Abstract. This study characterizes the spatial and vertical nature of aerosol hygroscopicity in Southeast Asia and relates it to aerosol composition and sources. Aerosol hygroscopicity via the light scattering hygroscopic growth factor, $f(\text{RH})$, is calculated from the amplification of PM₅ aerosol ($D_p < 5 \mu\text{m}$) scattering measurements from $< 40\%$ to 82% relative humidity during the Cloud, Aerosol, and Monsoon Processes Philippines Experiment (CAMP²Ex) between August to October 2019 over the northwest tropical Pacific. Median $f(\text{RH})$ is low (1.26 with lower to upper quartiles of 1.05 to 1.43) like polluted environments, due to the dominance of the mixture of organic carbon and elemental carbon. The $f(\text{RH})$ is lowest due to smoke from the Maritime Continent (MC) during its peak biomass burning season, coincident with high carbon monoxide concentrations ($> 0.25 \text{ ppm}$) and pronounced levels of accumulation mode particles and organic mass fractions. The highest $f(\text{RH})$ values are linked to coarser particles from the West Pacific and aged biomass burning particles in the region farthest away from the MC, where $f(\text{RH})$ values are lower than typical polluted marine environments. Convective transport and associated cloud processing in these regions decrease and increase hygroscopicity aloft in cases with transported air masses exhibiting increased organic and sulfate mass fractions, respectively. An evaluation of a global chemical transport model (CAM-chem) for cases of vertical transport showed the underrepresentation of organics resulting in overestimated modeled aerosol hygroscopicity. These findings on aerosol hygroscopicity can help to improve aerosol representation in models and the understanding of cloud formation.

1. Introduction

Aerosol particles affect climate and visibility through the direct and indirect extinction of solar radiation via absorption and scattering of light and through cloud formation, respectively. Aerosol hygroscopicity compounds aerosol effects on Earth's radiation budget (Zhao et al., 2018; Malm and Day, 2001), secondary aerosol formation and cloud formation (Köhler, 1936), and health (Dockery, 2001). Neglecting the effect of moisture on aerosol growth leads to incorrect estimation of the cooling at Earth's surface due to aerosol particles (Garland et al., 2007). For instance, a decrease in light extinction over the southeast U.S. was linked to reduced aerosol water uptake, coincident with decreases in the sulfate/organic ratio (Attwood et al., 2014). Particle aging/coating can cause underestimation of both aerosol hygroscopicity in the sub-saturated regime (Wang et al., 2018) and cloud condensation nuclei (CCN) activity in the supersaturated regime for aged particles in China by ~22% (Zhang et al., 2017). Remote sensing of aerosol optical properties is also affected by aerosol water content (Ferrare et al., 1998; Ferrare et al., 2023). Therefore, accurate aerosol hygroscopicity values are critical for remote sensing and satellite observation of aerosol particles (Ziemba et al., 2013; van Diedenhoven et al., 2022).

Aerosol hygroscopicity is described by physical quantities such as the diameter growth factor, $g(RH)$, and light scattering hygroscopic growth factor, $f(RH)$. The $g(RH)$ parameter relates the wet particle diameter of the aerosol at a high relative humidity to the dry diameter of the aerosol at low relative humidity, while $f(RH)$ relates total scattering due to the aerosol at high relative humidity (80%) to that at low relative humidity (<40%) (Waggoner et al., 1983; Hegg et al., 1993). Light scattering increases with relative humidity for most particles and is correlated to chemical composition and size (Baynard et al., 2006; Swietlicki et al., 2008) of particulate matter (Covert et al., 1972; Brock et al., 2016a).

Direct measurement of aerosol hygroscopicity, however, is difficult and is also not well-represented in climate models (Chen et al., 2014). The hygroscopicity parameter κ , is a single parameter that was developed to represent water uptake in models. It determines the volume (or mass or moles, with appropriate unit conversions) of water that is associated with a unit volume of a dry aerosol particle (Petters and Kreidenweis, 2007). A simple and commonly used water uptake model for calculating κ is based on the Zdanovskii, Stokes, and Robinson (ZSR) treatment for water soluble organic-inorganic mixed aerosol particles (Stokes and Robinson, 1966) where it is assumed that there are no interactions between the organic and inorganic species. In the ZSR model, water uptake of the individual non-interacting components can be summed up linearly to represent the total water uptake of the mixed aerosol. The interaction of organics and inorganics, however, along with the aging-specific density of organics is thought to influence hygroscopicity and affect both the ZSR calculation (Fan et al., 2020) and aerosol particle growth factor via changes in molecular structure, molecular weight, functionality, and/or other properties (Swietlicki et al., 2008).

Table 1: Hygroscopicity values of various aerosol types based on selected summary studies for measured $g(RH)$ (Swietlicki et al., 2008) and $f(RH)$ (Burgos et al., 2019; Titos et al., 2021) and modeled κ (Pringle et al., 2010).

Aerosol Type	g(RH=90%) (10 - 500 nm)	f(RH=85%/RH=40%) (< 1000 nm)	κ (5 - 500 nm)
Clean Marine	1.62 - 2.14	2.10 - 2.30	0.92
Polluted Marine	1.00 - 1.76	1.60 - 2.20	0.59
Background Continental	1.00 - 1.60	1.29 - 1.40	0.15 - 0.17
Urban Continental	1.00 - 1.68	1.38 - 2.10	0.21 - 0.36
Aged Biomass	1.15 - 1.30	1.02 - 2.10*	< 0.1
New Particle Formation	1.04 - 1.40	-	-
Free Troposphere	1.21 - 1.47	-	site specific
Arctic	1.19 - 1.44	2.70	~0.4

*Gomez et al., 2018 (f(RH=85%/RH=25%))

Observed and simulated aerosol hygroscopicity using aforementioned parameters are greater (Table 1) in clean marine air masses compared to air masses over land, near terrestrial biogenic sources which are secondary organics precursors, and under polluted conditions (Swietlicki et al., 2008; Duplissy et al., 2011; Petters and Kreidenweis, 2007; Burgos et al., 2019; Titos et al., 2021). In marine areas, hygroscopicity typically decreases with altitude with decreasing inorganic fractions (Pringle et al., 2010). Cloud processing over marine areas has been observed to increase the oxidation of organic aerosols (Che et al., 2022; Dadashazar et al., 2022) and hygroscopicity in general (Crumeyrolle et al., 2008). Continental aerosol particles have smaller diameters and are usually less hygroscopic due to more organic-rich aerosol particles ($\kappa = 0 - 0.1$ from Table S1) and pure elemental carbon particles (EC, $\kappa = 0 - 0.035$ from Table S1) (Wang et al., 2014; Kreidenweis and Asa-Awuku, 2014). Organics are generally less hygroscopic than inorganics ($\kappa = 0.56 - 1.24$ from Table S1), and their hygroscopicity is affected by oxidation level (e.g., O:C ratio), oxidation state, and solubility (Brock et al., 2016a; Wu et al., 2016; Thalman et al., 2017). Aging has also been found to increase aerosol hygroscopicity through the oxidation of secondary organic aerosols and organic aerosol interactions with inorganics (Engelhart et al., 2008; Liu et al., 2014; Saxena et al., 1995).

Although aerosol studies in the rapidly developing Southeast Asia (SEA) region are increasing, few are focused on the nature of aerosol particles and their interactions with water vapor and clouds (Tsay et al., 2013; Ross et al., 2018; Reid et al., 2023). There has been no comprehensive study of aerosol hygroscopicity in and around the Philippines in Southeast Asia. Understanding the interactions between aerosols and the complex geographic, meteorological, and hydrological environment in Southeast Asia remains challenging due to a still growing observational database, prevalence of clouds interfering with remote sensing, and limited modeling studies (Tsay et al., 2013; Lee et al., 2018; Chen et al., 2020; Hong and Di Girolamo, 2020; Amnuaylojaroen, 2023). This, along with increased local and transported emissions and prevalent moisture-rich conditions in the region, altogether motivate the need to understand aerosol hygroscopicity and associated impacts on radiative transfer and on climate (Brock et al., 2016a; Ziemba et al., 2013). How freshly emitted nearly hydrophobic particles transform into hygroscopic aerosol particles (Swietlicki et

al., 2008), for example, is an understudied topic in Southeast Asia where there are significant sources of particles with low hygroscopicity (Reid et al., 2023). Understanding aerosol hygroscopicity will also help in the need to improve remote sensing measurements in the region, which is affected by overlapping high and low level clouds (Burgos et al., 2019; Hong and Di Girolamo, 2020).

Predicting aerosol hygroscopicity, especially at higher relative humidity (RH), is especially difficult due to optical instruments underestimating particle light scattering at high RH and mechanisms other than hygroscopicity impacting particle growth (Gasparini et al., 2006; Mochida et al., 2006). This is important because atmospheric water content is high in Southeast Asia. For example, the hygroscopicity of secondarily formed organics (via gas-to-particle conversion) is found to be dependent on oxidation state for high RH (Shi et al., 2022). Southeast Asia has elevated levels of organics, inorganics, and elemental carbon (Cruz et al., 2019; AzadiAghdam et al., 2019; Oanh et al., 2006), allowing for an opportunity to see how hygroscopicity responds to a range of relative values of each of these elevated components. Therefore, relating aerosol particle composition to hygroscopicity, for closure (Xu et al., 2020), is particularly significant there.

