, and the model can capture the day-to-day variation in $\text{PM}_{2.5}$ concentrations at Luena as well as Lusaka sites,
422 with NMBs of -12% and 24% and correlation coefficients of 0.7 and 0.87, respectively. But in Luanda and Humpata, there
423 is a large overestimation in simulated $\text{PM}_{2.5}$ concentration and a large proportion of $\text{PM}_{2.5}$ components is contributed by
424 dust, possibly due to the influence of the Namib and Kalahari Deserts (Nyasulu et al., 2023). We excluded dust
425 concentration in the calculation of total $\text{PM}_{2.5}$ concentration for the time being, due to its large uncertainties in the GEOS-
426 Chem simulation (Weagle et al., 2018). After removing dust concentration, the NMB in the model will be reduced from
427 149% to 37% in Luanda.

428
429 In terms of $\text{PM}_{2.5}$ components, the highest contribution of OC to $\text{PM}_{2.5}$ concentrations is found at all the four sites, which
430 can be attributed to the effects from biomass burning (Nyasulu et al., 2023). Secondary inorganic aerosols account for
431 about 20% at Luanda and about 10% at other sites. In addition, we also compared the changes in $\text{PM}_{2.5}$ concentration
432 at each site after scaling up anthropogenic NO_x emissions by a factor of 10, and found that $\text{PM}_{2.5}$ at the Luanda site
433 can increase by up to $50 \mu\text{g m}^{-3}$. In previous studies, changes in $\text{PM}_{2.5}$ concentrations in Southern Africa have often
434 been attributed to BB (Nyasulu et al., 2023; Booyens et al., 2019). However, this study shows that anthropogenic

Figure 10. Comparison of simulated time series of PM_{2.5} and its components against with the observed PM_{2.5} (black line) during June-August 2023. (a) and (b) are for Humpata and Luanda, respectively, where we removed dust concentrations from the simulated PM_{2.5} due to the large uncertainties in the model, and (c) and (d) are for Luena and Lusaka, respectively. The pie charts show the percentage contributions of each component to total PM_{2.5} concentrations.

emissions in Luanda could also have a great impact on PM_{2.5} concentrations, highlighting the underappreciated role of anthropogenic emissions in urban air quality over the Southern Africa.

We further explored the sensitivity of ozone concentration to perturbed NO_x emissions. **Figure S6** shows the response of ozone concentration at each site after anthropogenic NO_x was increased by 10 times. Relative to the baseline run, the ten-fold NO_x simulation can increase ozone concentrations by 0-10 ppb in the Humpata and Luean regions. However, in Luanda there was increased ozone in June but decreased ozone in July-August in response to ten-fold NO_x emissions, indicating

