

## 25 **Abstract**

26           Geographic range has long been acknowledged as an important determinant of extinction  
27 risk. The trajectory of geographic range through time, however, has not received as much  
28 scientific attention. Here, we test the role of change in geographic range – assessed by a measure  
29 of proportional occupancy of grid cells – in determining the extinction risk in four major  
30 microplankton groups: foraminifera, calcareous nanofossils, radiolarians, and diatoms. Logistic  
31 regression was used to assess the importance of standing occupancy, occupancy change, and  
32 sampling probability in the extinction risk of species. We find that while standing occupancy is a  
33 major determinant of extinction risk in all microplankton groups, change in occupancy accounts  
34 for an average of 52% of the explanatory power of the three analyzed variables, with a maximum  
35 value of 92%. Sampling probability was also found to be consistently informative, with an  
36 average of 6% and a maximum value of 22%. Our results highlight the importance of  
37 incorporating both geographic range and its change through time, as well as sampling  
38 probability, into extinction models. The ability of occupancy trajectory to help predict extinction  
39 risk underlines the necessity of paleontological data in modern conservation efforts.

## 40 **1. Introduction**

41           There is a rich literature documenting the effect of smaller geographic range sizes in  
42 contemporary and ancient extinctions (e.g. Foote et al., 2016; Foote et al., 2007; McKinney,  
43 1997; Payne and Finnegan, 2007; Purvis et al., 2000; Staude et al., 2020). The International  
44 Union for the Conservation of Nature (IUCN) uses geographic range size as one of the five key  
45 criteria by which the “Red List of Threatened Species” risk status of a species is assessed (Mace  
46 et al., 2008). The temporal trajectory of geographic range as a predictor of extinction has been  
47 sparingly explored in the paleontological literature (Liow et al., 2010; Foote et al., 2007, Tietje

48 and Kiessling, 2013; Kiessling and Kocsis, 2016), but many studies looking at historic  
49 extinctions exclude this factor altogether. Increasing anthropogenic impact on biotic systems has  
50 been suggested as a contributing factor to species' extinction risks (Ceballos et al., 2015; De Vos  
51 et al., 2015; Payne et al., 2016; Wagler, 2011). Understanding factors that increase a species' risk  
52 of disappearance, and how they can be mitigated, is thus more important now than ever before.

53       Based on a data set of Cenozoic marine invertebrates from the Paleobiology Database  
54 (<https://paleobiodb.org/>), Kiessling and Kocsis (2016), suggested that the trajectory of  
55 geographic range has the potential to inform extinction risk. However, the coarse stratigraphic  
56 resolution of the macroinvertebrate record (geological stages, about 5 million years in duration)  
57 puts constraints on the fidelity of any approach that depends on the spatiotemporal distribution of  
58 species. Due to their sheer abundance, unicellular groups are less affected by such issues and can  
59 be used for finely resolved studies of assemblage changes (e.g., Strack et al. 2024) and  
60 biogeography (e.g., Swain et al., 2024). Variations in the material that make up their tests  
61 (calcareous or siliceous) are expected to manifest as either differential fossil sampling or as  
62 evolutionary patterns, which presents an opportunity to explore the sensitivity of extinction  
63 models under a wider range of scenarios. While accounting for sampling, we assess here the  
64 importance of geographic range (expressed as proportional grid occupancy) and its temporal  
65 trajectory on extinction risk of marine planktonic organisms. By using a temporally finely-  
66 resolved dataset of fossil plankton, as well as with the explicit incorporation of fossil sampling  
67 into our models, we can better assess whether the trajectory of geographic occupancy actually  
68 influences extinction risk in marine life.

69

70

71

72 **2. Data and Methods**

73 **2.1 Sourcing and cleaning of raw data**

74 We downloaded occurrence records of four major marine microplankton groups from the  
75 Neptune Sandbox Berlin ("NSB"; Lazarus, 1994; Renaudie et al., 2020; data downloaded 30  
76 August 2023) using the R package "NSBcompanion" (Renaudie 2019). These groups were  
77 planktonic foraminifera, calcareous nannofossils, radiolarians, and diatoms. The four data sets  
78 were downloaded with the taxonomy resolved using the IODP Taxonomic Name List Project  
79 (Renaudie et al., 2020), a built-in option that we specified prior to downloading. Additionally,  
80 questionably-identified taxa were excluded from the download. Open-nomenclature taxa and  
81 possibly problematic or reworked occurrences were also excluded using the built-in NSB  
82 download options. The NSB holds taxon occurrences stretching back to the late Jurassic, but we  
83 limit our analysis to the Cenozoic record (i.e. the last 66 million years) to ensure a consistent age  
84 range for all for taxonomic groups, since both the diatom and the radiolarian NSB records only  
85 exist for the Cenozoic.

86 The NSB database includes the estimated age as well as the modern and estimated paleo-  
87 coordinates (longitude and latitude) of each fossil occurrence calculated internally based on the  
88 plate tectonic reconstruction by Boyden et al. (2011, Fig. S1). Each dataset (foraminifera,  
89 calcareous nannofossils, radiolarians, diatoms) was cleaned to remove any occurrences that were  
90 missing age, paleo-coordinate, and/or relevant taxonomic information. The counts of unique  
91 species and the number of occurrence records in each data set (post-cleaning) are provided in  
92 Table 1. All cleaning and subsequent analyses were carried out in R 4.2.2 (R Core Team, 2022).