Aerosol hygroscopicity is a crucial factor in the understanding and modeling of aerosol-cloud interactions, because of the role hygroscopicity plays in cloud drop activation. The NASA Cloud, Aerosol, and Monsoon Processes Philippines Experiment (CAMP²Ex) was designed to understand the role of aerosol particles in cloud formation and in regulating solar radiation during the southwest monsoon (Reid et al., 2023). CAMP²Ex occurred between August and October 2019 over the Philippines and neighboring areas. The campaign provides an aircraft dataset with measurements focused on aerosol and cloud properties, which affords a valuable opportunity to evaluate models with these measurements for shallow to moderate convection, which is one of the biggest challenges for regional and global-scale atmosphere models to represent because these clouds are much smaller than the model grid spacing.

Global atmospheric model evaluation of aerosol extinction for the CAMP²Ex region suggests that biomass burning aerosol hygroscopicity is over-estimated by global atmosphere models, with both the model size representation of the aerosol particles and the size discrepancy between model and observations contributing to this (Collow et al., 2022; Edwards et al., 2022). The findings from Collow et al. (2022) and Edwards et al. (2022) bring up the need for a more thorough understanding of the components of biomass burning aerosols in the region that affect observed and modeled hygroscopicity. The overestimation of hygroscopicity due to biomass burning can affect the representation of clouds in the region. Clouds, especially shallow cumulus clouds, like those in the tropical West Pacific (which the CAMP²Ex region is part of) have been underestimated by models due to the lack of observational data to improve convective parameterizations (Chandra et al., 2015). Part of the challenge in modeling aerosol-cloud interactions is the ability to both have a high-resolution representation, at the scale of the shallow convection, in a large enough domain, which is important for understanding climatic effects to properly account for the bulk behavior of cloud fields (Spill et al., 2019). This could be addressed by evolving modeling infrastructures, with higher resolution schemes ranging from regional to convective scale within a larger domain (Pfister et al., 2020; Radtke et al., 2021).

Knowledge gaps identified above are addressed in this study using the CAMP²Ex dataset. To our knowledge, this is the first time this dataset has been explored extensively to characterize aerosol hygroscopicity properties in the region. The goals of this proposed study are to (i) characterize the spatial distribution of aerosol hygroscopicity in Southeast Asia during the CAMP²Ex airborne mission, (ii) relate aerosol hygroscopicity and composition, (iii) identify emission events that impact aerosol hygroscopic growth, and (iv) evaluate a global chemical transport model with regional refinement for aerosol vertical transport.

2. Methods

2.1 CAMP²Ex Field Campaign

CAMP²Ex included 19 research flights with a NASA P3 from 24 August to 5 October 2019. Twelve of these flights were associated with the southwest monsoon (SWM) followed by a flow reversal with seven flights conducted during the northeast monsoon (NEM) (Reid et al., 2023). As summarized by Reid et al. (2023), the combination of airborne and ship-based measurements helps to characterize interactions between various aerosol particle sources (e.g., biomass burning, industrial, natural) and small to congestus convection. Below we note the P3 instruments most relevant to this study.

2.2 Observations and Derived Quantities

2.2.1 P3 Instrumentation

As summarized in Table 2, data are used from a variety of aerosol particle and trace gas instrumentation. The aerosol particle scattering and absorption instruments measure the optical properties of bulk aerosol particles (PM₅): < 5 μm dry diameter (McNaughton et al., 2007). Aerosol composition and size data for submicrometer particles were considered when they were collected using a forward-facing shrouded isokinetic inlet. Non-refractory species in the submicrometer range studied using an aerosol mass spectrometer (AMS) included sulfate, nitrate, ammonium, organics, and chloride. We also use the ratio of the mass spectral marker m/z 44 marker relative to total organic mass, f_{44} , as a possible indicator of air mass age. Submicrometer refractory species of black carbon (also referred to as elemental carbon) from a single particle soot photometer (SP2) were also included in the study. Bulk water-soluble aerosol particles were collected using a particle-into-liquid sampler (PILS) and were analyzed using ion chromatography; species quantified included oxalate, NH_4^+ , dimethylamine (DMA), K^+ , SO_4^{2-} , Ca^{2+} , Na^+ , Mg^{2+} , Cl^- , NO_3^- , Br^- , and NO^- . Cloud-free conditions are identified to ensure the highest quality aerosol data using a cloud flag product based on measurements from the fast cloud droplet probe (FCDP) and two-dimensional stereo probe (2D-S). Aerosol particle composition data are considered for those cases when the total aerosol non-refractory particle mass was greater than $0.4 \mu\text{g sm}^{-3}$.

Table 2: Summary of instrument data used in this work.

Parameter	Instrument	Time Resolution	Uncertainty	Sampled Aerosol Particle Size	Reference
Latitude, Longitude, and Altitude	Northrop Grumman Litton 251 EGI	1 s	~5 m spherical error probable; 0.01°	N/A	Reid et al., 2023
Dry (RH < 40%) and humidified (RH = 80%)) light scattering coefficient ($\lambda = 450, 550, 700$ nm)	Parallel humidified TSI 3563 Nephelometers	1 s	30%	< 5 μ m diameter	Ziemba et al., 2013; McNaughton et al., 2007
Dry (RH < 40%) light absorption coefficient ($\lambda = 470, 532, 660$ nm)	Radiance Research 3 Particle Soot Absorption Photometer (PSAP)	1 s	15%	< 5 μ m diameter	Mason et al., 2018; McNaughton et al., 2007
Non-refractory aerosol (Organics, SO ₄ , NO ₃ , NH ₄ , Cl) mass concentration	Aerodyne High-Resolution Time-of-Flight Mass Spectrometer (AMS)	25 s	LLOD (μ g sm ⁻³): Organics, 0.169; SO ₄ , 0.039; NO ₃ , 0.035; NH ₄ , 0.169; Cl, 0.036; Uncertainty: 50%	approximate relevant size range is 60-600 nm vac. aero. diameter	DeCarlo et al., 2008
Water-soluble mass concentration	Particle-into-liquid sampler (PILS) followed by offline ion chromatography analysis	238 s	30%	< 5 μ m diameter	Sorooshian et al., 2006 Crosbie et al., 2020
Refractory black carbon (BC) mass concentration	Single Particle Soot Photometer (DMT SP2)	1 s	10%	100 - 700 nm diameter	Schwarz et al., 2006
CO concentration	Picarro G2401-m	1 s	5 ppb	N/A	DiGangi et al., 2021
Volume and number concentration of particles	TSI Laser Aerosol Spectrometer (LAS) Model 3340	1 s	20%	0.1 - 5 μ m optical diameter	Moore et al., 2021
Volume size distribution	Fast integrated mobility spectrometer (FIMS)	1 s	Concentration: 15%; Size: 3%	10 – 500 nm mobility diameter	Kulkarni and Wang, 2006;

Cloud particles (data used for cloud screening)	SPEC-Hawkeye 2D-S	1 s	20%	10 μm – 3 mm diameter	Lawson et al. 2006a, Woods et al. 2018

157

158 2.2.2 Aerosol Hygroscopicity, $f(\text{RH})$, and Other Aerosol Optical Properties

159 Aerosol hygroscopicity is reported using the parameter $f(\text{RH})$, which is unitless and is the amplification factor in
160 scattering due to a change in RH. The $f(\text{RH})$ parameter is calculated from the empirically derived exponential fit
161 coefficient gamma (γ) (Ziemba et al., 2013). The gamma parameter is based on parallel nephelometer measurements
162 of scattering at 550 nm at two different relative humidity levels: dry ($< 40\%: \text{RH}_{\text{dry}}$) and humidified (controlled to 82
163 $\pm 10\%: \text{RH}_{\text{wet}}$). Gamma (Eq. 1) was calculated for times when the dry (SC_{dry}) and humidified (SC_{wet}) scattering
164 coefficients (Table 2) are greater than or equal to 5 Mm^{-1} . The $f(\text{RH})$ (Eq. 2) was then derived from γ (Hänel, 1976).