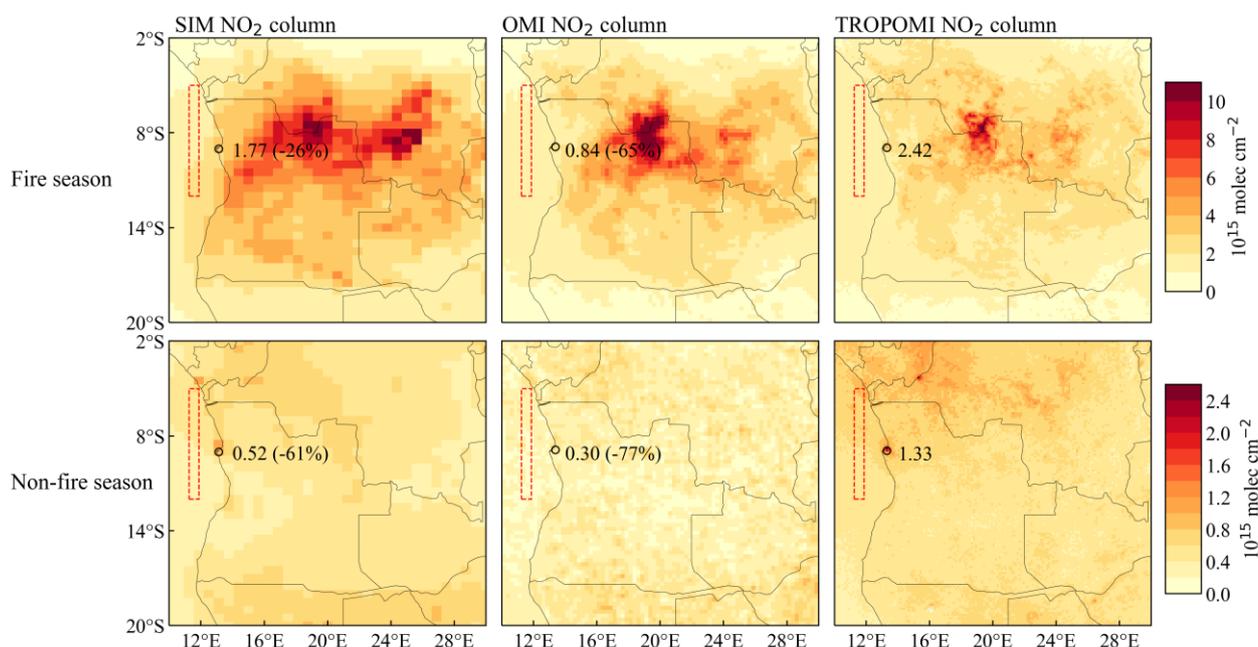

448 that ozone chemistry in Luanda may be likely shift into transition regime with increasing emissions. Again, these results
449 confirm that the underestimation of anthropogenic emissions in the urban areas of Southern Africa now can have an
450 important impact on local ozone assessment.

451
452 Although there is a lack of surface ozone observations in Southern Africa that can be directly compared with our model
453 results, we can conclude from the model evaluation against surface NO_2 and $\text{PM}_{2.5}$ measurements: 1) the large
454 underestimation in modeled urban scale NO_2 in Southern Africa is mainly due to high biases of NO_x emission in the
455 CEDSv2 inventory, i.e., an underestimated by a factor of about 10 in Luanda and the misrepresentation of anthropogenic
456 emissions estimates in Humpata and Luena, 2) the model is able to capture the observed variations in $\text{PM}_{2.5}$ concentrations
457 in the areas that are less affected by dust, and 3) the bias in anthropogenic emission inventories can strongly affect the
458 assessment of $\text{PM}_{2.5}$ and ozone concentrations in urban Southern Africa.

459 3.3.3 Model evaluation against satellite measurements

460 Satellite observations were further used to support the deduction of the underestimated urban emissions. As the capital of
461 Angola, Luanda is of much higher anthropogenic emissions compared to other cities in Southern Africa. In the following,
462 we focused on Luanda where satellite signals could be stronger to detect NO_x emissions. **Figure 11** shows the simulated
463 and satellite-based NO_2 columns for fire season (July-August 2019) and non-fire season (January-February 2020),
464 respectively. To minimize the effects from background levels, here the NO_2 values are the columns at Luanda minus the
465 mean columns averaged over the sea downwind. For July-August 2019, the urban NO_2 enhancement in Luanda simulated
466 by the model was 26% lower than that observed by the TROPOMI; for January-February 2020, the simulated NO_2
467 enhancement was underestimated by 61% compared to TROPOMI. The moderate underestimation during fire season (July-
468 August 2019) in Luanda can be attributed to the long-term transport of BB emissions to the urban region. As suggested by
469 TROPOMI satellite, therefore, NO_x emissions from CEDSv2 were underestimated by at least a factor of 2 in urban Luanda.
470 At the same time, we find that the NO_2 enhancement in Luanda observed by OMI was 70% lower compared to TROPOMI
471 and the OMI instrument cannot detect the high emissions in Luanda, demonstrating the advantage of TROPOMI instrument
472 in observing regions like Southern Africa.

