## Abstract.

Retrieving atmospheric water vapor and temperature profiles over land using microwave radiometry is challenging due to uncertainties in estimating surface emissions. To address this, we developed an approach that couples the atmospheric retrieval algorithm with the surface emission estimation in an iterative loop. Using sounding channels from Ka- to G- band on the Advanced Technology Microwave Sounder (ATMS), we retrieved temperature and humidity profiles across the Antarctic region throughout the year 2016. The atmospheric profiles are updated in each iteration and used in the following step to refine the surface emissivity. This process continues until the atmospheric solution converges. The main innovation is the integration of surface and atmospheric retrievals, which improves overall accuracy. We validated our results against in-situ radiosonde data. The algorithm accurately retrieved temperature profiles, along with surface emissivity across 23–165 GHz, and successfully detected ice sheet meltings. While it captured water vapor variability, accurate absolute humidity values still require an independent surface emissivity retrieval using additional observations.

## 1 Introduction

The Greenland and Antarctica ice sheets are major contributors to global sea level rise due to increasing ice melt [Rignot et al. 2011]. This highlights the need to monitor and understand the mechanisms driving the accelerated melt events [Noble et al. 2020]. Effectively monitoring and analyzing the ice sheets require a detailed understanding of the atmospheric conditions that influence these regions [Le clec’h et al. 2019], which is also essential for predicting the future evolution of ice masses [Le clec’h et al. 2019]. Current atmospheric temperature and humidity retrievals in the microwave spectral range face challenges, primarily due to uncertainties in estimating surface emission. These challenges are amplified over polar ice sheets, where the atmosphere is typically dry, the surface emissivity changes rapidly during melt seasons, and the background emission is relatively high [Miao et al., 2001]. Traditional retrievals are limited by the absence of direct surface emissivity measurements and uncertainties in modeling background emission. To overcome these issues, we implement an iterative strategy that couples atmospheric retrieval with surface emission estimation. This approach enhances the accuracy of retrieved atmospheric temperature and humidity profiles, supporting improved understanding of the processes that drive melt in the Greenland and Antarctic ice sheets.

Deleted: through Iterative Approach

Deleted: Retrieving atmospheric water vapor and temperature profiles presents considerable challenges over land surfaces using microwave radiometry due to uncertainties associated with estimating background surface emissions. In response, we have devised an approach that integrates the atmospheric retrieval algorithm with the background emission algorithm, establishing an iterative loop to refine the accuracy of atmospheric profiles. Leveraging optimal estimation techniques with sounding channels spanning from Ka- to G-band obtained from ATMS, we successfully retrieved atmospheric temperature and humidity profiles across space and time. These retrieved atmospheric profiles undergo continual updates throughout each iteration, exerting influence on subsequent surface retrievals. This iterative process persists until convergence is achieved in the atmospheric retrieval. The algorithm's novelty lies in its fusion of surface retrieval with atmospheric retrieval, thereby enhancing overall accuracy. We validated the retrievals against radiosonde data. Our iterative algorithm proved to be efficient and accurate in retrieving temperature profiles with surface emissivity and in detecting melting events. Though our algorithm was able to capture the water vapor variations, the results showed that to obtain accurate absolute values of the water content an independently retrieved surface emissivity is required.

160 The Advanced Technology Microwave Sounder (ATMS), on board polar-orbiting satellites, is designed to perform  
 161 atmospheric temperature and humidity sounding through oxygen and water vapor absorption bands (Goldberg et al.  
 162 2006, Muth et al. 2005]. We applied our iterative retrieval algorithm to ATMS data across Antarctica during 2016.  
 163 This year was selected due to the significant melt anomaly over Ross Ice Shelf during 2016 austral summer (e.g.,  
 164 Nicolas et al., 2017; Mousavi et al., 2022; de Roda Husman et al., 2024; Hansen et al., 2024), which provided ideal  
 165 conditions to assess the impact of varying surface emissivity on atmospheric retrievals. This analysis enabled us to  
 166 evaluate the performance and limitations of the iterative approach.

## 168 2 Observations

### 169 2.1 Observation Data - ATMS data

170 The satellite carrying ATMS follows a sun-synchronous polar orbit, completing about 14 orbits per day and enabling  
 171 frequent revisit opportunities, especially at high latitudes. Over the Antarctic region, this results in 4 to 10 ATMS  
 172 overpasses per day for any fixed location, with variations due to swath width (~2,500 km), scan angle geometry, and  
 173 Earth rotation. ATMS has 22 channels to receive and measure radiation from different layers of the atmosphere,  
 174 obtaining global data on tropospheric humidity and temperature at either quasi-vertical or quasi-horizontal polarization.  
 175 Table 1 summarizes the radiometric characteristics of the ATMS channels, while Figure 1 shows their spectral  
 176 positions relative to atmospheric opacity from oxygen and water vapor absorption. ATMS channels cover the oxygen  
 177 band (50–58GHz), the two water vapor lines at 22 GHz and 183 GHz, and several window channels (see Fig. 1). The  
 178 temperature information of the atmosphere is obtained from Channels 3-15. Channels 18-22 are centered at the 183.31  
 179 GHz water vapor line but with a successively narrower bandwidth from  $\pm 7$ GHz to  $\pm 1$ GHz, giving humidity  
 180 information on successively higher troposphere.