93

94

95

<b>Data Set Summaries</b>				
	Foraminifera	Calcareous Nannofossils	Radiolarians	Diatoms
Number of unique species	552	737	840	966
Number of occurrences	96 410	154 052	91 240	91 092
Proportion of extant species with usable records (>1 time bin)	0.051	0.015	0.093	0.119
Number of unique species-bin pairings with “gap-omission” approach, excluding first occurrences ( <i>occupancy change</i> = NA). Bin size = 1 million years.	3 471	4 814	5 626	4 938

96 **Table 1.** The number of unique species, the number of total occurrence records, the proportion of  
97 species that are extant and occur in more than one bin, and the number of species-bin pairings  
98 (post-cleaning).  
99

100 We assigned occurrences from each data set to time bins of either 0.1, 0.2, 0.5, or 1  
101 million years, noting that 0.1 million years is currently the lower limit for global correlation. For  
102 each time bin size, the first bin stretched from the present (0 Ma) to either 0.1, 0.2, 0.5, or 1  
103 million years into the past. Each subsequent bin encompassed the following increment stretching  
104 progressively further into the past. Ages are reported in millions of years before present (Ma).

105 We assessed stratigraphic ranges as defined by the oldest and youngest fossil  
106 occurrences. Due to reworking and other processes, the documented raw ranges may not reflect  
107 the true durations of species. Therefore, we also applied the recommended “Pacman profiling”  
108 (Lazarus et al., 2012), a stratigraphic outlier correction, to reduce the impact of outliers and  
109 reworking on the data. The degree of Pacman trimming on the NSB data was determined via a  
110 calibration process that used speciation and extinction ages of a given subset of each taxonomic

111 group. Based on this subset, the degree of trimming necessary to restore the “true” temporal  
112 ranges of species could be estimated. Calibration ages were sourced from the Triton database  
113 (Fenton et al. 2021) for foraminifera, Nigrini et al. (2006, obtained from Lazarus et al., 2012) for  
114 radiolarians, the “Barron Diatom Catalog” (Lazarus et al., 2014) for diatoms, and a custom  
115 species list constructed from Mikrotax ([www.mikrotax.org](http://www.mikrotax.org); Huber et al., 2017) for calcareous  
116 nannofossils. Potential trim values ranging from 0% to 16% of the raw ranges, at 1% intervals,  
117 were analyzed. Pacman calibration was carried out on datasets after they had been trimmed to the  
118 last 66 million years. Trim values were selected such that they minimized the average absolute  
119 difference between the actual and the represented speciation or extinction ages of the species  
120 present in the calibration set. The best-performing trim values were implemented in this study,  
121 although the key results presented here do not change in the absence of Pacman profiling. Those  
122 trim values were as follows: foraminifera (top: 15%, bottom 3%), calcareous nannofossils (top:  
123 14%, bottom: 4%), diatoms (top: 11%, bottom: 4%), radiolarians (top: 10%, bottom: 6%). Per  
124 capita extinction rates were calculated using the formula from Foote (1999).

125

## 126 **2.2 Analysis of completeness**

127 In order to quantify the degree to which sampling completeness affected downstream  
128 analyses, we employed two separate completeness metrics: the simple completeness metric  
129 (“SCM”; Benton, 1985) and the three-timer completeness metric (Alroy, 2008). The three-timer  
130 completeness metric was calculated from the three-timer and part-timer counts returned by the  
131 “divDyn” R extension package (Kocsis et al., 2019).

132

133

134

### 135 **2.3 Calculating occupancy**

136 For each data set, paleo-coordinates of samples were assigned to equal-area geographic  
137 cells using the R package “*icosa*” (Kocsis, 2020) for the calculation of proportional grid  
138 occupancy. Proportional grid occupancy is a recognized metric for assessing geographic range in  
139 the fossil record, where contemporaneous sampling is impossible and incomplete preservation is  
140 common (Foote et al., 2007; Darroch et al. 2022). Several cell-sizes were analyzed ranging in  
141 edge length between  $3.33^\circ$  to  $2^\circ$ . There was little variation in results within this range, so the  
142 highest resolution (4002 cells with  $2^\circ$  edge length, mean area of  $1.3 \times 10^5 \text{ km}^2$ ) was selected for  
143 this study. The present-day distribution of samples can be seen in supplementary Fig. S1.

144 As counts of occupied cells tend to be biased by sampling (Kiessling, 2005), we  
145 calculated proportional occupancy of each species in every time bin. Proportional occupancy is  
146 simply the number of geographic cells occupied by the species divided by the total number of  
147 sampled cells in a given time bin. For clarity, we refer to what is actually proportional occupancy  
148 as simply *occupancy* from here forward. Furthermore, the number of unique Longhurst (2007)  
149 biogeographic planktonic provinces that were occupied by each species in each time bin was  
150 calculated, and the Pearson correlation of this value with the raw number of occupied geographic  
151 cells was calculated. Autocorrelation was accounted for by differencing temporally consecutive  
152 values prior to calculating correlations.

153

### 154 **2.4 Change in occupancy**

155 In addition to standing *occupancy*, the change in *occupancy* between consecutive time  
156 bins was calculated by taking the natural log of the ratio of *occupancy* in time bin  $i$  to *occupancy*  
157 in time bin  $i-1$ . The log transformation serves to standardize the magnitude of change and

158 produces positive values for increases in *occupancy* (range expansions) and negative values for  
159 decreases in *occupancy* (range contractions).

160 Initially, instances where *occupancy* values in bin  $i$  or  $i-1$  were 0 (no occurrences) were  
161 coded as missing data for *occupancy change* and removed from the final data set. While  
162 removing these records prevents the inclusion of undefined *occupancy change* values in the final  
163 data set, it greatly reduces the number of occurrences for a given taxon, especially for species  
164 whose sampling is fragmentary. This effect is magnified by the fact that for each time bin with  
165 zero occurrences of a given taxon (a “gap” in that taxon’s fossil record), two data points are  
166 removed from the final data set for that taxon. This overall loss of data becomes more  
167 pronounced with smaller bin sizes.

168 To combat this effect, we employed a “gap-omission” approach, whereby the change in  
169 *occupancy* was calculated based on the previous occurrence of the taxon (regardless of when that  
170 was) rather than the previous time bin, *per se*. Thus,  $i$  and  $i-1$  do not necessarily correspond to  
171 sequential time bins in this approach, but rather consecutive positive sampling intervals for each  
172 given taxon. With this approach, consecutive taxon occurrences are included even when  
173 separated by “gaps”, thus retaining more data to the final data set. Although both approaches  
174 yield the same basic results (see Tables S1 and S2), we used the “gap-omission” approach for the  
175 sake of retaining a larger data set.