473
474 To further identify the key emission sectors in Luanda, we perturbed the NO_x emissions from three sectors (transportation,
475 industrial, and energy) by a factor of 10 in **Figure 9a**. Surface NO_2 concentrations in Luanda responded better to changes
476 in NO_x emissions from the energy and transportation sectors, with NMB reduced by 20% and 11%, respectively. **Figure**
477 **S7** shows the NO_2 column changes in response to the emission perturbations. When all sources of NO_x emissions in the
478 CEDSv2 inventory were increased by a factor of 10, the simulated NO_2 column enhancement in Luanda will be 3-4 times

479

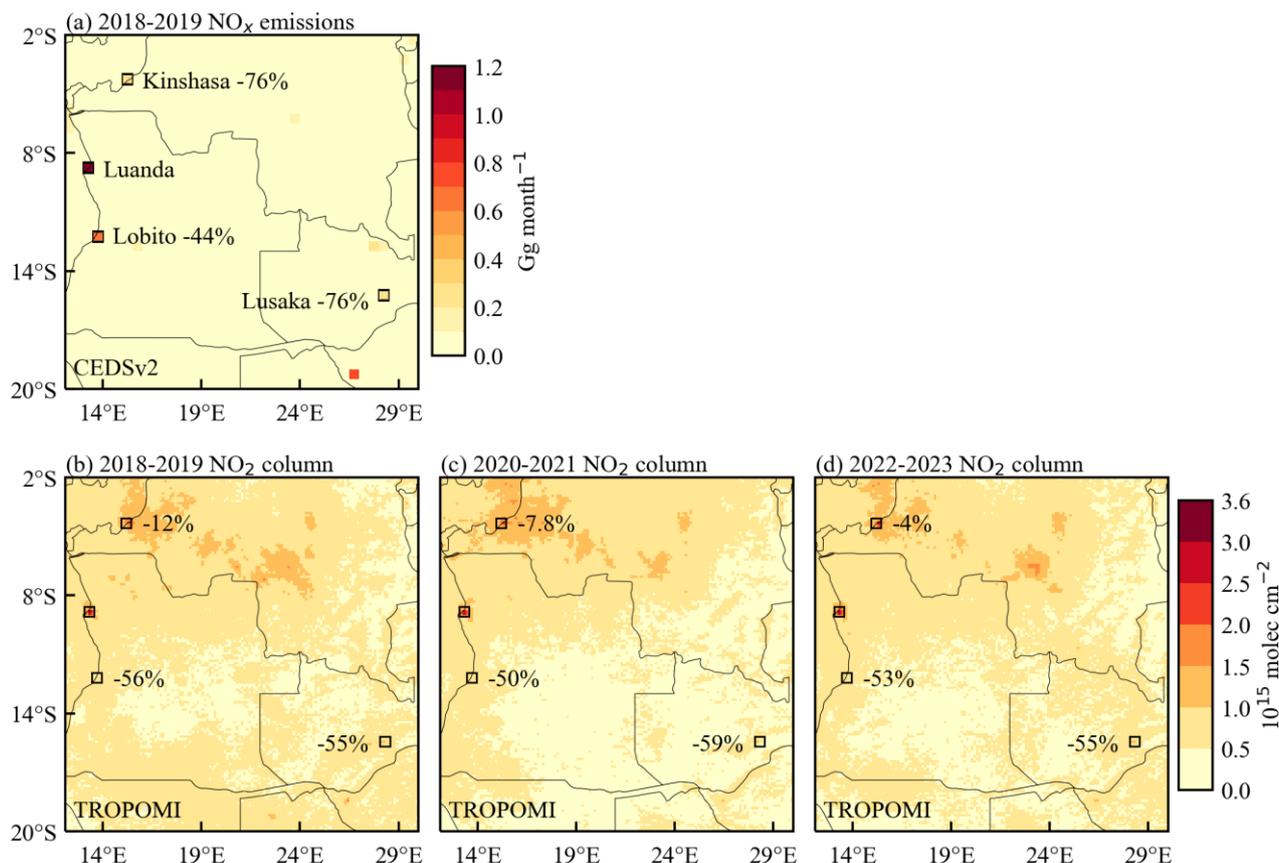

480 **Figure 11.** Spatial distribution of NO₂ columns from the model, OMI, and TROPOMI during the fire season (top) and non-
481 fire season (bottom). Circles indicate the Luanda city and numbers around them indicate NO₂ column enhancement in the
482 Luanda city. The dashed boxes indicate the downwind ocean region whose concentrations were subtracted to obtain the
483 NO₂ column enhancement in Luanda. Percentages are their difference in Luanda relative to the observed NO₂ columns
484 from TROPOMI.