181 Figure 1 shows the zenith opacity of a typical polar dry atmosphere for the ATMS frequency range. The opacity is  
 182 dominantly caused by water vapor and oxygen in the atmosphere. The contribution of nitrogen, orders of magnitude  
 183 smaller and without any spectral line at this frequency range, can be neglected. The total opacity is computed by  
 184 integrating the opacity per unit length from the top of the atmosphere toward the surface [Meeks and Lilley 1963].  
 185 Channels 1, 2, 16, and 17 are located at transparent window regions, where the opacity is low. Jacobians of temperature  
 186 and water vapor channels typically peak near the maximum of the weighting function, which often corresponds  
 187 approximately to the atmospheric level where the optical depth is near unity [Petty 2004]. For the window channels,  
 188 the overall opacity is much less than one. These channels can see through the atmosphere and are sensitive to Earth's  
 189 surface emission; therefore, they can be used for deriving surface emissivity. However, at oxygen (58 GHz) and water  
 190 vapor (183 GHz) absorption bands, the observed brightness temperature is not very sensitive to the surface emission.  
 191 The surface emissivity at these frequencies will be derived using the adjacent channels that have relatively low opacity:  
 192 CH3 (50.3 GHz) will be used to derive the emissivity in the range of 50.3-57.29 GHz (CH3 to CH15) at QH  
 193 polarization; CH18 (183.31 $\pm$ 7 GHz) for the emissivity near 183.31 GHz (CH18 to CH22) at QH polarization. In all,  
 194 we derive surface emissivity for the window channels 1 (23.8 GHz), 2 (31.4 GHz), 3 (50.3 GHz), 16 (88.2 GHz), 17  
 195 (165.5 GHz), and 18 (183.31 $\pm$ 7GHz), and assume linear emissivity variation between these frequencies.

263

264 The beam width of ATMS varies with frequency: 1.1° for channels in the 160-183 GHz range, 2.2° for the 50-60 GHz

265 and 80 GHz channels, and 5.2° for the 23.8 GHz and 31.4 GHz channels [Kim et al. 2014, 2020]. Both SNPP (Suomi

266 National Polar-orbiting Partnership) and the NOAA-20 (National Oceanic and Atmospheric Administration 20, also

267 known as Joint Polar Satellite System 1, JPSS-1) satellites orbit at an altitude of approximately 830 km. This results

268 in instantaneous spatial resolutions on the ground at nadir of about 16 km, 32 km, or 75 km, depending on the channels.

269 Due to the cross-track scanning approach, the instrument provides observations at a wide range of incidence (off-nadir)

270 angles. To ensure accuracy, we include only observations with an incidence angle less than 60°, as the instrument

271 footprint increases approximately with  $1/(\cos^2\theta)$ . For each fixed reference location, we use only those ATMS

272 observations whose beam boresight lies within 22.24 km (corresponding to 0.2° angular separation), ensuring spatial

273 relevance. The ATMS data used in this work were obtained from the Comprehensive Large Array-data Stewardship

274 System (CLASS) of NOAA.

Deleted: Figure 1 shows the zenith opacity of a typical polar dry atmosphere for the ATMS frequency range. The opacity is dominantly caused by water vapor and oxygen in the atmosphere. The contribution of nitrogen, orders of magnitude smaller and without any spectral line at this frequency range, can be neglected. The total opacity is computed by integrating the opacity per unit length from the top of the atmosphere toward the surface [Meeks and Lilley 1963]. Channels 1, 2, 16, and 17 are located at transparent window regions, where the opacity is low. The atmosphere becomes opaque to a channel at the layer of the atmosphere where the integral of the total opacity reaches the value of one [Petty 2004]. The Jacobians of the temperature and water vapor channels peak when the opacity becomes one. For the window channels, the overall opacity is much less than one. These channels can see through the atmosphere and are sensitive to Earth's surface emission; therefore, they can be used for deriving surface emissivity. However, at oxygen (58 GHz) and water vapor (183 GHz) absorption bands, the observed brightness temperature is not very sensitive to the surface emission. The surface emissivity at these frequencies will be derived using the adjacent channels that have relatively low opacity: CH3 at 50.3 GHz will be used to derive the emissivity in the range of 50.3-57.29 GHz (CH3 to CH15) at QH polarization; CH18 at 183.31 ± 7 GHz (CH3 to CH15) at QH polarization; CH18 at 183.31 ± 7 GHz (CH3 to CH15) at QH polarization. In all, we derive surface emissivity for the window channels 1 (23.8 GHz), 2 (31.4 GHz), 3 (50.3 GHz), 16 (88.2 GHz), 17 (165.5 GHz), and 18 (183.31 ± 7 GHz) and assume the emissivity variation is linear between the frequencies. ¶