176

## 177 **2.5 Binomial logistic modeling**

178 For every species, a record of each time bin in which that species occurred was included  
179 in the final table as a single row. Each unique species-bin pairing (row) is characterized with the  
180 *occupancy* and binary extinction indicator in the focal time bin as well as the change in  
181 *occupancy* from the previous time bin. An extinction indicator value of 1 was assigned if an

182 occurrence was the last time bin in which a species occurred for the entire data set (the species  
183 went extinct or permanently disappeared from the fossil record during this interval). An  
184 extinction value of 0 was assigned for all other occurrence records (the species did not go extinct  
185 during this interval).

186 Species that are still extant, or those which only went extinct during the most recent time  
187 bin (which spans up to the present), would by default be assigned an extinction value of 1 in the  
188 most recent time bin (because the most recent bin is the last occurrence of those species in the  
189 data set). To avoid this edge effect, all occurrences from the most recent time bin were removed  
190 prior to model fitting.

191 Binomial logistic models were constructed to examine the dependency of extinction on  
192 *occupancy* and *occupancy change*. Both the additive and multiplicative effects of *occupancy*,  
193 *occupancy change*, and *sampling* (represented by the three-timer value calculated for each bin),  
194 as well as the impact of each variable independently, were examined with respect to the per-  
195 interval probability of extinction. The multiplicative generalized linear model structure of  
196 “`glm(extinction ~ occupancy * occupancy_change * sampling, family = binomial(link =`  
197 `‘logit’))`,” was used. The best model was selected based on its AIC value.

198

## 199 **2.6 Model performance and predictor importance**

200 We calculated the adjusted amount of deviance ( $D^2$  of Guisan and Zimmermann, 2000)  
201 accounted for by each computed logistic model. Deviance in a generalized linear model is  
202 analogous to variance of ordinary linear regression. In each of the 16 data sets (four groups with  
203 four time resolutions each), the Lindeman, Merenda, and Gold (1980) indices of correlated input  
204 relative importance (henceforth referred to simply as “relative importance”) were calculated for  
205 the *occupancy*, *occupancy change*, and *sampling* terms with respect to predicting the *extinction*

206 term. The relative importance of the *occupancy change* term was standardized as a proportion of  
207 “total importance”. This statistical approach was used to represent the explanatory power of each  
208 model term with respect to one another, an insight that is not directly apparent with simple model  
209 coefficients. Additionally, for each of the additive model outputs, the ratio of the standardized  
210 *occupancy change* coefficient to the standardized *occupancy* coefficient was calculated to  
211 estimate the relative explanatory power of the *occupancy change* term between data sets.

212 For each of these metrics, the standard error was estimated by bootstrapping the species  
213 that make up each set of occurrence records. For each of the 1000 bootstrapping iterations, the  
214 set of species whose occurrence records were retained in the data set was determined by  
215 resampling with replacement. After each resampled set of species and their occurrence records  
216 was determined, every model was re-fit and every metric was recalculated. The standard  
217 deviation of all bootstrapped values for a single metric approximates the standard error.

218

## 219 **2.7 Extinction probabilities of extant species**

220 The World Register of Marine Species (<https://www.marinespecies.org/>), with the  
221 assistance of the R package “taxize” (Chamberlain and Szoecs, 2013), was used to identify  
222 extant species. These data on extant taxa were downloaded on 25 September 2023.

223 In order to predict the extinction probabilities of extant species, the data sets were  
224 reanalyzed and re-fit to models using only the extinct species. Although this technique reduced  
225 the overall amount of data used to fit the model, it allowed for the prediction of extinction  
226 probabilities of extant species without circularity. Other than removing extant species, all other  
227 processes were carried out in the same way as described above.

228 After selecting the best model for each plankton group, that model was used to predict the  
229 extinction probability of extant species. Using the fitted models along with the *occupancy* and

230 *occupancy change* values for each extant species in the present bin (that which ends at the  
231 present, 0 Ma), a probability of the binary response variable occurring as a 1 (extinction) can be  
232 calculated. This represents the probability that the species will *not* appear again during the next  
233 time bin of the same length (that which begins at the present, 0 Ma) or in other future time bins.  
234 Because three-timer sampling calculations require bins both before and after the target bin, the  
235 present bin lacked a three-timer sampling value. Models were thus fitted without the sampling  
236 term for future extinction probability predictions. Extinction predictions were made on extant  
237 species subsets without upper Pacman trimming, and the average probability of extinction for all  
238 extant species were calculated in each data set.

239

## 240 **2.8 Robustness testing**

241 Further analyses tested the robustness of our results, specifically for the proportional  
242 occupancy's utility as a metric of geographic range and for different datasets. The same analyses  
243 at a bin size of 1 million years were carried out using latitudinal range and change of latitudinal  
244 range instead of proportional occupancy and its change. Additionally, the same analyses were  
245 carried out using proportional occupancy of Longhurst (2007) provinces and the change in  
246 proportional occupancy of Longhurst provinces for data sorted into 1 million-year bins.