165

$$166 \quad \gamma = \frac{\ln \frac{\text{SC}_{\text{wet}}}{\text{SC}_{\text{dry}}}}{\ln \frac{100 - \text{RH}_{\text{dry}}}{100 - \text{RH}_{\text{wet}}}} \quad (1)$$

$$167 \quad f(\text{RH}) = \left(\frac{100 - \text{RH}_{\text{wet}}}{100 - \text{RH}_{\text{dry}}} \right)^{-\gamma} \quad (2)$$

168 Each nephelometer was calibrated with pure CO_2 prior to the campaign and zero checks were performed periodically
169 during the flights to prevent baseline drift. Hydrophilic polystyrene latex (PSL) aerosol were also introduced
170 periodically in-flight to ensure the nephelometers were consistent. All nephelometer scattering coefficient
171 measurements were corrected for truncation errors using a documented method (Anderson and Ogren, 1998). System
172 response was verified in flight by introducing hydrophobic PSL spheres into the sample stream to ensure an $f(\text{RH})$
173 value of 1.0 is observed. Relative humidity measurements for the calculation of $f(\text{RH})$ were calibrated in the laboratory
174 using nebulized monodisperse 200 nm ammonium sulfate to ensure deliquescence at $\sim 80\%$ RH and at the typical
175 measurement flow rates (i.e. 10 L min^{-1}) (Brooks et al., 2002). The RH was slowly ramped up from $\sim 60\% - 90\%$ and
176 the apparent deliquescence RH was calculated based on the sharp increase in scattering in the humidogram. The offset
177 between the calculated RH and the deliquescence RH for ammonium sulfate (i.e., $\sim 79.5\%$) was applied to the data
178 post-processing. Calibration at $\sim 80\%$ RH increases the confidence in the humidified nephelometer data accuracy.
179 Non-linearities can occur at low RH measurements and add to uncertainties, but the $f(\text{RH})$ calculation is much less
180 sensitive at the dry end of the spectrum. Internal RH sensors were used because their placement is most relevant to

the sampling condition inside the nephelometer. Note that sampling efficiency decreases for supermicrometer diameter particles with increasing size up to the 5- μm inlet cutoff, due to losses in transport tubing and in the drying/humidification control system. Thus, derived $f(\text{RH})$ is applicable to accumulation-mode particles and is partially sensitive to coarse-mode particles from 1-5 μm diameter.

Single scattering albedo (SSA) was calculated when both the scattering and absorption coefficients (smoothed with 30 s running average) were greater than 2 Mm^{-1} . The Ångström exponent (AE) was calculated using the smoothed 30 s running average of the scattering and absorption coefficients. The scattering Ångström exponent (SAE, 450-700 nm) was computed when the scattering coefficient was greater than 2 Mm^{-1} based on Ziemba et al. (2013) and the absorption Ångström exponent (AAE, 470-660 nm) was computed when the absorption coefficient was greater than 2 Mm^{-1} to try to minimize noise issues (Mason et al., 2018). Absorption measurements were corrected for a variety of errors using the method from Virkkula (Virkkula, 2010). The PSAP filters were changed before transmission dropped below 70%. This standard practice minimizes non-linearity effects due to filter loading.

2.2.3 Sea Salt

Bulk sea salt mass concentration was calculated using summed PILS concentrations of Na^+ , Cl^- , and Mg^{2+} along with the respective concentrations of the mass concentrations of K^+ , Ca^{2+} and SO_4^{2-} in sea salt (0.037, 0.04 and 0.25, respectively, by mass) (Crosbie et al., 2022).

2.2.4 Aerosol Particle Classification

Aerosol particle optical data were grouped depending on their AAE and SAE (Section 2.2.2) values and based on the method of Cazorla et al. (2013), which used sun photometer measurements to arrive at the following classifications as part of evaluating aircraft data over California, USA: coated large particles, dust and elemental carbon mix, dust dominated, organic carbon and dust mix, organic carbon dominated, elemental carbon and organic carbon mix, mixed, and elemental carbon dominated. This method has been used for cases when chemical composition is not available (Höpner et al., 2019), and can be useful because the composition data from the AMS is limited to submicrometer particles (0.06 to 0.6 μm vacuum aerodynamic diameter) while the $f(\text{RH})$ includes relatively larger particles ($< 5 \mu\text{m}$ dry diameter).

2.2.5 Effective Particle Density

Following Shingler et al. (Shingler et al., 2016b), effective particle density was calculated by dividing the sum of the 30 s total mass concentration from the AMS species (organics, SO_4^{2-} , NO_3^- , NH_4^+ , and Cl^-) and 30 s averaged black carbon from SP2 by the 30 s averaged integrated (for particles with diameter from 0.1 to 1 μm) volume concentration from the LAS (Table 2).

2.3 Modeling

2.3.1 Trajectory Analysis

This work leverages trajectory results explained in detail by Hilario et al. (2021) using the National Oceanic and Atmospheric Administration (NOAA) Hybrid Single Particle Lagrangian Integrated Trajectory Model (HYSPLIT) (Stein et al., 2015; Rolph et al., 2017). Five-day HYSPLIT back trajectories from specific CAMP²Ex flight locations were associated with air masses undergoing long-range transport from either the Maritime Continent (MC), East Asia (EA), peninsular Southeast Asia (PSEA), or the West Pacific (WP) when they were within the regions at altitudes below 2 km for more than 6 h. The back trajectories were generated based on 1-minute resolution aircraft locations and 0.25° x 0.25° resolution NOAA Global Forecasting System (GFS) archived meteorological data. The source regions are approximately within the following lowest and highest latitude and longitude values, respectively: MC (-9.5° - 6.5° and 95° - 119°), EA (22° - 47° and 105° - 121.5°), PSEA (10° - 20° and 98° - 106 °), and WP (3°-25° and 120.5°-122.5°). The classification “Other” was used for back trajectories that either passed by the regions but at elevations above the boundary layer (defined as 2 km), came from sources farther away than the four listed above, were more localized to the Philippines, had too few sample counts, or were from stagnant air (Hilario et al., 2021).

2.3.2 CAM-chem Model Configuration

The Community Atmosphere Model with comprehensive tropospheric and stratospheric chemistry CAM-chem is used here as the atmospheric component of the Community Earth System Model (CESM2). CAM-chem includes the modal aerosol model (MAM4) (Liu et al., 2016) and results were evaluated with the CAMP²Ex AMS composition and f(RH) observations for two case studies. Two CAM-chem simulations with different horizontal resolutions were performed using the spectral element grid mesh and dynamical core. The grid mesh resolution for one simulation was uniform with ~111 km (labeled ne30). The other simulation employed regional refinement over East Asia with grid spacing ~27 km (labeled MUSICA) in the regionally refined region and ~111 km elsewhere across the globe; a configuration as part of the Multi-Scale Infrastructure for Chemistry and Aerosols version 0 (MUSICAv0) (Schwantes et al., 2022). More information about CAM-chem is in the supplementary section (S1).

In CAM-chem, aerosol hygroscopicity is represented with the kappa value (Petters and Kreidenweis, 2007) using the mixing rule (Stokes and Robinson, 1966). Kappa was calculated from the CAM-chem Aitken (0.015 – 0.053 μm) and accumulation mode (0.058 – 0.48 μm) outputs based on the volume fractions of the aerosol constituents (ϵ , Eq. 3) that were derived from their densities (Table S1). The following internally mixed aerosol species from CAM-chem were included in the analysis: organics (primary/hydrophobic, aged/hygroscopic, and secondary (C₁₅H₃₈O₂)), sulfate (NH₄HSO₄), sea salt, dust (AlSiO₅), and black carbon (primary/hydrophobic and aged/hygroscopic) (Tilmes et al., 2023). Some limitations in the calculation of kappa are that CAM-chem does not include nitrate aerosol, and that constant kappa values for primary and aged organics based on past work (Table S1) were used, even if it is known that kappa of organics varies with aging (Kuang et al., 2020). Kappa was also calculated from the submicrometer AMS and SP2 observations using the assigned species properties for available aerosol species in CAM-chem: aged organics, aged black carbon, and ammonium sulfate. Submicrometer sea salt and dust data are not available and were not included in the calculation for submicrometer kappa from observations.

$$\kappa_{chem} = \sum \kappa_i \varepsilon_i \quad (3)$$

To enable a corresponding evaluation based on actual aerosol hygroscopicity observations, the $f(RH)$ from CAMP²Ex were converted to kappa based on past studies (Brock et al., 2016b; Kuang et al., 2017; van Dienenhoven et al., 2022). The approximate wet (80%) and dry (20%) relative humidity values of the scattering measurements were used to convert $f(RH)$ to an optical kappa (κ_{opt}) based on Equation 4 (Brock et al., 2016b; Kuang et al., 2017). This was approximated from the proportional relationship between the aerosol scattering cross section (which is the basis of $f(RH)$) and aerosol volume (the change of which is usually described as growth factor) which Brock et al. (2016b) in their study had associated with kappa. The optical kappa was converted to the chemical kappa (κ_{chem}) based on the slope of the relationship between κ_{opt} and κ_{chem} from Brock et al. (2016b). This method (Eq. 5) of converting κ_{opt} to κ_{chem} was also used by van Dienenhoven et al. (2022) for the $f(RH)$ data for CAMP²Ex and is associated with 40% uncertainty (van Dienenhoven et al., 2022). The derived chemical kappa values for bulk aerosol particles are compared to the kappa calculated using the ZSR mixing rule from the submicrometer observations (AMS and SP2) and model outputs.

$$f(RH) = \frac{1 + \kappa_{opt} \frac{RH_{wet}}{100 - RH_{wet}}}{1 + \kappa_{opt} \frac{RH_{dry}}{100 - RH_{dry}}} \quad (4)$$

$$\kappa_{chem} \approx \frac{\kappa_{opt}}{0.56} \quad (5)$$

3. Results and Discussion

3.1 General Characterization of $f(RH)$ for CAMP²Ex

3.1.1 Spatial Distribution of $f(RH)$

The $f(RH)$ values in the CAMP²Ex campaign (Fig. 1a) had an interquartile range of values between 1.05 and 1.42 and were low (median of 1.24 for 143,107 1 s points) compared to other (Table 1) polluted marine environments (Titos et al., 2021). We note that the comparisons to other studies may be affected by the slight difference in relative humidity ($f(RH)=85\%/RH=40\%$ for Titos et al. (2021) and $f(RH)=82 \pm 10\%/RH<40\%$ for this study) used to calculate $f(RH)$. The distribution of $f(RH)$ and ambient RH values is narrowest in the lowest altitudes (< 3 km), where most of the samples were taken (Fig. 1b). Both $f(RH)$ and RH distributions become broader at higher altitudes, where there is a higher prevalence also for higher $f(RH)$ values and lower RH values. Broadening of the $f(RH)$ distribution at higher altitudes is at least partially attributed to lower dry scattering coefficients that result in increased uncertainty in the calculation of $f(RH)$. The different aerosol sources (Fig. 1a) in the region also contribute to the range of measured $f(RH)$, with transported emissions from more distant sources presumably more influential at the highest altitude ranges.