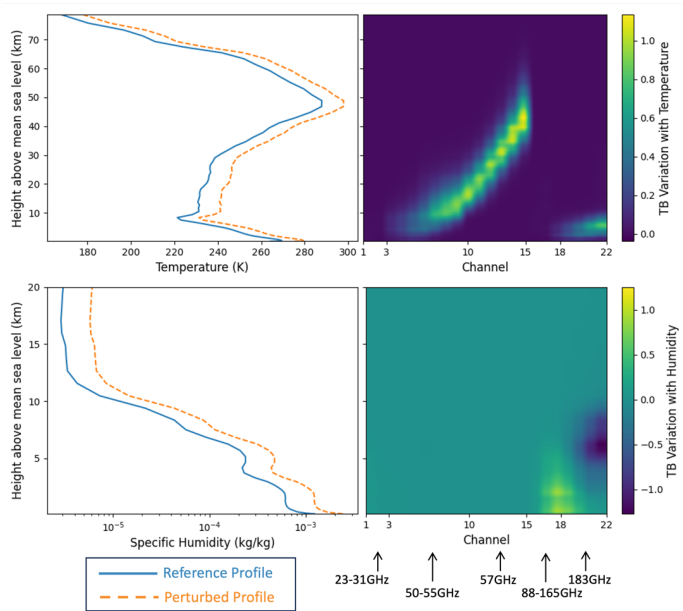

... [21]

357

358 To better understand the vertical sensitivity of each ATMS channel to atmospheric temperature and water vapor, we  
359 examine the Jacobians, which describe how changes in these variables influence observed brightness temperature.  
360 Figure 2 shows the temperature (upper right) and water vapor (lower right) Jacobians at all 22 ATMS channels for  
361 December (austral summer) atmospheres, representative of Antarctica conditions. The Jacobians are calculated by  
362 increasing the water vapor and temperature at each vertical layer to the orange dashed line, using the same 73-layer  
363 vertical grid as MERRA profiles (see Section 2.2), ranging from two meters above the surface to over 70 km in altitude.  
364 Therefore, a positive value implies that adding water vapor or increasing temperature will increase the radiance  
365 observed by the instrument and vice versa. The Jacobian shows the sensitive altitudes of each channel. Near the oxygen  
366 absorption band, CH3 to CH15 are sensitive to successively higher altitudes, up to ~60 km above the sea level.  
367 Channels 18–22 are located near the water vapor line at 183.31 GHz. The atmospheric opacity for these channels  
368 differs significantly, making these channels sensitive to different layers of the atmosphere. The bandwidth of these  
369 channels decreases with the channel number, with Channel 22 being the narrowest and Channel 18 being the broadest.  
370 The water vapor Jacobians for Channels 18–22 indicate sensitivity to distinct atmosphere layers extending up to  
371 several kilometers above the surface. Above approximately 10 km, the atmospheric water vapor content is so low that  
372 typical perturbations fall below the detection threshold of ATMS. The Jacobians shown are from the nadir view (0°  
373 incidence angle). Jacobians corresponding to off-nadir angles peak at slightly higher altitudes due to the longer  
374 atmospheric path length traversed by the radiation.

## 401 2.2 The Prior – MERRA-2

402  
 403 Using ATMS microwave thermal emission measurements, we applied Optimal Estimation (OE) to retrieve the  
 404 atmospheric temperature and humidity profiles. OE, as outlined by Maahn et al. (2020), is a widely used physical  
 405 retrieval method that incorporates measurements, prior information, and their uncertainties. Based on Bayes' theorem,  
 406 OE estimates the most probable atmospheric state. Prior information plays a critical role in the retrieval process. We  
 407 use the Modern-Era Retrospective analysis for Research and Applications, version 2 (MERRA-2), as the prior for  
 408 temperature and water vapor profiles. We use the "tavg3 3d asm Nv" dataset, which offers three-hourly averaged  
 409 atmospheric profiles across 72 hybrid sigma-pressure levels. [Rienecker et al. 2008], with a spatial resolution of 0.625°  
 410 longitude by 0.5° latitude. For ice and liquid water cloud distributions, we used the MERRA-2 3D cloud fields, which  
 411 provide vertically and horizontally resolved profiles of cloud water and ice content. To account for surface  
 412 characteristics such as skin temperature, temperature/humidity/wind speed at two meters, and surface pressure, we  
 413 integrated MERRA-2 single-level diagnostics data labeled as "tavg1\_2d\_slv\_Nx". By merging the three-dimensional  
 414 assimilated meteorological data with the single-level diagnostics data, our analysis extends across 73 vertical layers  
 415 starting from two meters above the surface and extending beyond 70 kilometers into the atmosphere. The vertical grid  
 416 is close to equidistant in the logarithm of the pressure and approximately equidistant in altitude.

417  
 418 To illustrate the structure and seasonal variability of the a priori profiles used in the retrievals, Figure 3 presents the  
 419 seasonal mean temperature and specific humidity profiles from MERRA-2 at three representative Antarctic sites:  
 420 McMurdo Station, the South Pole, and the Antarctic Peninsula. These locations span different climate regimes, and  
 421 the profiles exhibit clear seasonal contrasts—especially the colder, drier winter atmosphere and the distinctive  
 422 temperature inversions near the tropopause. This spatial and temporal variability highlights the importance of location-  
 423 and season-specific a priori knowledge in OE retrievals. It is also important to note that the MERRA-2 priors are  
 424 provided with respect to height above mean sea level, and the surface elevation differences among the selected sites  
 425 (e.g., higher elevation at the South Pole vs. coastal McMurdo) are preserved in the a priori structure. This ensures that  
 426 retrievals remain physically consistent with the local topography and atmospheric structure. In addition to the mean  
 427 state profiles, the OE algorithm also incorporates the a priori error covariance matrix, which encodes the expected  
 428 variability and vertical correlation of atmospheric parameters. It plays a critical role in weighting the influence of the  
 429 prior relative to the measurements and governs the vertical smoothing and retrieval precision.