247 Although containing only records of planktonic foraminifers (many of which were  
248 sourced from the NSB), the Triton database includes information on the original purpose of each  
249 study from which records were sourced, as well as the age of speciation and extinction for each  
250 species. With this additional information, the Triton dataset can be used to confirm the suitability  
251 of methods used with the Neptune dataset with a different collection of fossil occurrences. Given  
252 that some studies may not record every present taxon if it is not a zonal marker or thought to be  
253 particularly informative, the Triton dataset was subset to include only studies whose purpose was

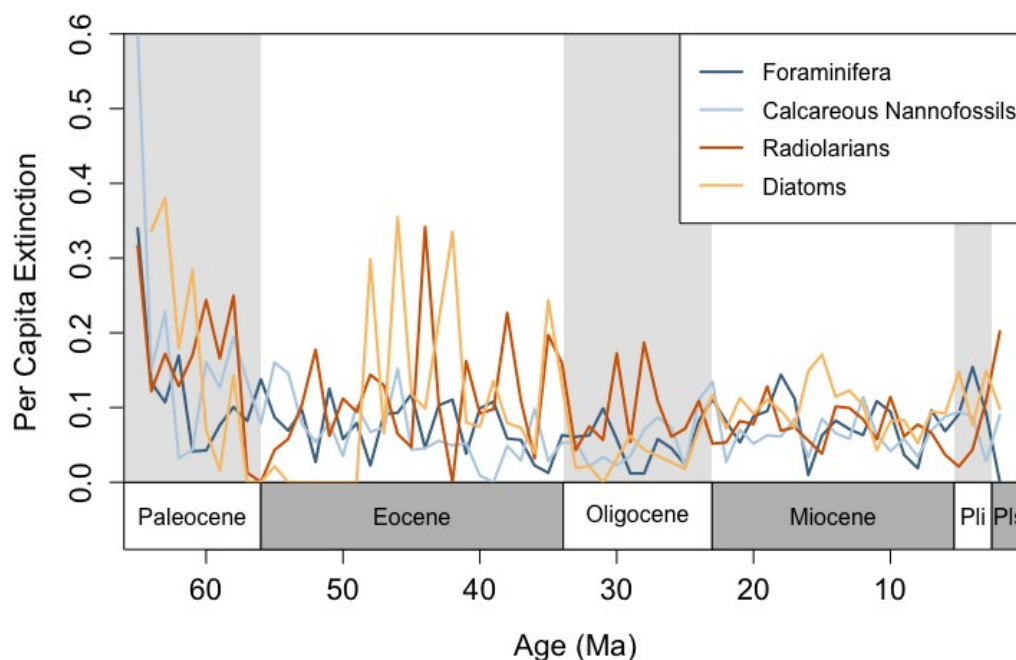

254 noted as “community analysis” (Fenton et al. 2021). Because studies whose purpose was to  
255 analyze community structure would likely document all present species, by using this subset,  
256 studies that potentially excluded some species were removed from the final data set.  
257 Additionally, each included species history was subset to exclude any occurrences that occurred  
258 before or after the speciation and extinction ages noted in the Triton dataset (Fenton et al. 2021),  
259 respectively, reducing the potential impact of reworked fossils in the analysis. Because each  
260 species in Triton was trimmed in this manner, these data did not undergo Pacman profiling as the  
261 NSB data did. After these additional data-cleaning actions were taken, the Triton dataset had  
262 197,871 usable occurrence records and was analyzed in the same way as the NSB data.

263

### 264 **3. Results**

265 The utilized datasets show all four groups with elevated extinction rates coming out of  
266 the K-Pg and returning to relative stasis approximately 5-15Ma after the K-Pg boundary (Fig. 1).  
267 Shortly thereafter, all groups, but especially the siliceous groups, undergo decreases in diversity,  
268 corresponding with the Paleocene-Eocene Thermal Maximum (PETM, Fig. S4). Both  
269 foraminifera and calcareous nannofossils retain relatively low and stable extinction rates ( $<0.2$ )  
270 for the rest of the Cenozoic (Fig. 1).

271  
272

273 **Figure 1.** Per capita extinction rates calculated using the formula in Foote (1999) for each of the  
274 four taxonomic groups during the Cenozoic, calculated for 1-million-year bins. The timescale of  
275 Gradstein et al. (2012) was used here to match age assignments in the NSB.

276

277 The extinction rates (Fig. 1) and diversity patterns (Fig. S4) of each plankton group  
278 match those of previous analyses of Neptune data (Jamson et al., 2022), and various biotic events  
279 in the Cenozoic can be detected. In all analyzed combinations of taxonomic group and bin size,  
280 standing *occupancy*, *occupancy change*, and *sampling* were all retained in the AIC-selected  
281 models as informative (Table 2). When considering strictly the simpler additive models, both  
282 *occupancy* and *occupancy change* were determined significant in all models ( $p = 0.05$ ).  
283 *Sampling* was deemed significant across all bin sizes for calcareous nannofossils, at 0.2 and 1.0  
284 Ma for foraminifera, at 0.2 and 0.5 Ma for diatoms, and never for radiolarians.