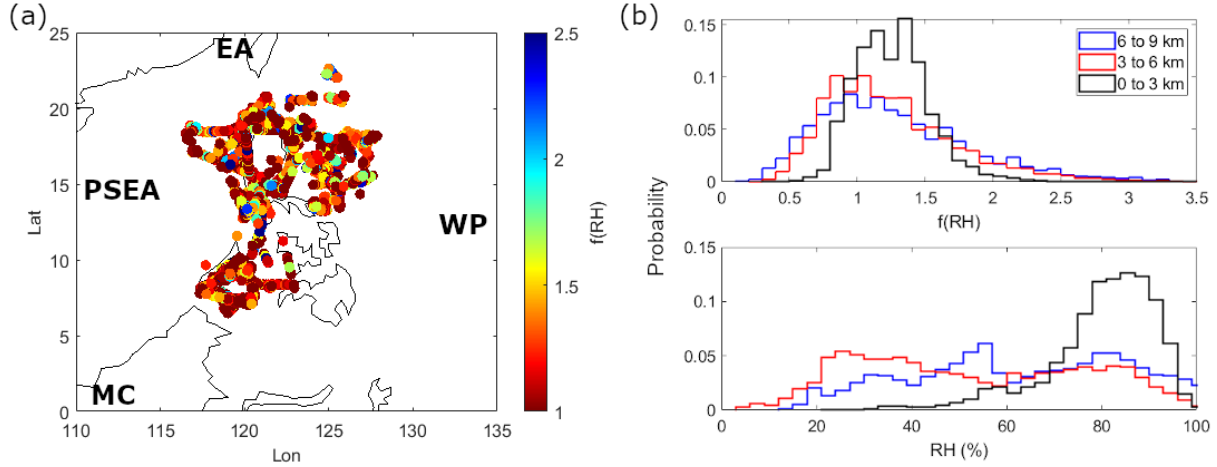

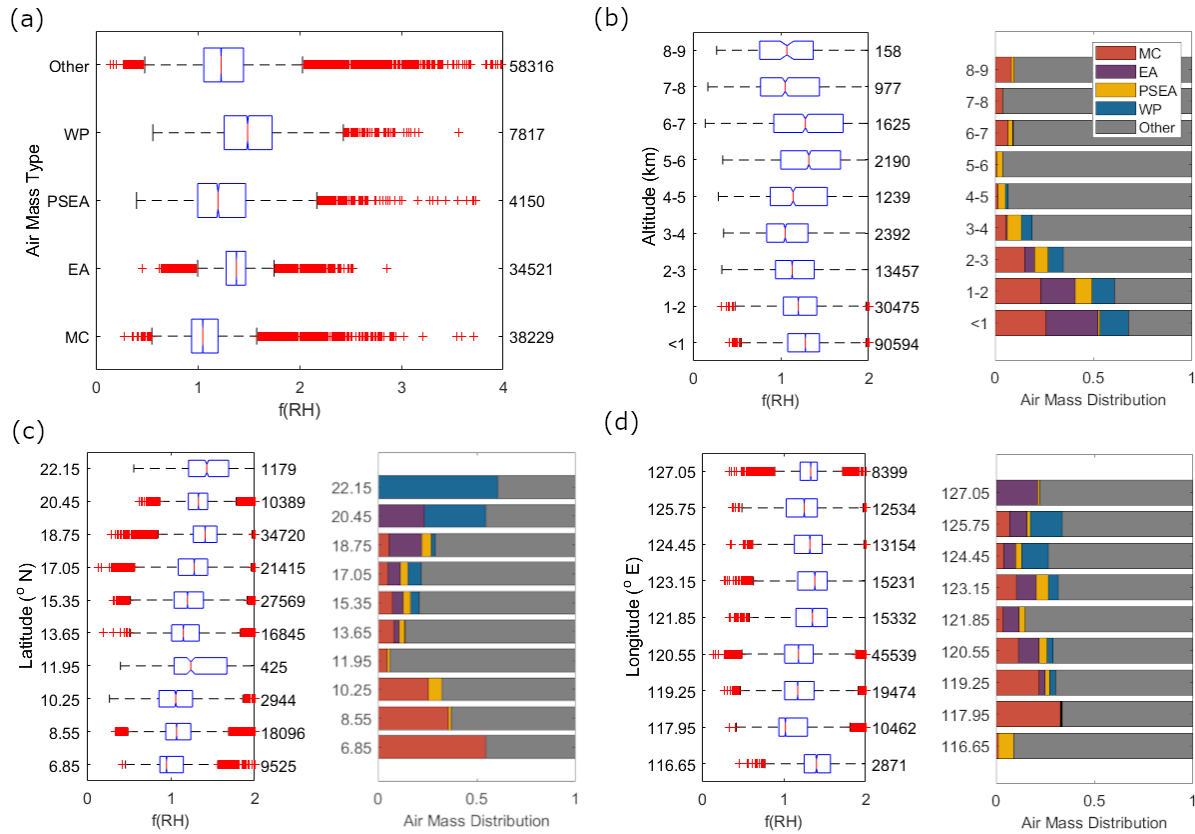

Figure 1. (a) Map showing flight locations during CAMP²Ex color coded by $f(RH)$ values and approximate locations of the air mass sources (black text) identified by Hilario et al. (2021) that affected CAMP²Ex: Maritime Continent (MC), East Asia (EA), peninsular Southeast Asia (PSEA), and the West Pacific (WP) (PSEA is farther west at $\sim 105^\circ\text{E}$ and EA extends farther north) of air mass sources (Hilario et al., 2021) around the region. (b) Histograms of $f(RH)$ and relative humidity (RH) for three altitude bins with the following counts: $n_{(0 \text{ to } 3 \text{ km})}$: 139,026, $n_{(3 \text{ to } 6 \text{ km})}$: 10,321, and $n_{(6 \text{ to } 9 \text{ km})}$: 7,260.

The lowest median $f(RH)$ (1.05 with Q1 and Q3 of 0.94 and 1.2) is from air masses traced to the MC (Fig. 2a), which coincide with influence from smoke particles. The air mass from EA (Fig. 2a) has the narrowest range of values (Q1: 1.28, median (Q2): 1.38, Q3: 1.47) compared to other air masses, likely representative of urban aerosol particles. The highest median $f(RH)$ (1.49 with Q1 and Q3 of 1.26 of 1.73) are from air masses with back trajectories from the WP (Fig. 2a), likely due to marine aerosol particles interacting with particles from the MC and other regional sources. This mixing of the otherwise clean marine air with regional pollution sources effectively decreases aerosol hygroscopicity and this type of environment is often called a polluted marine environment (Titos et al., 2021).

Most (98%) of the $f(RH)$ data were calculated for observations below 3 km (Fig. 2b), due to the relatively clean free troposphere in the region. Median $f(RH)$ values generally decrease with altitude in the lower 3 km. An increase in median $f(RH)$ is observed between 4 – 6 km (median from 1.14 to 1.32), where the contribution of the mixed air mass (“Other”) is most dominant. The $f(RH)$ values decrease above 6 km to the lowest median $f(RH)$ (1.07) between 8 – 9 km, where air masses are generally from Other and the MC.

Latitudinally (Fig. 2c), $f(RH)$ is lowest nearest Borneo in the MC (median of 0.95 to 1.07 in the regions from 6.85°N – 10.25°N), coincident with the dominant influence of biomass burning. There were active fires in the area during the time samples were taken from this latitude. $f(RH)$ is highest in the northern Philippines (median of 1.33 to 1.44 in the regions from 18.75°N – 22.15°N), where the influence of WP and EA air was most prevalent. This is consistent with the longitude data (Fig. 2d), which exhibit the lowest $f(RH)$ values for longitudes (median of 1.02 to 1.18 in the regions from 117.95°E – 120.55°E) that had the highest MC contribution. The highest $f(RH)$ is observed in longitudes (median of 1.38 to 1.40 in the regions west of 116.65°E and east of 123.15°E) that were more associated with the northern Philippines (Fig. 1a). To delve deeper into our analysis, we discuss next the size and composition data.