### 2.3 In Situ and Ground-Based Remote Sensing Observations

Across Antarctica, a network of radiosonde stations provides in situ measurements of atmospheric profiles. These stations contribute to the Integrated Global Radiosonde Archive (IGRA), which provides valuable long-term in situ measurements, though often at limited temporal resolution depending on station operations [Durre et al. 2006]. However, efforts such as the Atmospheric Radiation Measurement (ARM) West Antarctic Radiation Experiment (AWARE) have enhanced observational capabilities by delivering high temporal resolution radiosonde data at key locations, including the West Antarctica Ice Sheet (WAIS) and McMurdo Station [Lubin et al. 2017]. AWARE employed ground-based remote sensing instruments, such as microwave radiometers, Atmospheric Emitted Radiance Interferometers (AERIs), and cloud radar systems, to derive continuous atmospheric profiles of temperature and humidity. To approximate higher temporal resolution, AWARE introduced an interpolated atmospheric profile product. While AWARE did include multiple radiosonde launches per day, the 1-minute time-resolution profiles were not direct radiosonde observations but were interpolated between sonde launches and adjusted using integrated water vapor values derived from microwave radiometer observations. These ground-based retrievals assume horizontal homogeneity and are subject to radiative transfer model assumptions. They typically offer high temporal resolution (1-minute) but at lower vertical resolution (often on the order of hundreds of meters) compared to radiosonde profiles (with vertical resolution of 20–200 meters). These profiles capture fine-scale temperature and humidity structures that are crucial for validating satellite and model retrievals.

Deleted: During 2016, AWARE collected atmospheric profiles every minute, offering unprecedented insights into the dynamic atmospheric processes in this critical region. Observing stations in Antarctica that measure ground-based meteorological data are located mostly around lower elevations and coastal areas. We only found two stations on the high plateau (above 2500 m), including South Pole Station (90° S) [Xu et al. 2019] and WAIS DIVIDE (79° S) [Lubin et al. 2017], that have measurements during 2016. The radiosonde measurements reveal detailed features in temperature and humidity profiles at high altitude resolution ranging from 20 m to a few hundred meters.

Deleted: ¶

... [5]

In our study, we evaluated the performance of the iterative retrieval algorithm using data from 5 radiosonde stations across Antarctica during 2016. This assessment allowed us to test the algorithm under a range of atmospheric conditions, geographical settings, and ice sheet melting scenarios. Retrieval results were compared against radiosonde-derived temperature and humidity profiles, serving as a benchmark for assessing accuracy. Importantly, radiosonde profiles were used solely for validation and not as climatological priors in the retrieval process, as our goal is to enable retrievals across all of Antarctica, including areas without radiosonde coverage. The validation results provided valuable insights into the strengths and limitations of our method, and informed refinements to improve its accuracy and reliability for atmospheric and cryospheric studies.

### 3 Iterative Retrieval Algorithm

#### 3.1 Iterative Process

We developed a channel-selective iterative approach to retrieve surface emissivity along with the atmospheric temperature and humidity profiles, as illustrated in Figure 4. The procedure begins with an initial estimation of surface emissivity, which is then used to derive temperature and humidity profiles. Next, these profiles are utilized to refine the surface emissivity in a continuous loop until the update in emissivity reaches a margin of 0.01. Typically, the results converge within six iterations. The final discrepancy between observed and modeled brightness temperatures (the residual) is compared against the noise equivalent delta temperature to assess the accuracy. The noise equivalent delta temperature (NEAT) represents the level of instrument noise inherent in brightness temperature measurements. For a total power radiometer like ATMS, NEAT is influenced by several system-level factors, including the system noise temperature (which incorporates atmospheric and instrumental contributions), the radiometer's bandwidth, the integration time, and fluctuations in instrument gain. Any residual falling within 1.5 times the noise equivalent delta temperature is considered a valid match. The outcome of the retrieval includes the profiles of temperature and humidity as well as the surface emissivity for all frequency channels (23GHz to 183GHz). We initialize emissivity,  $\epsilon_0 = 0.8$

**Figure 4.** Flow diagram of the iterative retrieval process. The process starts with an initial guess of surface emissivity  $\epsilon^0$  to retrieve temperature  $T^i$  and humidity profiles  $Q^i$ , which are then utilized to adjust the surface emissivity  $\epsilon^i$  for subsequent iterations. Residuals are defined as the difference between observed and modeled brightness temperature and assessed against the observation noise equivalent delta temperature. Any residual falling within 1.5 times the noise equivalent delta temperature is considered a valid match. The final outcomes are the temperature and humidity profiles alongside the surface emissivity.

**Figure 5.** Histogram of AMSU-A surface emissivity values at 23 GHz, 31 GHz, and 50 GHz over the Antarctic region during 2016. These values are obtained from the AMSU-A emissivity data archive. The median emissivity across these frequencies is near 0.8, which serves as the initial value ( $\epsilon_0$ ) in our iterative retrieval process.