485

486 the TROPOMI measurement. Namely, the ten-fold increase in NO_x emissions to be consistent with surface measurement
487 cannot reconcile with satellite measurements. In addition, the response of NO₂ column in Luanda to sectoral perturbations
488 in NO_x emissions is mainly linear (**Figure S7**). These model-satellite comparisons suggest an underestimation of NO_x
489 emissions from CEDSv2 by at least a factor of 2 in urban Luanda.

490

491 **Figure 12** shows the difference between anthropogenic NO_x emissions and satellite NO₂ columns for other cities with
492 respect to Luanda. The selected cities are grid cells with high NO_x emissions in the CEDSv2 inventory. In Kinshasa (the
493 capital of the DRC), anthropogenic NO_x emissions are 76% lower than those in Luanda, but their difference in satellite
494 NO₂ columns was only 4-12%, suggesting that anthropogenic emissions from Kinshasa were also underestimated; In
495 Lusaka (the capital of Zambia), its NO₂ columns were 55 % lower than those in Luanda while the difference is 76% in
496 anthropogenic NO_x emissions. Combining satellite data with CEDSv2 NO₂ emissions provides additional evidence of the
497 prevalent underestimation in anthropogenic NO_x emissions in major cities over Southern Africa.

498

499 **Figure 12.** Anthropogenic NO_x emissions from CEDSV2 and NO₂ columns from TROPOMI in typical cities in Southern
500 Africa. (a) Spatial distribution of NO_x emissions from the CEDSV2 inventory in March-April of 2018-2019. (b-d) Spatial
501 distribution of NO₂ columns observed by TROPOMI in March-April, 2018-2023. All of the numbers in the plots are the
502 percentage changes by taking Luanda as a reference.

503

4. Conclusions and discussion

504 In this study, we focused on Southern Africa where tropospheric ozone levels were thought extremely high but have been
505 less studied. By integrating the nested GEOS-Chem model and the newly-available surface and satellite observations to
506 evaluate the tropospheric ozone and its main drivers in Southern Africa. In particular, we quantified the impact of biomass
507 burning (BB) on tropospheric ozone at the regional scale in Southern Africa and the effects of anthropogenic emissions in
508 urban ozone level. This study provides a better understanding of the impacts of key emission sources on air quality
509 modeling in Southern Africa, which will be also important for health risk assessment, climate change prediction, and

510 sustainable strategy development.

511

512 The anomalously high values of dry-season tropospheric ozone in Southern Africa are mainly caused by BB, but there is a
513 large discrepancy of a factor of 2-3 in estimated BB emissions among different inventories. Comparison of model
514 simulations against NO₂ satellite observations revealed that the widely-used GFED4.1 inventory tends to strongly
515 overestimate NO_x emissions in Southern Africa, while model results with the QFED2 inventory were more consistent with
516 observations. This is consistent with the finding by Anderson et al. (2021) that their model driven by the GFED4.1 inventory
517 tended to overestimate NO₂ concentrations in the Africa, with a bias of about 100%. Consequently, the simulated regional
518 surface MDA8 ozone was decreased from 74 ppb by GFED4.1 inventory to 56 ppb by QFED2 inventory, and accordingly
519 the model bias in TCO was reduced from 14% to 2.3%. The modeled HCHO and CO columns are consistent between
520 GFED4.1 and QFED2 inventories. Using the QFED2 inventory, we explored the impact of BB emission heights on ozone
521 simulations and found that the effect of the vertical emission distribution was in the range of ± 2.4 ppb for surface MDA8
522 ozone and from -0.4 to 1.6 DU for TCO over Southern Africa; in contrast, the difference in BB aerosol emissions between
523 the inventories could affect ozone simulation strongly through aerosol chemistry.