317 3.1.2 f(RH) Relationships with Size and Composition

318 The relative size of particles per air mass can be inferred from the extinction Ångström exponent (AE), which relates
 319 the extinction of light at specific wavelengths to particle size (Ångström, 1929). Since scattering is the dominant
 320 component of extinction, the scattering Ångström exponent (SAE) is often used to relate to particle size, where larger
 321 SAE suggests smaller particles. The median SAE values (Fig. 3a) are similar and between 2.09 (MC with Q1 and Q3
 322 of 1.92 and 2.26) to 2.16 (Other with Q1 and Q3 of 1.75 and 2.32) for four of five air masses, indicative of smaller
 323 particles. The WP has a median value of 1.37 (with Q1 and Q3 of 1.05 and 1.88), suggestive of the presence of a
 324 mixture of accumulation-mode and coarse-mode particles (SAE < 1 occurs for large particles like sea salt and dust)
 325 (Schuster et al., 2006; Bergstrom et al., 2007). Past studies have suggested that biomass burning particles exhibit SAE
 326 values greater than 1.4, which does not discount the fact that most of the f(RH) data collected during CAMP2Ex is
 327 possibly impacted by biomass burning.

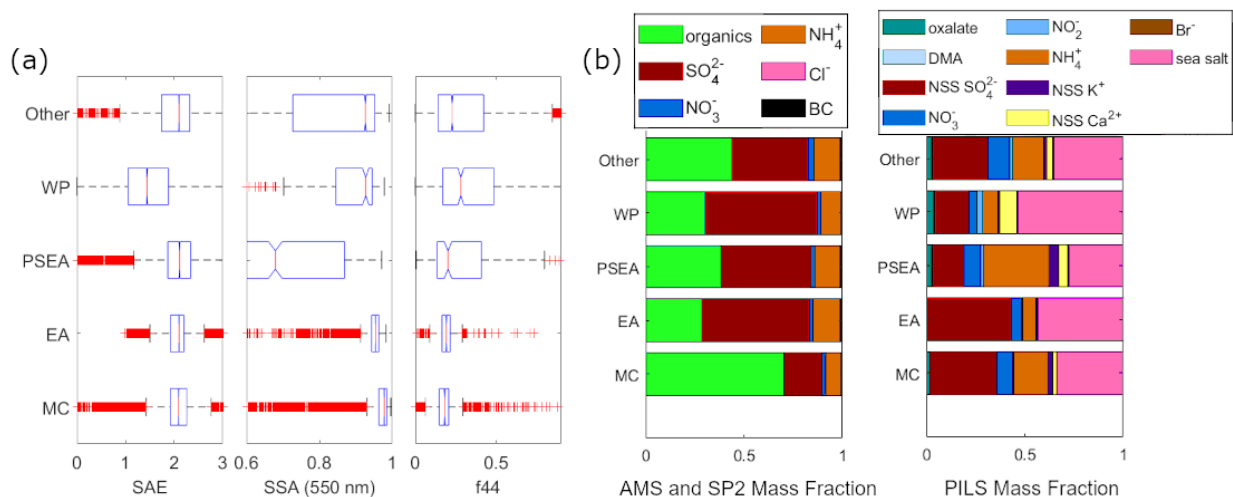

Figure 3. (a) Boxplots of 1 s scattering Ångström exponent (SAE), single scattering albedo (SSA, 550 nm), and ratio of the mass spectral marker m/z 44 marker relative to total organic mass (f_{44}) and (b) (left) submicrometer mean organic, SO_4^{2-} , NO_3^- , NH_4^+ , Cl^- , and black carbon (BC) mass fractions and (right) bulk ($< 5 \mu\text{m}$) oxalate, dimethylamine (DMA), non-sea salt SO_4^{2-} , NO_3^- , NH_4^+ , non-sea salt K^+ , non-sea salt Ca^{2+} , Br^- , and sea salt mass fractions per air mass (Hilario et al., 2021).

One of the indicators of biomass burning in Southeast Asia is organic matter (Adam et al., 2021). The MC air mass (Fig. 3b) has the greatest (71%) mass fraction of organics among the air masses and the highest median SSA (0.98 with Q1 and Q3 of 0.96 and 0.99) (Fig. 3a) that suggests more scattering, rather than absorbing, particles (Moosmüller and Sorensen, 2018). This is consistent with observations from field work in tropical peatland fire in Southeast Asia, where particles were mostly from smoldering combustion and were moderately absorbing, with brown carbon dominating absorbance (Stockwell et al., 2016). Smoldering combustion, which is more common in the Maritime Continent (Reid et al., 2013), is known to produce less elemental carbon (Reid et al., 2005) and potassium (Robinson et al., 2004) compared to flaming combustion. Biomass burning activities were active in the MC during the field campaign (Reid et al., 2023). The MC air mass also has the lowest f_{44} median values (0.18 with Q1 and Q3 of 0.15 and 0.21) (Fig. 3a) suggesting it is the least-oxidized and least photochemically-aged air mass and thus closest to the source compared to other air masses. Chen et al. (2022) who studied tropical peat smoldering (similar to those in MC) showed that primary organics were not oxidized ($f_{44} < 0.02$) while secondary organics were highly oxidized, that oxidation increases f_{44} (oxidized organics: $0.01 < f_{44} < 0.11$), and that high RH speeds up the oxidation process especially for smaller particles ($\sim 100 \text{ nm}$) (Chen et al., 2022). In the U.S., as another example, f_{44} from wildfire plumes up to 8 hours old did not exceed 0.12 (Garofalo et al., 2019). The high RH during CAMP²Ex (Fig. 1b) likely led to the increased oxidation of secondary organics resulting in median f_{44} values that are relatively high (for all air masses even in MC), suggesting that most of the particles sampled during CAMP²Ex are aged. The high organic mass fraction is consistent with the MC having the lowest median $f(\text{RH})$ as organics are known to reduce aerosol hygroscopicity (Kalberer, 2014; Sorooshian et al., 2017; Shingler et al., 2016a).

There is an inverse relationship between hygroscopicity and organic mass fraction data that is most evident in $f(\text{RH})$ values collected within the boundary layer ($< 3 \text{ km}$) during CAMP²Ex (Fig. 4a). Those data points that have the highest organic mass fraction values (> 0.6) are also associated with CO concentrations ($> 250 \text{ ppb}$) that are typically

associated with biomass burning (Shingler et al., 2016a) and are mostly from the MC area (Fig. 4b). The slope of the inverse relationship between $f(\text{RH})$ and organic mass fraction is most steeply negative (-0.81) for the air masses coming from EA (Fig. 4c).