### 3.2 Forward Model - Radiative Transfer Model

RTTOV (Radiative Transfer for TOVS<sup>1</sup>) is a fast radiative transfer code widely used in atmospheric remote sensing research [Saunders et al. 2018]. The model incorporates detailed representations of atmospheric properties, including temperature, humidity, pressure, and optionally, trace gases, aerosols, and hydrometeors, together with surface parameters and viewing geometry, allowing for accurate simulations of radiative transfer processes in diverse atmospheric conditions. We incorporate a Python interface written for RTTOV v11.3. The model was not only used to calculate radiances but also to calculate the associated Jacobians. The profile is assumed to be linear between the vertical grid points. The grid used is close to equidistant in the logarithm of the pressure; hence, it is approximately equidistant in altitude. RTTOV computes the top-of-atmosphere radiances from both atmospheric and surface emission in each of the sensor channels. The radiance can be represented as:

$$L(\nu) = \int_{\tau_s}^1 B(\nu, T) d\tau + [1 - \epsilon_s(\nu)] \cdot \tau_s^2(\nu) \cdot \int_{\tau_s}^1 \frac{B(\nu, T)}{\tau^2} d\tau + \epsilon_s(\nu) \cdot \tau_s(\nu) \cdot B(\nu, T_s)$$

where  $L$  is the radiance at frequency  $\nu$ ,  $B(\nu, T)$  is Planck's law,  $\tau$  is the transmittance from the top of the atmosphere to depth  $\tau$ , and  $\tau_s$  is the transmittance from the top of the atmosphere to the surface, both of which depend mostly on oxygen and water vapor absorption;  $\epsilon_s$  is the surface emissivity, while  $1 - \epsilon_s$  is the respective surface reflectivity, and  $T_s$  is the surface skin temperature. The three terms on the right-hand side correspond to the upwelling atmospheric emission, the downwelling atmospheric emission reflected by the surface, and the surface emission respectively.

<sup>1</sup> TOVS: Television InfraRed Observation Satellite (TIROS) Operational Vertical Sounder, a suite of three instruments that measure upwelling radiation from the atmosphere from which surface properties, clouds, and the vertical structure of the atmosphere can be determined.

**Deleted:** Figure 4. In the iterative retrieval process, the starting value of  $\epsilon_0$  is set at 0.8 for all frequencies based on AMSU-A surface emissivity data in the Antarctic region. The histogram depicting AMSU-A surface emissivity records at 23GHz, 31GHz, and 50GHz shows a median value near 0.8.

**Deleted:** RTTOV is a fast radiative transfer model for passive visible, infrared, and microwave downward-viewing satellite radiometers, spectrometers, and interferometers. RTTOV computes the top-of-atmosphere radiances in each of the sensor channels being simulated.

**Deleted:** The required geophysical inputs of the model are humidity and temperature profiles, the surface skin temperature, and the surface emissivity.

**Deleted:**  $K_j(\theta) = \frac{\partial T_B(\theta)}{\partial x_j} \rightarrow \dots [2a]$

where  $j$  is the vertical grid index and  $x_j$  can be the water vapor mass mixing ratio ( $Q$ ) in fractional units or temperature ( $T$ ) in Kelvin

$$x_j = \frac{Q_j^{H_2O}}{Q_j^{ref}} \text{ or } x_j = T \dots [2b]$$

The  $Q_j^{ref}$  are identical to the profile for which the Jacobian is calculated. This type of Jacobian shows the sensitivity of  $T_B$  to relative changes in the humidity/temperature at each vertical grid point.

**Deleted:** The brightness temperature coming from both atmospheric and surface emission can be calculated using Equation 3

### 3.3 Retrieved Profiles

We utilized our iterative retrieval method, as described in Section 3.1, on the ATMS data collected over the Antarctica region during 2016. Figure 6 presents an example of the retrieval evolution over six iterations, including temperature profiles (top left), specific humidity profiles (top right), and frequency-dependent surface emissivity (bottom left). The bottom right panel shows the residual (the difference between observation and model) divided by the observation noise. As discussed in Section 3.1, if the residuals for all frequencies/channels are under 1.5 times of the noise, the model is considered a valid match. Following six iterations, we observe convergence in the iterative process. Fig. 6 shows temperature profiles up to 16 km above sea level and specific humidity profiles up to 10 km, corresponding to the altitude range covered by available radiosonde data. In the upper two panels, the purple curves display the radiosonde *in situ* measurements, used to validate the iterative retrieval algorithm. The radiosonde measurements reveal fine-scale temperature and humidity structures with vertical resolution ranging from 20 m to a few hundred meters that the microwave radiometer-based algorithms cannot resolve. Despite these fine features, the temperature profile obtained through iterations matches the radiosonde measurements. The specific humidity below 6 km also shows good agreement with the measurements. However, the retrieval method becomes less sensitive above 6 km, primarily due to humidity levels that are orders of magnitude lower at higher altitudes.

As shown in Eqn. 1, when atmospheric profiles are known, the observed brightness temperature from the top of the atmosphere can be expressed as a linear function of the surface emissivity. By combining radiosonde-measured atmospheric profiles with ATMS brightness temperatures, we compute the surface emissivity at ATMS frequencies, referred to as the radiosonde reference surface emissivity (the black dotted line, the lower left panel in Figure 6). Our iteratively retrieved surface emissivity (red curve), is in good agreement with these radiosonde reference values. However, at 183 GHz - the water vapor absorption band -, surface emission is tightly coupled with near-surface humidity, making accurate emissivity retrieval more difficult. As a result, the iterative method may yield less reliable results at this frequency (see Section 4.1). Using the reference surface emissivity, the black dotted lines in the upper panels of Fig. 6 represent the best-fit atmospheric profiles achievable with ATMS's 22 channels, serving as a benchmark for evaluating our iterative retrieval approach. The comparison between the radiosonde reference profile and the iterative retrieved profile in the upper panels indicated a high level of consistency.