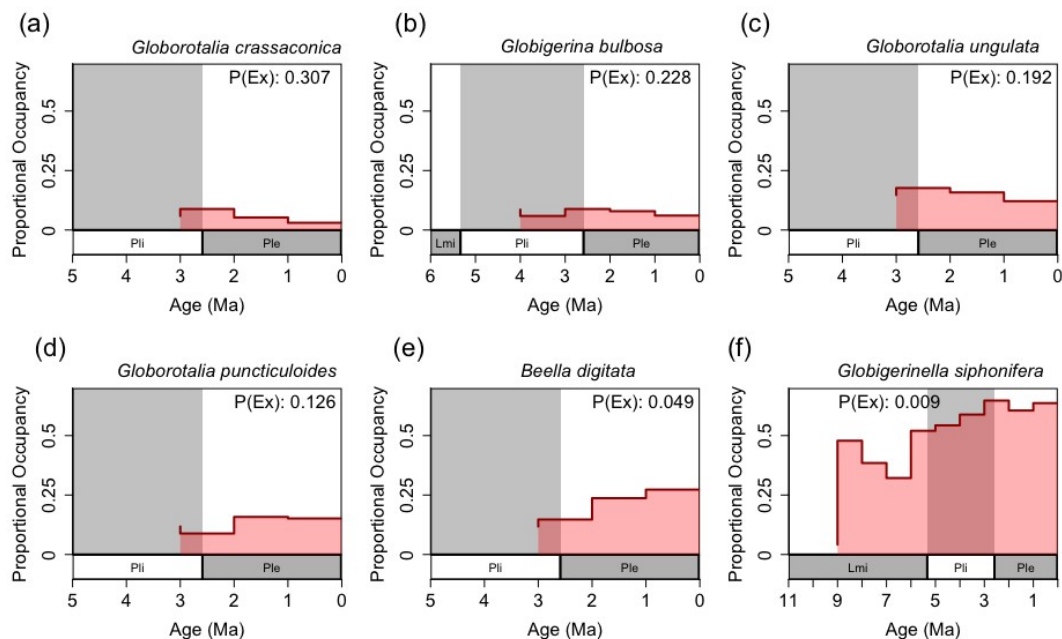

285

<b>Bin size (Ma):</b>	<b>0.1</b>	<b>0.2</b>	<b>0.5</b>	<b>1.0</b>
<b>Foraminifera</b>	<i>multiplicative</i>	<i>additive</i>	<i>multiplicative</i>	<i>multiplicative</i>
<b>Calcareous Nannofossils</b>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>
<b>Radiolarians</b>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>
<b>Diatoms</b>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>	<i>multiplicative</i>

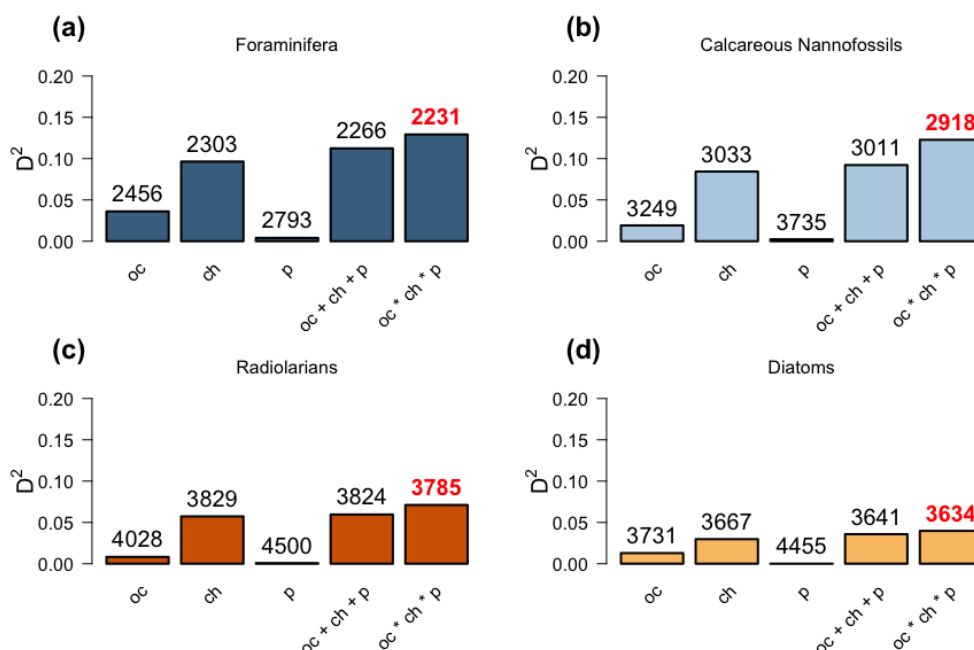

286 **Table 2.** The AIC-selected model formula for each group and bin size combination, on data that  
287 was processed with the “gap-omission” approach. “*multiplicative*” refers to the model with the  
288 formula:  $ex \sim oc * ch * p$ , and “*additive*” refers to the model with the formula:  $ex \sim oc + ch + p$ .  
289 “*ex*” represents the binary response variable *extinction*, “*oc*” represents the *occupancy* term, “*ch*”  
290 represents the *occupancy change* term, and “*p*” represents three-timer sampling probability.  
291

292 The signs of the *occupancy* and the *occupancy change* coefficients were always negative  
293 in single-term models, meaning that smaller instantaneous geographic range sizes and more-  
294 negative changes in geographic range size both correspond to larger extinction probabilities (Fig.  
295 2). The  $D^2$  values and AIC values of each analyzed model combination for each 1-million-year  
296 binned data set are depicted in Fig. 3. The maximum  $D^2$  for any model was 0.129, occurring for  
297 the multiplicative foraminifera model at a bin size of 1.0 Ma (Table 3). The relative importance  
298 of the *occupancy change* term averaged 52.0%, with higher values being achieved with larger  
299 bin sizes.  
300

301  
302

303 **Figure 2.** A selection of proportional occupancy through time plots for 6 species of foraminifers  
304 sourced from the NSB in one-million-year bin size. In each panel, the current extinction  
305 probability of that species—predicted using that species’ historical geospatial records with the  
306 model that was fit using extinct species of the same taxonomic grouping—is shown. Panels A  
307 through F are ordered according to decreasing current extinction probability. Notice the  
308 association of relatively small standing occupancy values and relatively large occupancy  
309 decreases with increased probability of extinction.  
310

**Figure 3.**  $D^2$  values (bars) and AIC values (numbers displayed above each bar) for each examined model formula. Shown for each of the NSB data sets with bin size = 1 million years. The lowest AIC value for each data set is shown in red.

311  
 312  
 313

Bin size (Ma):	0.1	0.2	0.5	1.0
<b>Foraminifera</b>	0.042	0.053	0.079	0.129
<b>Calcareous Nannofossils</b>	0.053	0.053	0.090	0.123
<b>Radiolarians</b>	0.015	0.025	0.060	0.071
<b>Diatoms</b>	0.021	0.030	0.027	0.040

314 **Table 3.** The  $D^2$  of each best-fit model (see Table 2) for each data set at each bin size.  
 315

316  $D^2$  values increase systematically with bin size, and calcareous organisms tend to have  
 317 higher  $D^2$  values than siliceous organisms for their best-fit model (Table 3), indicating better  
 318 overall explanatory power in calcareous organisms. A maximum relative importance value of  
 319 91.9% was achieved for radiolarians binned to 1.0 million years (the  $D^2$  of this particular

320 multiplicative model was 0.071). In all but the smallest bin size, radiolarians consistently have  
321 the highest standardized coefficient ratios and relative importance values of the *occupancy*  
322 *change* term. Not surprisingly, sampling completeness increases with larger temporal grain.  
323 Foraminifera and calcareous nannofossils had consistently higher three-timer sampling  
324 completeness than the siliceous groups across all bin sizes (Table 4).