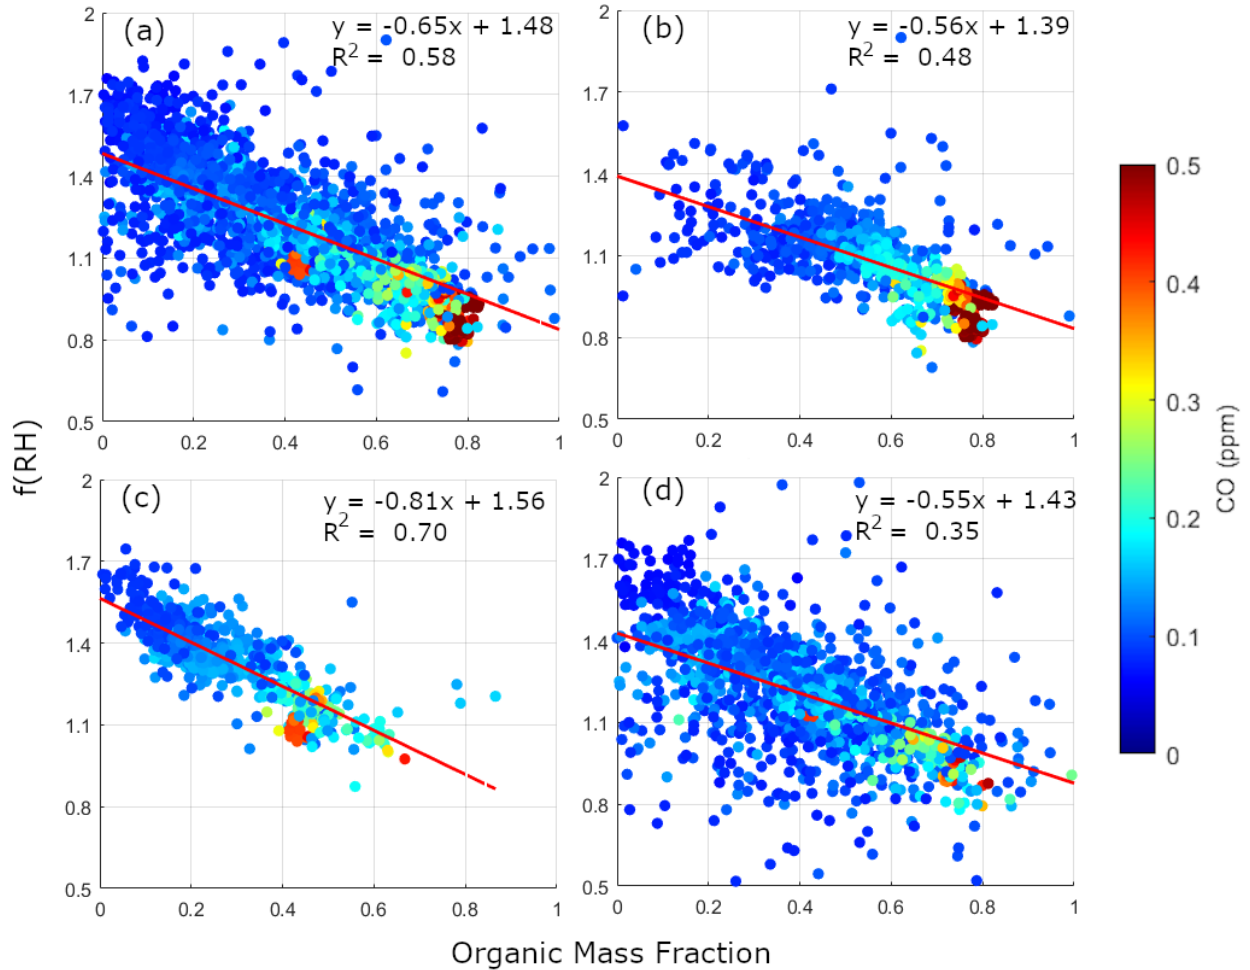

Figure 4. (a-d) Scatter plots of 30 s averaged $f(\text{RH})$ and corresponding organic mass fraction contribution to total submicrometer aerosol mass (sum of organic, SO_4^{2-} , NO_3^- , NH_4^+ , Cl^- , and black carbon (BC) mass concentration) for (a) all data collected at altitudes below 3 km and (b-d) for air masses coming from (b) the Maritime Continent (MC), (c) East Asia, and (d) Other. The dots are colored by their CO concentration.

The highest median $f(\text{RH})$ values are from the WP and EA air masses (Fig. 2a). Both have lower organic mass fractions (0.29 and 0.30, respectively) compared to other air masses and are therefore expected to have higher $f(\text{RH})$ based on Fig. 4. The WP air masses have coarser particles, based on their SAE values (Fig. 3a), and have a marine origin (with higher DMA mass fraction, Fig. 3b) with high sea salt fraction (54%, Fig. 3b), contributing to it having the highest median $f(\text{RH})$ amongst the air masses. The WP air masses appear to have interacted with aged organic particles from biomass burning and industry including fine absorbing particles potentially from industry and dust owing to its relatively high median f_{44} (0.26 with Q1 and Q3 of 0.17 and 0.48) and low median SSA (0.93 with Q1 and Q3 of 0.85 and 0.95). Particles with predominantly clean marine sources tend to have higher (≥ 0.97) SSA

(Dubovik et al., 2002), thus the WP data suggest a polluted marine source (Lacagnina et al., 2015). Though, we note that the air masses from the WP have relatively low scattering and absorption coefficients and that these could have affected the calculations for SSA. EA air exhibits the highest non-sea salt sulfate mass fraction (0.43) (Fig. 3b) that, along with its predominantly fine particle size and median SSA (0.95 with Q1 and Q3 of 0.94 and 0.96), strongly suggests that it was transported from an urban source. Sulfate is a known industrial product of East Asia (Smith et al., 2011; Li et al., 2017; Lorenzo et al., 2023).

Particles from PSEA have the lowest median SSA (0.68 with Q1 and Q3 of 0.55 and 0.87) (Fig. 3a). This suggests the presence of more absorbing particles relative to scattering, possibly including elemental carbon and aged dust. Based on the PSEA air masses having the highest non-sea salt potassium mass fraction (0.05, Fig. 3b) the particles could be from biomass burning. It is well-documented that dust can be entrained in smoke plumes due to reasons such as turbulent mixing around flames and burn fronts (Palmer, 1981; Kavouras et al., 2012; Maudlin et al., 2015; Schlosser et al., 2017). Dust from East Asia and biomass burning from PSEA have been observed to be mixed in the boreal spring in Taiwan (Dong et al., 2018), and though CAMP²Ex sampled during a different season, it is still possible that this mixing of East Asian dust and PSEA biomass burning could have occurred and impacted the CAMP²Ex region during the field campaign.

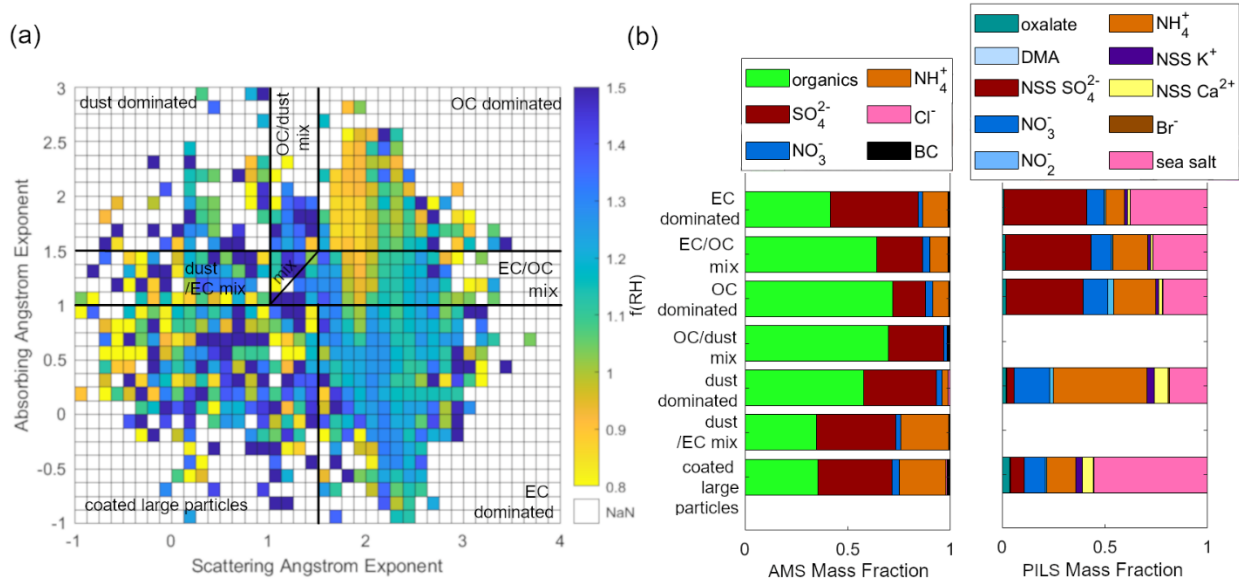

Figure 5. (a) Median $f(RH)$ of data points with absorbing Ångström Exponent (AAE) and scattering Ångström Exponent (SAE) values that correspond to suggested aerosol types from past studies (Cazorla et al., 2013) with following counts and bulk median $f(RH)$ per aerosol type: EC dominated (16,908 and 1.19), EC/OC mix + mix (20,686 and 1.03), OC dominated (1942 and 0.94), OC/dust mix (55 and 1.31), dust dominated (79 and 1.15), dust/EC mix (204 and 1.12), and coated large particles (729 and 1.21). (b) (left) Submicrometer mean organic, SO₄²⁻, NO₃⁻, NH₄⁺, Cl⁻, and black carbon (BC) mass fractions and (right) available bulk (< 5 µm) oxalate, dimethylamine (DMA), non-sea salt SO₄²⁻, NO₃⁻, NO₂⁻, NH₄⁺, non-sea salt K⁺, non-sea salt Ca²⁺, Br⁻, and sea salt mass fractions per aerosol type.

Using the AAE and SAE with categorization determined by Cazorla et al. (2013), the $f(RH)$ can be related to the types of aerosols. Note that the median $f(RH)$ values for the aerosol types may be slightly different than the raw 1 s $f(RH)$ data because the median $f(RH)$ is only calculated for the aerosol types when both the scattering and absorbing

Ångström Exponent values are available. The highest median $f(RH)$ of 1.31 (with Q1 and Q3 of 0.89 and 1.46) and 1.21 (with Q1 and Q3 of 0.88 and 1.68) are from the OC/dust mix and coated large particles aerosol types (Fig. 5), respectively, though there are only 55 data points for the OC/dust mix so the aerosol classification for it may not be as robust. The high $f(RH)$ for the coated large particles is consistent with its largest bulk sea salt mass fraction (0.56) (Fig. 5b) compared to other aerosol types, though they only make up 1.8 % of the total number of particles. Dust dominated particles make up only 0.05% of the total number of particles and had the highest non-sea salt calcium and a median $f(RH)$ of 1.15 (with Q1 and Q3 of 0.94 and 1.43).