**Figure 6.** Retrieved temperature profiles (top left), specific humidity profiles (top right), and frequency-dependent surface emissivity (lower left) over six iterations (for clarity, only iterations 1, 3, and 6 are displayed). The lower right panel shows the residual divided by the observation noise (the model's fit is considered good when the absolute residuals at all frequencies are less than 1.5 times of the noise, indicated by the dashed lines). The iteration process converges within six iterations. The gray curve shows the prior for the temperature and humidity profiles. In the bottom two figures, the oxygen and water vapor absorption frequency bands/channels are shaded in gray. In the upper two panels, the purple curve shows the radiosonde *in situ* measurements. The black dotted line shows the reference profiles retrieved using the radiosonde ~~reference~~ emissivity. This demonstrated example is a particularly good fit where the retrieved surface emissivity closely matches ARM-derived values; not all cases show this level of agreement.

## 4 Validation and Discussion

We assess the performance of our iterative retrieval method by comparing the retrieved atmospheric profiles with radiosonde measurements. This comparison demonstrates both the capability and limitations of our approach in capturing seasonal variations and surface-atmosphere interactions across Antarctica.

### 4.1 Mid-January 2016 Melting Event Near the Ross Ice Shelf

In this section, we examine the atmospheric and surface conditions during the mid-January 2016 melting event by analyzing retrieval results at three key Antarctic sites—McMurdo Station, WAIS Divide, and Ross Ice Shelf—over

the same time period, each of which shows corresponding variations in atmospheric profiles, surface emissivity, or both during the melt.

#### McMurdo Station

The McMurdo Radiosonde Station is located on Ross Island at coordinates 77.85°S, 166.66°E. In 2016, radiosonde observations were obtained with high temporal resolution at this station. Figure 7 presents a histogram of the differences between atmospheric profiles retrieved by our iterative algorithm and the radiosonde reference profiles as described in Section 3.3. The upper panels depicts the temperature difference below 70 km height, while the lower panels shows the specific humidity difference below 10 km height, spanning the entire year of 2016. The left panels show the median value and the 68% confidence intervals (one standard deviation). The accuracy of the temperature profile retrieval was high, with a standard deviation of 0.5K. However, while most humidity variations were detectable (to be further discussed in the next paragraph), the absolute value was not precise compared to the measurement, with a standard deviation of approximately 25%. The humidity was strongly linked to the surface emissivity at 183 GHz. In addition to the iteratively retrieved profiles, we also include histograms of deviations for the MERRA-2 archived profiles as a baseline. The results indicate that the iterative retrieval approach improves accuracy in both temperature and humidity, yielding distributions more closely aligned with radiosonde-derived observations. Fig. 8 shows the histogram displaying the difference between the surface emissivity retrieved iteratively and the radiosonde reference value. The surface emissivity retrieved iteratively is highly accurate within a range of  $\pm 0.01$  for window channels like 23.8 GHz, 31.4 GHz, and 88.2 GHz. In the oxygen absorption band between 50 and 58 GHz, most of the retrieved surface emissivity values fall within  $\pm 0.02$  of the radiosonde reference value, aligned with the fact that retrieved temperatures have a one-sigma difference within  $\pm 0.5K$  from the actual value. The channels above 165 GHz are affected by water vapor absorption. At 165 GHz, the emissivity retrieval shows a standard deviation of 0.03, while at 183 GHz, the standard deviation increases to  $\sim 0.1$ . These discrepancies are too substantial to permit accurate retrieval of the humidity profile. An independent estimate of the ice sheet surface emissivity is required to separate the effects of ice sheet emissions and atmospheric humidity.

**Figure 7.** Histogram of the differences between atmospheric profiles retrieved by our iterative algorithm and the radiosonde reference profiles. The upper panels shows temperature differences below 70 km (in K), and the lower panels shows specific humidity differences below 10 km, expressed as a percentage relative to the reference profiles. We use percentage differences for specific humidity to account for its strong vertical gradient, which spans approximately two orders of magnitude; this approach avoids biasing the evaluation toward near-surface values. In the left column, dashed black lines represent the median and the 68% confidence interval (one standard deviation) in each panel. Same histograms for the MERRA-2 profiles are included as a baseline, demonstrating that the iterative retrieval method improves agreement with observations by reducing deviations in both temperature and humidity. The right column show the root mean square error (RMSE) with respect to altitude.

**Figure 8.** Histogram of the surface emissivity retrieved in our study compared to the radiosonde reference value. The dashed black lines represented the median value and the 68% confidence intervals (one standard deviation) in the lower middle and lower right panels.