524

525 We conducted further sensitivity experiments using the QFED2 inventory to explore the contribution of anthropogenic
526 emissions. Compared with surface NO₂ and PM_{2.5} observations, we found that the CEDSv2 anthropogenic inventory likely
527 underestimated anthropogenic emissions in typical Southern African cities by a factor of 2-10 and even incorrectly
528 represented anthropogenic sources in some areas. Our study also found that the TROPOMI performs effectively in these
529 low emission areas where there is a lack of observational data, and the OMI instrument is unable to capture urban-scale
530 hotspots in NO₂ columns over Southern Africa. We also found that ozone and PM_{2.5} concentrations are strongly influenced
531 by the underestimated anthropogenic emissions. For example, a ten-fold increase in anthropogenic NO_x emissions can
532 change ozone concentrations by up to 10 ppb and increase PM_{2.5} concentrations by up to 50 $\mu\text{g m}^{-3}$ in some cities.

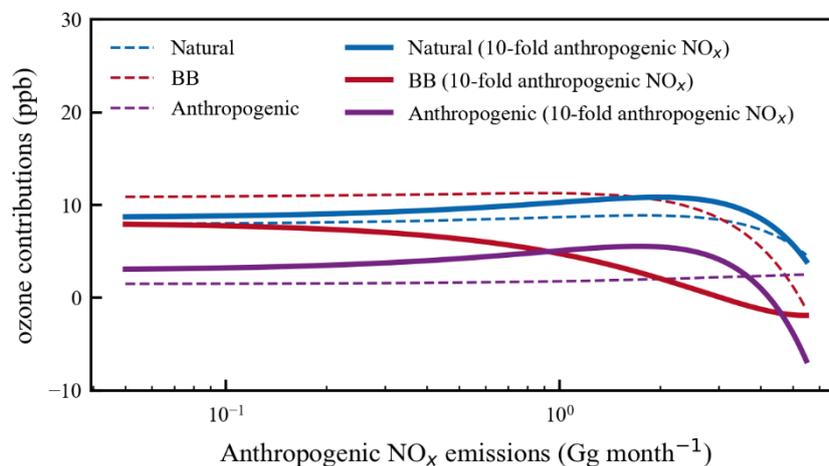

533

534 Although several studies examined high ozone levels in Southern Africa (Meyer-Arnek et al., 2005; V. Clarmann et al.,
535 2007), they only highlighted the role of biomass burning but overlooked the role of anthropogenic emissions. Although
536 recent findings by Wiedinmyer et al. (2023) have pointed out the large uncertainties in bottom-up BB emissions, they failed
537 to constrain the uncertainties due to the lack of observational data. Here we found that the difference among BB inventories
538 can have a great impact on urban air quality assessment. In addition, with combined surface observations, satellite data and
539 model simulations, we demonstrated for the first time that anthropogenic emission inventories are strongly low-biased in
540 urban Southern Africa. It suggests the important impacts of anthropogenic emissions in Africa with increasing urbanization.

541

542 The rapid change in anthropogenic emissions is already affecting air pollution and health risks in Southern Africa (Health
543 Effects Institute, 2022), as well as might have impacts on regional climate change (Fotso-Nguemo et al., 2023). Assessing
544 and predicting the impacts of different emission sources on air quality and human health rely heavily on model simulations.
545 The performance of these model estimations is significantly influenced by the accuracy of emission inventories. For
546 example, our finding of overestimated biomass burning emissions and underestimated anthropogenic emissions can
547 strongly affect the ozone source attribution over Southern Africa due to the nonlinear ozone chemistry. As shown in **Figure**
548 **S8**, in the dry season of 2019, regional surface MDA8 ozone over Southern Africa was contributed by 11 ppb, 8.0 ppb, and
549 1.5 ppb from BB emissions, natural emissions (mainly biogenic VOC), and anthropogenic emissions, respectively.
550 However, when anthropogenic NO_x emissions were increased by a factor of 10, estimated contributions from natural and
551 anthropogenic emissions will be increased to 9.0 ppb and 3.3 ppb, respectively. In particular, the ozone source attribution
552 spatially varies depending on the levels of anthropogenic NO_x emissions (**Figure 13**). This suggests the ignored but critical
553 role of anthropogenic emissions in ozone levels over Southern Africa.
554