325

326

Three-Timer Completeness				
Bin Size (million years)	0.1	0.2	0.5	1.0
Foraminifera	0.821 ± 0.006	0.899 ± 0.006	0.928 ± 0.007	0.933 ± 0.009
Calcareous Nannofossils	0.874 ± 0.004	0.899 ± 0.005	0.925 ± 0.006	0.936 ± 0.008
Radiolarians	0.792 ± 0.005	0.825 ± 0.006	0.886 ± 0.007	0.926 ± 0.008
Diatoms	0.729 ± 0.006	0.781 ± 0.007	0.838 ± 0.008	0.861 ± 0.010

327 **Table 4.** Three-timer completeness scores (Alroy 2008) calculated for each full data set at each  
328 of the four examined bin sizes. Shown with 95% confidence intervals.  
329

330 When fit to extinct-only data subsets, AIC-selected models were still either the additive  
331 or multiplicative three-term models for all groups at all bin sizes (Table S4). Extant diatoms  
332 showed a significantly higher probability of extinction than all other groups, followed by extant  
333 radiolarians, and then by the two calcareous groups. Extinct radiolarians had a significantly  
334 lower extinction probability than calcareous nannofossils and diatoms (Table 5). Extinction  
335 values through time for each group are visualized in Fig. 1.

336

337

	Species	
	Extant	Extinct
<b>Foraminifera</b>	0.097± 0.051	0.219 ± 0.034
<b>Calcareous Nannofossils</b>	0.060 ± 0.038	0.240 ± 0.016
<b>Radiolarians</b>	0.122 ± 0.011	0.187 ± 0.013
<b>Diatoms</b>	0.141 ± 0.009	0.256 ± 0.020

338 **Table 5.** Mean of all extant-organism extinction probabilities (left) and extinct-organism  
339 extinction probabilities (right) produced for each data set. Means are shown with 95%  
340 confidence interval.  
341

342 The raw number of cells occupied by each species during each time bin showed a strong  
343 positive correlation with the number of occupied Longhurst provinces for each taxonomic group  
344 at each bin size, even when autocorrelation was removed (Table S5). The same analyses  
345 conducted on proportional occupancy of Longhurst provinces and the change in proportional  
346 occupancy of Longhurst provinces, as well as on the latitudinal range of species and the change  
347 in latitudinal range of species, yielded best-fit models that related all three model terms  
348 multiplicatively (Figs. S2 and S3). When the logistic modeling was applied to the Triton data, the  
349 three-term multiplicative or additive models always performed the best (Fig. S6).

350

## 351 **4. Discussion**

### 352 **4.1 Geographic range as a driver of microplankton diversity**

353 Our observations agree with the findings of Jamson et al. (2022), which observed  
354 increased extinction rates for siliceous organisms during the PETM. Additionally, the authors  
355 found a net diversification rate of around 0, as well as a stable extinction rate, for calcareous  
356 groups between the PETM and the modern. Our results show diatoms and radiolarians having  
357 several spikes in extinction between 40-50 Ma, which may indicate the termination of the Early

358 Eocene Climatic Optimum. There is another localized spike in extinction for the siliceous groups  
359 around 35Ma, perhaps corresponding with the end of the Middle Eocene Climatic Optimum.

360 Jamson et al. (2022) observed a brief increase in diatom extinction rate during this event.

361 While absolute geographic range size is an informative predictor of extinction risk,  
362 various other factors relating to geographic range also play an important role in global  
363 biodiversity patterns. Powell and Glazier (2017) found that in the same four groups of  
364 microplankton analyzed in this study, latitudinal diversity gradients are produced by asymmetric  
365 shifts in geographic range, rather than variations in diversification rate with respect to latitude.

366 On the contrary, Raja and Kiessling (2021) found that the extratropics had higher average  
367 origination rates than the tropics. Supporting Powell and Glazier's (2017) finding that  
368 asymmetric shifts in geographic range are key drivers of latitudinal diversity gradients, Raja and  
369 Kiessling (2021) showed that dispersal was more likely to occur from the extratropics towards  
370 the tropics. Both studies suggest that latitudinal diversity gradients, and thus the geographic  
371 distribution of a species, are closely linked to paleoclimate regimes. Indeed, changes in global  
372 circulation patterns as well as water column stratification and temperature are the key influences  
373 on global plankton diversity (Lowery et al., 2020)

374 As paleoclimate regimes shift over geologic time, marine microplankton ranges often do  
375 not shift to follow changes in temperature; instead, populations may simply go extinct as local  
376 temperatures become inhospitable without a comparable range expansion into more-hospitable  
377 zones (Trubovitz et al., 2020). Trubovitz et al. (2023) found that radiolarian abundance is not a  
378 significant predictor of extinction risk and that external drivers (such as climate) are more likely  
379 to predict extinctions. Thus, larger geographic ranges may provide species with a geographic  
380 cushion: as local temperatures change, more widespread species undergo a more drawn-out  
381 series of local extirpations before global extinction occurs. This agrees with the well-established

382 phenomenon, and that which we also report here, that larger instantaneous geographic occupancy  
383 reduces a species' risk of extinction.