Most of the aerosol particles ($< 5 \mu m$ dry diameter and 93% of all particles) collected during the CAMP²Ex field campaign have optical properties (Fig. 5a) that resembled EC/OC mix + mix (in this case we combined the sub-categories of EC/OC mix and mix) (51%) and EC dominated (42%) aerosol types. These carbonaceous particles are less hygroscopic, and their dominance helps to explain the low median $f(RH)$ in the CAMP²Ex region. The EC dominated particles have the third highest median $f(RH)$ at 1.19 (with Q1 and Q3 of 1.05 and 1.33), which is unusual because EC is known to be hydrophobic. Compositional data sheds some light on this, because the particles classified as EC dominated have higher submicrometer sulfate (0.43) and bulk sea salt (0.38) mass fractions (Fig. 5b) compared to particles classified as OC (0.16 and 0.22) and dust dominated (0.35 and 0.19), which are known to have low hygroscopicity in general. This mixing of sulfate and sea salt with EC dominated particles increases their bulk $f(RH)$. The EC dominated particles come from the EA, MC, and Other air masses. East Asia is a known sulfur source and shipping contributes to sulfate in the region (Miller et al., 2023). Peat smoke particles from MC have also been found in past studies to have sulfate mixed with carbonaceous species (Nakajima et al., 1999), where up to ~20% of the mass fraction of secondary organic aerosol from lab experiments on peat burning was attributed to sulfate (Chen et al., 2022).

The OC dominated type have the highest submicrometer organic mass fraction (0.72) and a median $f(RH)$ of 0.94 (with Q1 and Q3 of 0.85 and 1.06), which is consistent with the expected effect of organics to lower hygroscopicity. The median $f(RH)$ values below 1, though, are counterintuitive given that the presence of moisture in the region is thought to generally increase the particle size and consequently the amount of aerosol light scattering. Data where $f(RH)$ is less than unity have been observed in past studies due to a number of suspected factors including (but not limited to) volatilization effects, changes in optical properties during humidification, and particle restructuring (Shingler et al., 2016b).

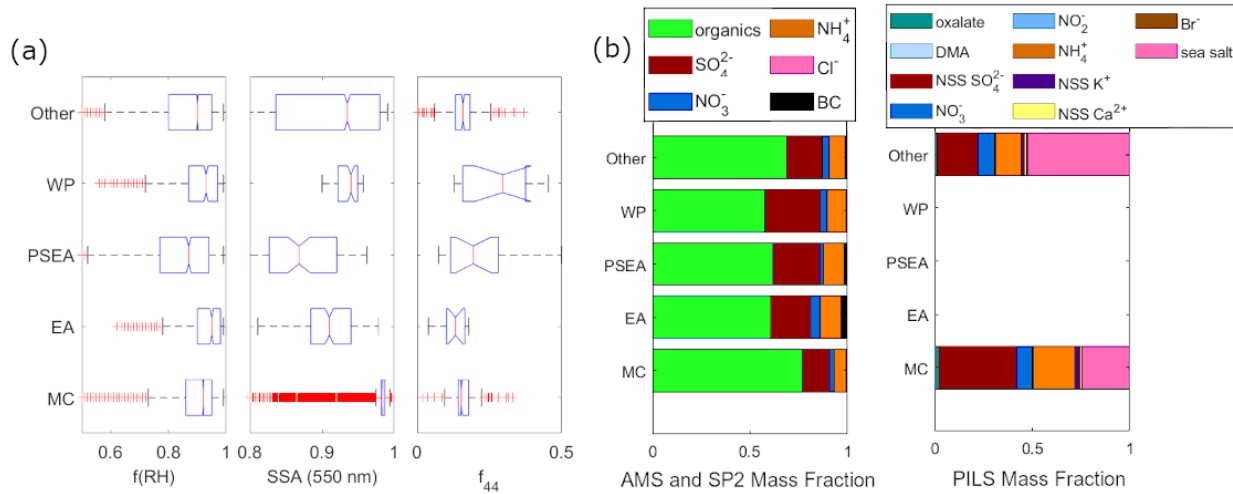

Figure 6. (a) Boxplots of 1 s $f(RH) < 1$ (MC: 14,612, EA: 473, PSEA: 986, WP: 483, and Other: 9919 counts) and the corresponding single scattering albedo (SSA, 550 nm) and ratio of the mass spectral marker m/z 44 marker relative to total organic mass (f_{44}) and (b) (left) submicrometer mean organic, SO_4^{2-} , NO_3^- , NH_4^+ , Cl^- , and black carbon (BC) mass fractions and (right) available bulk ($< 5 \mu m$) oxalate, DMA, non-sea salt SO_4^{2-} , NO_3^- , NO_2^- , NH_4^+ , non-sea salt K^+ , non-sea salt Ca^{2+} , Br^- , and sea salt mass fractions per regional air mass (Hilario et al., 2021) for times with $f(RH) < 1$.

To investigate aerosol characteristics when $f(RH)$ is < 1 , we plot the $f(RH)$ box plots from each of the regions for data points where $f(RH) < 1$ (Fig. 6a). There are several instances (26,473 times or 19% of the time for the whole campaign) when the $f(RH)$ was below 1. In general, 30 s resolution organic mass fractions greater than 0.75 correspond to sub-1 $f(RH)$ (Fig. 4a). The most prevalent regional air mass association for sub-1 $f(RH)$ is with the MC air masses ($f(RH) < 1$ from the MC was 56% of all data). The mean organic mass fraction is dominant (0.57 – 0.77) and almost doubled compared to the whole campaign (Fig. 3b), for all the air masses with sub-1 $f(RH)$ (Fig. 6b). Mean organic mass fraction is highest for the MC (0.77) air mass. The organics from the sub-1 $f(RH)$ data are the least aged throughout the campaign for the MC, PSEA, and Other air masses (Fig. 6a). The CAMP²Ex data offer an opportunity to inspect the prevalence of such values and to see what factors coincide with such situations. However, the unique sample make-up of the particles in the CAMP²Ex region makes other reasons, including sample losses due to volatilization, also plausible (Reid et al., 2023). Shingler et al. (Shingler et al., 2016b) also observed such sub-1 values for both $f(RH)$ and the humidified diameter growth factor $g(RH)$ in air masses enriched with carbonaceous components over North America.

The most dominant aerosol types for the sub-1 $f(RH)$ data are the carbonaceous ones (96%) (Fig. 5b), with the EC/OC component contributing the most: EC/OC mix + mix (the combined sub-categories of EC/OC mix and mix) (68%), EC-dominated (18%), and OC-dominated (10%). Both bulk ammonium and sulfate mass fractions for the MC also are higher for the sub-1 $f(RH)$ cases (Fig. 6b) compared to the whole campaign (Fig. 3b, PILS), while the bulk sea salt mass fraction was lower. The bulk sea salt mass fraction of the Other category (Fig. 6b) increases for the sub-1 $f(RH)$. Most of the particles contributing to the sub-1 $f(RH)$ are fine particles (median Ångström Exponent ~ 2 , Fig. 6a) with

more reflective characteristics ($SSA \geq 0.90$) compared to data for the entire campaign. To understand more about sub-1 f(RH), we will look at a selected case in the succeeding section.

3.2 Case Studies

3.2.1 Sub-1 f(RH) from Biomass Burning Smoke

The chosen case study is part of a flight on 16 September 2019 that occurred closest to the Maritime Continent, which is the source of the air masses that had the most counts of sub-1 f(RH) (Section 3.1.2). This flight coincided with an active biomass burning event on 14 September 2019 (NASA, 2020) and fire hotspots in the Maritime Continent were numerous throughout September 2019 (Othman et al., 2022). The back trajectories at 01:00 UTC, when the aircraft began to make measurements closest to the surface (~300 m altitude) and perpendicular to the wind, all come from the southwest of the aircraft location (Fig. 7a), in the direction from where biomass burning emissions were being transported. Details about the flight and conditions during this case study are found in Crosbie et al. (2022). In their study they note the smoke to be from Kalimantan with an age between 48 and 72 h. Consistently low f(RH) (all below 1, Fig. 7b) values were observed for a little less than an hour, until the aircraft began its ascent (Fig. 7b). The aerosol mass concentrations of $>70 \mu\text{g m}^{-3}$ were among the highest in the entire field campaign and were dominated by organics (Fig. 7b).