555 **Figure 13.** The simulated source contributions to surface ozone in July-August 2019 using the CEDSv2 emissions (dash
556 lines) and 10-fold CEDSv2 NO_x emissions (solid lines). Here the natural emissions refer to the biogenic VOC and soil NO_x
557 emissions. The x-axis is the anthropogenic NO_x emissions in each grid cell and the y-axis the corresponding ozone
558 contributions estimated from the sensitivity simulations.
559

560
561 There are also some uncertainties and limitations in our assessment of the major drivers of high ozone over Southern Africa.
562 Firstly, due to the lack of observational data on surface ozone and VOCs, the effect of anthropogenic emissions on surface
563 ozone over Southern Africa was explored by only comparing surface NO_2 concentrations, which may lead to biases in
564 determining ozone chemical formation. Secondly, although we have used ozonesonde data from Ascension Island

565 downwind of Southern Africa for comparison and the study by Jenkins et al. (2021) suggests that BB plumes in Southern
566 Africa can have an impact on downwind regions, the long-range effects of BB emission on downwind urban regions were
567 also not well validated due to the lack of vertical ozone measurement. Thirdly, although the GEOS-Chem model has been
568 shown to be able to capture spatial and temporal variations of ozone and its precursors over typical urban regions (Travis
569 and Jacob, 2019), it is still challenging to capture the urban scale air quality in Southern Africa. Without accurate bottom-
570 up anthropogenic inventories, we highlight the importance of high-resolution satellite observations for understanding air
571 quality in developing regions such as Southern Africa.

572

573 Overall, this work provides a comprehensive understanding of the drivers and uncertainties of tropospheric ozone in
574 Southern Africa, particularly the overestimation in BB emissions and the underestimation of anthropogenic emission
575 inventories. More importantly, with more frequent BB and rising anthropogenic emissions in Africa, this study highlights
576 the urgency of establishing the surface network for air quality measurement over Southern Africa. The more accurate
577 estimates of anthropogenic emission sources and more regular surface observations are the key to understand atmospheric
578 chemistry over Southern Africa that is driven by rapidly changing anthropogenic and biomass burning emissions. The
579 deepened understanding of major emission sources in Southern Africa will not only help us to provide a solid scientific
580 basis for policymakers to effectively address air quality issues, but also will enhance the model capability to predict future
581 air quality and climate change. In the future, anthropogenic air pollutants (e.g., NO_x emissions) in Southern Africa under
582 future scenarios are projected to increase all the way by 2060 (**Figure S9**); along with more fires under a warming future,
583 Southern Africa will be a hotspot suffering from complex atmospheric chemistry and climate issues, presenting a grand
584 challenge to realize the Sustainable Development Goals for having a healthy, climate-friendly, and resilient development
585 in Africa. Our study serves as a baseline understanding of these key emission sources which are key drivers for modelling
586 future air quality, climate change, and their socioeconomic impacts.

587

588

589 **Data availability.** Daily real-time air quality indexes for NO₂ and PM_{2.5} were obtained from the Worldwide Air Q
590 uality Index (<https://aqicn.org/station>). The Ascension Island's ozonesonde data from the Southern Hemisphere Addi
591 tional Ozone Sounding network (<https://tropo.gsfc.nasa.gov/shadoz/>). The OMI satellite data for O₃, NO₂ and HCH
592 O are available at <https://disc.gsfc.nasa.gov/datasets/>. The TROPOMI data for NO₂ are available at <https://www.eart>
593 [hdata.nasa.gov/sensors/tropomi](https://www.eart.hdata.nasa.gov/sensors/tropomi). The MODIS data for AOD are available at <https://ladsweb.modaps.eosdis.nasa.gov/s>
594 [earch/](https://ladsweb.modaps.eosdis.nasa.gov/search/). The MOPITT data for CO are available at <https://giovanni.gsfc.nasa.gov/giovanni/>.