384         Additionally, the trajectory of a species' geographic range through time might indirectly  
385 reflect shifts in regional or global climate. As paleoclimate zones shift, geographic cells may  
386 become inhospitable to a species, and the species may undergo extirpation in that geographic  
387 cell. A more rapid change in a species' occupancy through time may reflect a more rapid change  
388 in paleoclimate and hospitable regions of Earth. Continued reduction in occupancy over time can  
389 thus provide insight into the effects of long-term climatic, geographic, or biological trends on the  
390 extinction probability of marine microplankton.

391

#### 392 **4.2 History of occupancy / legacy effects**

393         The trajectory of various ecological variables through time has been shown to impact the  
394 current and future direction of species diversity trends. These legacies may include past climatic  
395 events or geographic range shifts influencing modern distributions or extinctions of species  
396 (Svenning et al., 2015). The interaction of historic information with current information can  
397 provide insight about ecological processes that neither historic nor current information could  
398 provide on its own.

399         The historic trajectory of climate change impacts the probability of extinction occurring  
400 with a short-term change in climate. A warming event occurring after a long-term warming trend  
401 leads to greater extinction rates (Mathes et al., 2021a) and lower origination rates (Mathes et al.,  
402 2021b) than a warming event occurring after a long-term cooling trend. Understanding the  
403 historical conditions leading up to a study period of interest thus may be essential to  
404 understanding the key drivers as to what goes extinct versus what survives.

405           Although the effect of climate and geographic range legacies on instantaneous  
406 geographic range itself is well-studied (Svenning et al., 2015), the effect of geographic range  
407 legacies on instantaneous extinction probability has not received as much attention. Kiessling  
408 and Kocsis (2016) found that the legacy of geographic range (represented as its change to the  
409 present from the previous bin) is an informative predictor for extinction risk in marine  
410 macroinvertebrates. Our results build upon those of Kiessling and Kocsis (2016), demonstrating  
411 both that these findings hold true for marine microplankton, as well as that temporal scale (bin  
412 size) is a key variable in detecting the importance of geographic legacy effects.

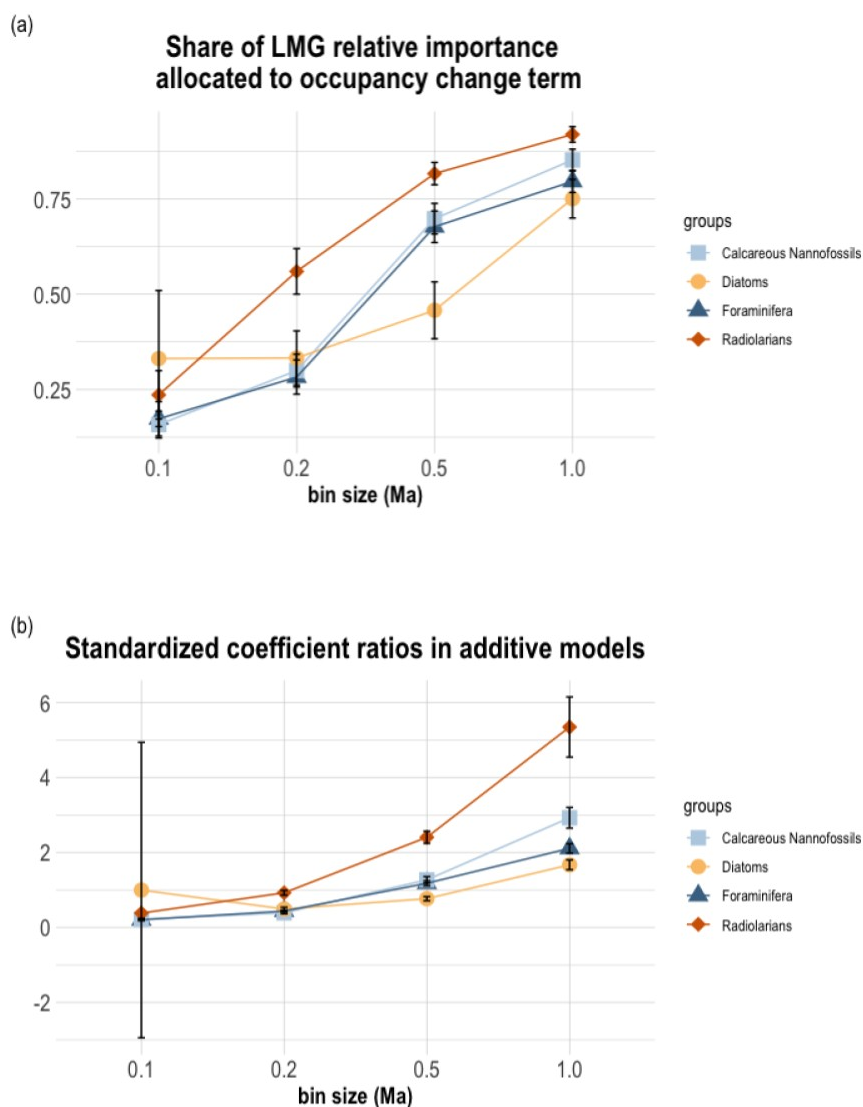

413

#### 414 **4.3 Scale dependency of extinction drivers:**

415           Although previous studies have analyzed various drivers of extinction through geologic  
416 time, relatively little research has gone into understanding the scale-dependency of these  
417 extinction drivers. Scale-dependency in extinction studies manifests in various variables, such as  
418 area (Fagan et al., 2005; Guardiola and Rodá, 2013) or taxon age (Diaz et al., 2019). Analyzing  
419 data at different temporal scales is also imperative to detect true ecological signals (Hewitt et al.,  
420 2010). We find here that as temporal resolution decreases (bin size increases), the relative  
421 explanatory power of the occupancy change variable increases while the relative explanatory  
422 power of the other two variables decreases (Fig. 4).

423

424 **Figure 4. A.)** Share of the Lindemann, Merenda and Gold relative importance (1980) allocated  
425 to the *occupancy change* term, taken as a proportion of “total importance”. Shown for each data  
426 set at each bin size. **B.)** Standardized coefficient ratios in AIC-selected models for each bin size.  
427 Error bars represent the bootstrap-estimated standard error. Note that as bin size increases  
428 (temporal resolution decreases), the relative importance of the occupancy change term as well as  
429 the standardized coefficient ratio (occupancy change : standing occupancy) both increase.