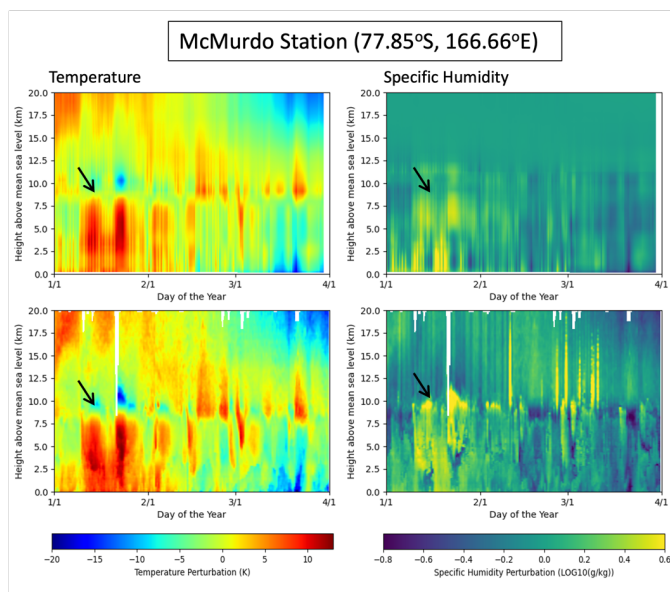

The changes in surface emissivity over the year provide information about melting events in the ice sheet. Figure 9 presents surface emissivity from November 2015 to the end of 2016 at three window frequencies and near the oxygen absorption band. The blue curve represents values obtained from our iterative algorithm, while the red dashed line shows the radiosonde reference values. These values are in good agreement with each other. Two melting events were observed around mid-December 2015 and mid-January 2016, as indicated by the black arrows. The melting event in mid-January was more significant. Following the melting event, the emissivity decreased due to ice crust formation within the surface snow during the refreezing, which increases scattering and depresses brightness temperature, resulting in reduced effective emissivity. Figure 10 displays temperature and specific humidity perturbations from January to March 2016, covering the period of the melting events and the availability of radiosonde measurements. These perturbations show deviations of the profiles from the average values during the specified period (from 2016.01.01 to 2016.03.31). The top row shows results from our iterative algorithm, while the bottom row shows profiles measured using radiosonde. Despite the higher vertical resolution in radiosonde measurements, our iterative algorithm captures the temperature and humidity variations effectively. The melting events in mid-January corresponded with increases in near-surface temperature and humidity, as indicated by the black arrows. Temperature increased by over 10 K during the melting event.

The deviations from average values are displayed for that period. The top row presents results from our iterative algorithm, while the bottom row shows data from radiosonde measurements. Melting events in mid-January correspond to the temperature and humidity increases around the same time. The X-axis shows the month of the year, from 2016/01/01 to 2016/03/31. The temporal resolution in the map is based on an interpolation of ATMS observed data time intervals, which are approximately a few hours apart.

## WAIS Divide Station

The WAIS Divide Station is located at coordinates 79.468°S, 112.086°W, with an altitude of approximately 1.8 km above sea level. Detailed radiosonde measurements were taken between January 1st and January 15th, 2016. Figure 11 compares the temporal fluctuations of temperature and specific humidity throughout January, along with surface emissivity (bottom panel), between the iterative retrievals (top row) and radiosonde measurements (middle row). By utilizing the iterative retrieval method, we were able to accurately track the rise in temperature and humidity from January 10th to January 15th, aligning with the melting of the Ross Ice shelf as recorded at McMurdo Station in mid-January. In contrast to the surface emissivity changes observed at McMurdo Station, no substantial variations in surface emissivity were noted at the WAIS Divide Station, indicating stable ice crust structures and limited snowfall during the summer months. Although near surface temperatures increased, they did not reach levels sufficient to initiate melting at this inland location.

## Ross Ice Shelf

In January 2016, a significant surface melting event was documented that impacted a significant section of the Ross Ice Shelf (Nicolas et al., 2017; Mousavi et al., 2022; de Roda Husman et al., 2024; Hansen et al., 2024). The melting is associated with the strong and continuous transport of warm marine air to the region, likely influenced by the

concurrent powerful El Nino event. The broad atmospheric fluctuations during and following the melting incident are found to be established by the El Nino event and mitigated by the positive Southern Annular Mode. These atmospheric changes are identified by our iterative method, as illustrated in Fig. 10 and Fig. 11. We present findings at the coordinates 83°S, 153°W at the center of the melting incident. As indicated in Figure. 12, there is a sharp rise in surface emissivity from 23.8 to 58 GHz, indicating surface melting over ice sheets and the presence of liquid water in the snowpack. Our iterative analysis of temperature and humidity perturbations captures the significant and vertically extensive intrusion of marine air from 10-13 January.

#### 4.2. West & East Coast Ice Shelves During 2016

In the Antarctica region, ice shelves cover approximately 1.5 million square kilometers and include major formations such as the Ross, Ronne-Filchner, and Larsen Ice Shelf. Ice shelf melt can lead to an accelerated ice discharge from the land into the ocean, significantly contributing to the global sea level rise. Melting events over these ice shelves are, therefore, critical to understanding and predicting future sea level changes.