430 This could result from there being more records in a single temporal bin as bin size  
431 increases, thus creating a more complete set of data in any given time bin. This may be  
432 especially true when working with fragmentary fossil data, such as that which we analyze here.  
433 With larger bin sizes, it is easier to detect biological signals that may otherwise be lost in the  
434 noise of fragmentary data. The temporal scale by which we analyze these data can influence our  
435 understanding of extinction risk in marine microplankton. We show here that the seemingly-  
436 arbitrary selection of temporal bin size can have major impacts on conclusions drawn about  
437 microplankton diversification.

438

#### 439 **4.4 Calcareous vs siliceous microfossils**

440 In general, the explanatory power of each of the model terms is smaller in the siliceous  
441 groups than in the calcareous groups. Although *occupancy* and *occupancy change* were found to  
442 be informative across all groups, the signals are weaker in diatoms and radiolarians (Table 3). As  
443 both siliceous and calcareous organisms are sensitive to nutrient limitation (Kamikuri et al.,  
444 2005; Lazarus et al., 2009; Bristow et al., 2017), this discrepancy likely results from minor  
445 variations in sampling, as evidenced by lower 3-timer completeness values for the two siliceous  
446 groups. Furthermore, the *sampling* term was found to be significant in the three-term additive  
447 model across all bin sizes for calcareous nannofossils, in two bin sizes for both foraminifera and  
448 diatoms, and never for radiolarians. The greater importance of the *sampling* term in the  
449 calcareous groups suggests that fossil preservation and sampling rate has a greater influence on  
450 when a species disappears from the fossil record, a piece of information that is crucial to  
451 distinguishing “true” from “apparent” extinction. This discrepancy may be a result of variable  
452 taphonomic pathways between the calcareous and siliceous organisms (Boltovskoy 1994).  
453 Nonetheless, both *occupancy* and *occupancy change* are important predictors of extinction

454 regardless of the group, and these findings further underscore the importance of accounting for  
455 sampling when analyzing paleontological data.

456

#### 457 **4.5 Robustness testing**

458           There is a strong correlation between the number of occupied Longhurst provinces and  
459 the number of individual occupied geographic cells for each species-bin pairing. This  
460 demonstrates that, although the locations of the various drilling expeditions that sourced much of  
461 the data in the Neptune database are not entirely random, when taken together they still account  
462 for a diverse spread of planktonic biogeographic regions around the globe. This supports the idea  
463 that the collection of data contained in the Neptune database, while only a snapshot of the global  
464 microplankton fossil record, is comprehensive enough to study large-scale biogeographic trends.  
465 Additionally, AIC-selected models contained both the *occupancy* and *occupancy change* terms  
466 even when geographic range was measured as latitudinal expanse or as a proportion of occupied  
467 Longhurst provinces. This suggests that the significance of proportional occupancy change in  
468 predicting extinction is not merely an artifact of data processing.

469           The AIC-selected model for each bin size in the Triton data set was either the three-term  
470 additive or multiplicative model. Although the Triton dataset has substantially more occurrence  
471 records after preprocessing, it has consistently lower diversity compared to the other taxonomic  
472 groups from the NSB (Fig. S4). This could indicate a greater propensity for “lumping” in the  
473 Triton dataset than in the NSB, which in turn could change how spatio-temporal signals  
474 manifest. The similar results obtained from the Triton dataset further confirms the suitability of  
475 these methods with an alternative data set and reaffirms the importance of *occupancy* and  
476 *occupancy change* when modeling extinction.

477           Taken together, our findings suggest that the change in geographic occupancy is an  
478 important metric for predicting extinction across the tree of life. Kiessling and Kocsis (2016)  
479 looked exclusively at skeletal macroinvertebrates, whereas here we analyzed several protist  
480 lineages of marine plankton. The broad taxonomic scope of these findings emphasizes the  
481 fundamental importance of the trajectory in geographic range as a biological metric, which can  
482 be a key aspect of taxon dynamics through time. Although the explanatory power of the model  
483 may seem low (up to 12.9%), it is an important factor given the many other variables that  
484 influence extinction risk (McKinney 1997)

485           Although modern studies can track geographic occupancy change over the course of  
486 decades (if there is a history of consistent data collection), estimates of marine species durations  
487 average between 5-10 million years (Foote and Raup, 1996; Raup, 1991), much longer than  
488 human-collected records can encompass. To fully understand the change of occupancy through a  
489 species' duration, records extending beyond those which could have been manually recorded by  
490 conservation biologists are needed. Although some modern conservation practitioners have been  
491 hesitant to fully embrace long-term paleontological data, this study provides yet another  
492 argument for the incorporation of historical perspectives and fossil evidence in conservation  
493 efforts (Dietl et al., 2019; Kiessling et al., 2019; Smith et al., 2018).

494           While for simplicity's sake, this study only looked at the interaction of *occupancy* and the  
495 first degree of *occupancy change* (bin number  $i$  to  $i-1$ ), future iterations could incorporate entire  
496 occupancy histories into model fitting using even more advanced techniques. This may help the  
497 model overcome variations in sampling intensity or localized paleoenvironmental events, and let  
498 the models provide information not only on decline, but information on *continued* decline —  
499 another hallmark of increased extinction risk.

500

501 **5. Conclusion**

502 In providing evidence that the geological history of species distributions plays a  
503 significant role in species extinction risk, our study demonstrates the importance of  
504 paleontological data for assessing modern species extinction risk. Incorporating paleontological  
505 range data may allow for more-informed decisions about how to spend limited conservation  
506 funding in the future. We also demonstrate here the importance of temporal grain in detecting  
507 biological signal in fragmentary fossil data.