1339 ▼  
 1340 The west coast of Antarctica is home to several ice shelves, including the Larsen C ▼, Wilkins ▼ and George VI Ice  
 1341 Shelf, all situated on the Antarctic Peninsula. These ice shelves exhibit similar annual variations in surface properties.  
 1342 Notably, multiple surface emissivity increases are observed throughout the year (Figure 13, upper left panel). labeled  
 1343 as events 1 through 8. Figure 14 presents the temperature and humidity perturbations associated with these surface  
 1344 emissivity changes, with each event number indicated. These emissivity changes are generally correlated with  
 1345 increases in atmosphere temperature and humidity, though they likely arise from a range of underlying causes. Figure  
 1346 13, upper middle panel displays the skin temperature data from ERA5 [Hersbach et al., 2023], with the black dashed  
 1347 line representing the melting point at 273K. During the summer months (January to March and November to  
 1348 December), increased emissivity corresponds to elevated skin temperatures reaching the melting threshold. An  
 1349 additional melting event detected in early May (event 4) is attributed to concurrent rises in both near-surface  
 1350 atmospheric temperature and skin temperature. Conversely, the increased emissivity observed in late May (event 5)  
 1351 is attributed to rainfall. These findings underscore the complex interplay of climatic factors driving the surface  
 1352 emissivity change on the Antarctic Peninsula's ice shelves, highlighting the sensitivity of these regions to both  
 1353 temperature and precipitation changes.  
 1354  
 1355 On the other hand, East coast ice shelves, such as the Amery and Shackleton Ice Shelf, exhibit very difference yearly  
 1356 variations in surface conditions. Unlike the complex interactions observed around the west coast, potential melting  
 1357 events on the east coast—indicated by increases in surface emissivity as shown in Fig. 13 (lower left)—are detected  
 1358 exclusively during the summer months of January and December. According to ERA5 data (Fig. 13, lower middle and  
 1359 right), the east coast experiences extremely dry conditions with nearly no precipitation of rain. These melting events  
 1360 are attributed solely to the increase in near-surface atmospheric temperature and skin temperature, which rise above  
 1361 the melting point during the summer. ▼

### 4.4 More Comparison With Radiosonde Measurements Throughout the year

The Integrated Global Radiosonde Archive comprises radiosonde and pilot balloon observations from multiple stations distributed around the Antarctic coastline. Although the time resolution of these radiosonde measurements is lower than that of the ARM campaign, some stations provide data covering the entire year. Davis Station, located at 68.5744°S, 77.9672°E on the east coast, experiences significant variations in surface emissivity (Figure 13a). As shown in Figure 13c, the ATMS 3db beam at all emission angles ( $\leq 60^\circ$ ) partially intersects both the ground and sea ice. During the summer, the melting of sea ice causes a drop in emissivity. Our iterative algorithm can accurately determine the effective surface emissivity for observations where the beam covers mixed surface types, which otherwise for traditional retrieval process, the surface emissivity is unknown. This capability will benefit the atmospheric retrieval. Additionally, we detected two more melting events at SYOWA (Figure S.1) and MARIO ZUCHELLI Radiosonde Station (Figure S.2). When compared with *in situ* measurements from radiosondes, our iterative retrieval process efficiently captures all temperature and water vapor variations.

DAVIS Radiosonde Station [19]

Deleted: **Figure.12** Amery Ice Shelf (70°S, 71°E). left) and specific humidity (upper right) perturbations throughout the year of 2016. The deviations from average values are displayed. Surface emissivity variation at 23.8 GHz (lower left) shows potential melting events only during the summer months. The results are retrieved using our iterative algorithm. Skin temperature (lower middle) and precipitation of rain (lower right) from ERA5 are presented. The X-axis shows the month of the year, from 2016/1/1 to 2016/12/31.

Deleted: [20] [21]

retrieval of atmospheric states in the challenging conditions of polar environments where surface emission is complex and temporally variable due to melting and refreezing events. Validation against high-resolution radiosonde measurements from multiple Antarctic stations in 2016 demonstrates the algorithm's capability in retrieving atmospheric temperature profiles, with a typical retrieval accuracy of  $\pm 0.5$  K. Surface emissivity estimates at transparent window and oxygen absorption channels (i.e., 23.8 - 88.2 GHz) are accurate within  $\pm 0.01$ – $0.02$ . However, atmospheric humidity retrieval accuracy diminishes at higher frequencies, especially near the 183 GHz water vapor absorption band, where emissivity is entangled with near-surface humidity contributions. Water vapor retrievals, though able to resolve temporal variability, showed an absolute uncertainty up to 25%, indicating that reliable retrieval of humidity requires independent emissivity estimates at water vapor-sensitive frequencies.

The study also reveals significant spatial variability across Antarctic regions. The Ross Ice Shelf exhibited pronounced emissivity and atmospheric changes during the 2016 mid-January melting event, aligning with observed marine air intrusions. In contrast, locations such as the WAIS Divide showed minimal emissivity variation despite similar atmospheric warming. West Antarctic coastal ice shelves (e.g., Larsen) exhibit complex emissivity variations throughout the year, influenced by both temperature fluctuations and precipitation events, whereas East Antarctic shelves (e.g., Amery) maintain more stable surface emissivity characteristics.

Future improvement hinges on integrating this retrieval framework with independent multi-frequency algorithms for estimating ice sheet surface properties (e.g., meltwater fraction, snow density), which can decouple surface and atmospheric signals. Such hybrid retrieval schemes are vital for robust long-term monitoring of polar climate feedbacks and for improving the accuracy of model-based predictions of how ice sheets will respond to future atmospheric conditions.