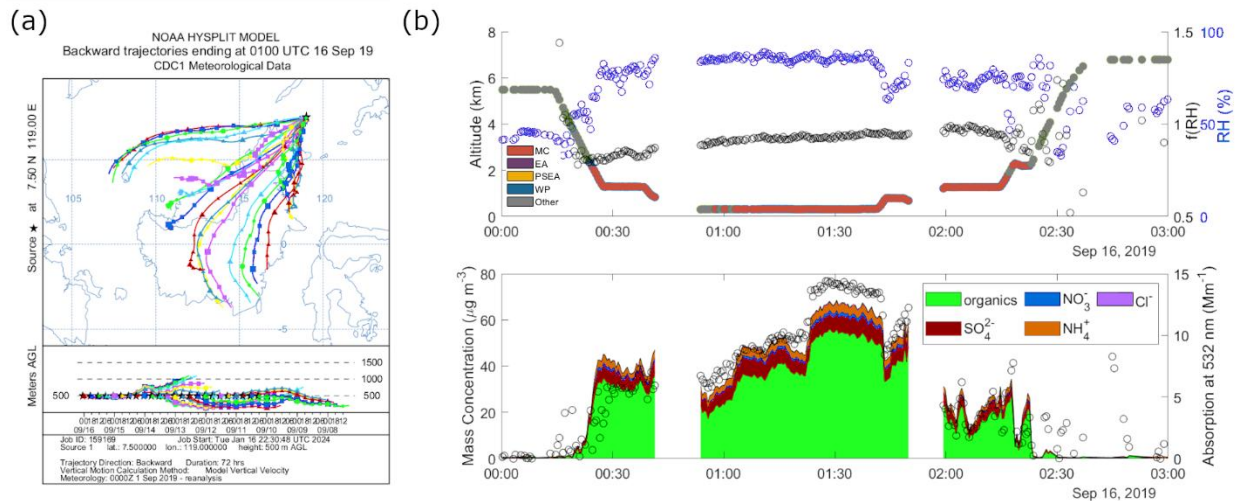

Figure 7. Case study of sub-1 f(RH) on 16 September 2019. (a) Five-day back trajectories at the approximate flight location at 01:00 UTC. (b) (top) Time series plots of altitude colored by regional air mass, f(RH) in black circles, and RH (blue circles), and (bottom) aerosol mass concentrations from the AMS and absorption at 532 nm (black circles) during one of the flight legs closest to the surface from 00:00 to 03:00 UTC.

The sub-1 f(RH) during the lowest altitudes of the aircraft, from 01:00 to 01:40 UTC, are correlated with approximations of the submicrometer particle effective density (Fig. 8a). Absorption measurements along with back trajectories linked to active fires point to the increasing presence of EC and brown carbon with increasing particle density (even if there were no valid EC measurements for this specific time). Submicrometer number concentration,

dry absorption (532 nm), organic mass fraction, and single scattering albedo are highest for the smallest effective density values for sub-1 f(RH) (Fig. 8b) during the entire campaign, likely due to the presence of EC and OC. This is consistent with the most dominant aerosol type during the field campaign, which is a mix of elemental and organic carbon based on SAE and AAE values. The dataset cannot be used to prove particle restructuring and very likely the sub-1 f(RH) values are due to other factors since particles' history included passes through humid areas where restructuring presumably would have already occurred prior to reaching the aircraft. In addition, smoldering from peat, which is dominant in the MC fires (Reid et al., 2023), is known to produce homogenous spheres, with no voids, that are similar to OC particles (Pokhrel et al., 2021), making restructuring unlikely to be the dominant mechanism to explain our findings. However, we present these results for the sake of documenting a Southeast Asia case of these unusual events occurring in EC/organic-rich air masses similar to past work (e.g., Shingler et al., 2016b and references therein) to emphasize that these events occur throughout the world and to motivate more research into the matter.

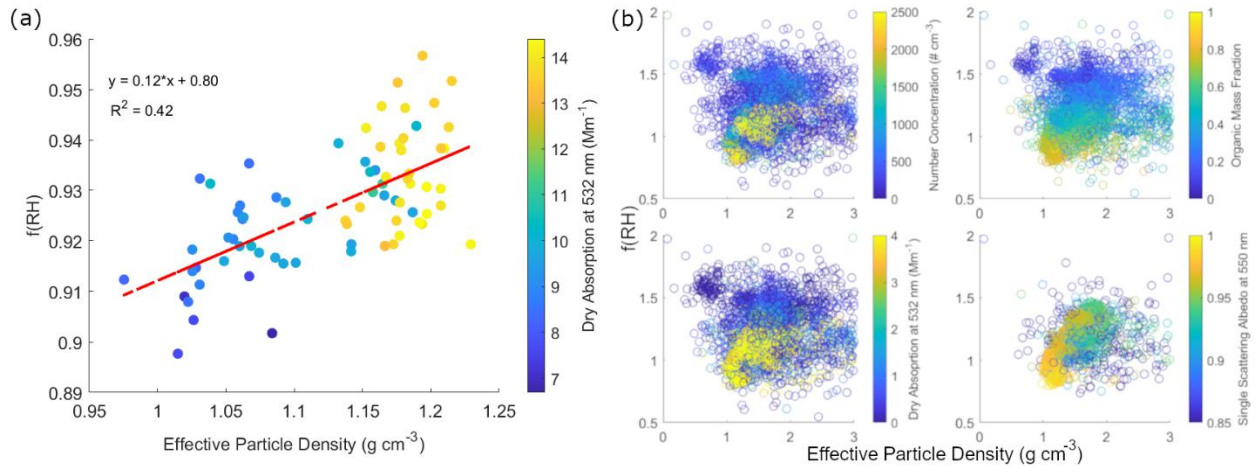

Figure 8. 30 s f(RH) and effective particle density plots for (a) 16 September 2019 from 01:00 to 01:40 UTC colored by dry absorption at 532 nm, and (b) for the entire CAMP²Ex field campaign and colored by (clockwise from top left) LAS number concentration of particles with diameters between 100 and 1000 nm, organic mass fraction, single scattering albedo at 550 nm, and dry absorption at 532 nm.

Smoke particles are known to have a range of density values, depending on their degree of atmospheric aging, affecting their size, and the processes they undergo. The effective particle density is usually lower for biomass burning particles from smoldering that have larger diameters (Pokhrel et al., 2021), compared to flaming. Freshly emitted smoldering particles have effective densities from 1.03 g cm⁻³ to 1.21 g cm⁻³ that do not vary much with diameter based on a laboratory study (Pokhrel et al., 2021). Our calculated values fall within this range (Fig. 8). This adds confidence to our observation that organics (brown carbon), which dominate smoldering emissions, are the major contributors to the sub-1 f(RH). Both aerosol hygroscopicity and effective particle density are important for properly modeling cloud condensation nuclei, one of the most important factors in aerosol-cloud interactions.

3.2.2 Vertical Transport

The vertical distribution of aerosols affects cloud formation, we investigate this through two cases of aerosol vertical transport. The vertical transport cases were identified from averages of the available vertical profiles made during CAMP²Ex. A large-scale event (01:53 to 06:20 UTC 20 Sep 2019) north of Luzon, Philippines, due to a tropical cyclone, and a smaller-scale event (02:55 to 06:02 UTC 24 Sep 2019) east of Luzon, due to shallow convection were chosen for the case studies. The measured median CO mixing ratio was used as a tracer for vertical transport (Kar et al., 2004). An increase in the median CO mixing ratio at higher altitudes along with multi-level winds from a similar direction were the main criteria used to identify the cases.

Northerly to northwesterly winds are the dominant source for the first case (Fig. 9a) influenced by tropical cyclone Tapah (TC Tapah's center was ~600 km northeast of the aircraft location). This suggests the influence of East Asia on the sample as described in Crosbie et al. (2022), where the meteorology is discussed in more detail. There is a general decrease in $f(\text{RH})$ from the lower levels that follows a similar trend to the decrease in total mass (Fig. 9b) and sulfate mass fraction. Sulfate is hygroscopic so it is understandable that the $f(\text{RH})$ decreased with altitude as the sulfate decreased. The increase in CO between 6-7 km (Fig. 9b) suggests vertical transport aloft and was accompanied by a subsequent decrease in $f(\text{RH})$ and ammonium mass fraction and increase in organic mass fraction (Fig. 9b) between 6-8 km. This is consistent with analysis in previous sections, which show decreased $f(\text{RH})$ with increased organic mass fractions.

Accompanying the general decrease of $f(\text{RH})$ with altitude are decreasing submicrometer median volume size distribution (VSD) magnitudes and volume weighted average diameters (Fig. 10). Possible reasons for these trends are that larger hygroscopic particles, such as sulfate (which make up the largest mass fraction at lower levels), were scavenged (especially at lower altitudes) and/or activated into cloud drops, leaving the smaller particles behind. Submicrometer aerosol mass also decreases with altitude, with values below $1 \mu\text{g m}^{-3}$ (Fig. 9b). There is a slight increase in VSD magnitude from 6-8 km compared to 4-6 km, and especially at larger diameters, broadening the VSD curve which may suggest cloud processing (Eck et al., 2012). Though sulfate enhancements have traditionally been the marker for cloud processes (Barth et al., 2000; Faloona, 2009), more recent studies have observed potential cloud processing cases with increased organics (i.e. Wonaschuetz et al., 2012; Dadashazar et al., 2022). This case could thus be showing vertically transported organic matter that has possibly affected or was affected by the clouds between 6-7 km. Another observation is the increase of ammonium and nitrate mass fractions above 4 km (Fig. 9b). There is no corresponding valid $f(\text{RH})$ data, and we can only infer based on the CO profile that begins to shift toward a more positive slope with increasing altitude that this increase in ammonium could also be associated with cloud processing. Ammonia is abundant in East Asia (Pawar et al., 2021) And although there are still limited studies, the scavenging efficiencies of organics and ammonium (compared to sulfate) could also be contributing to their increasing mass fractions with altitude (Yang et al., 2015; Hilario et al., 2025).

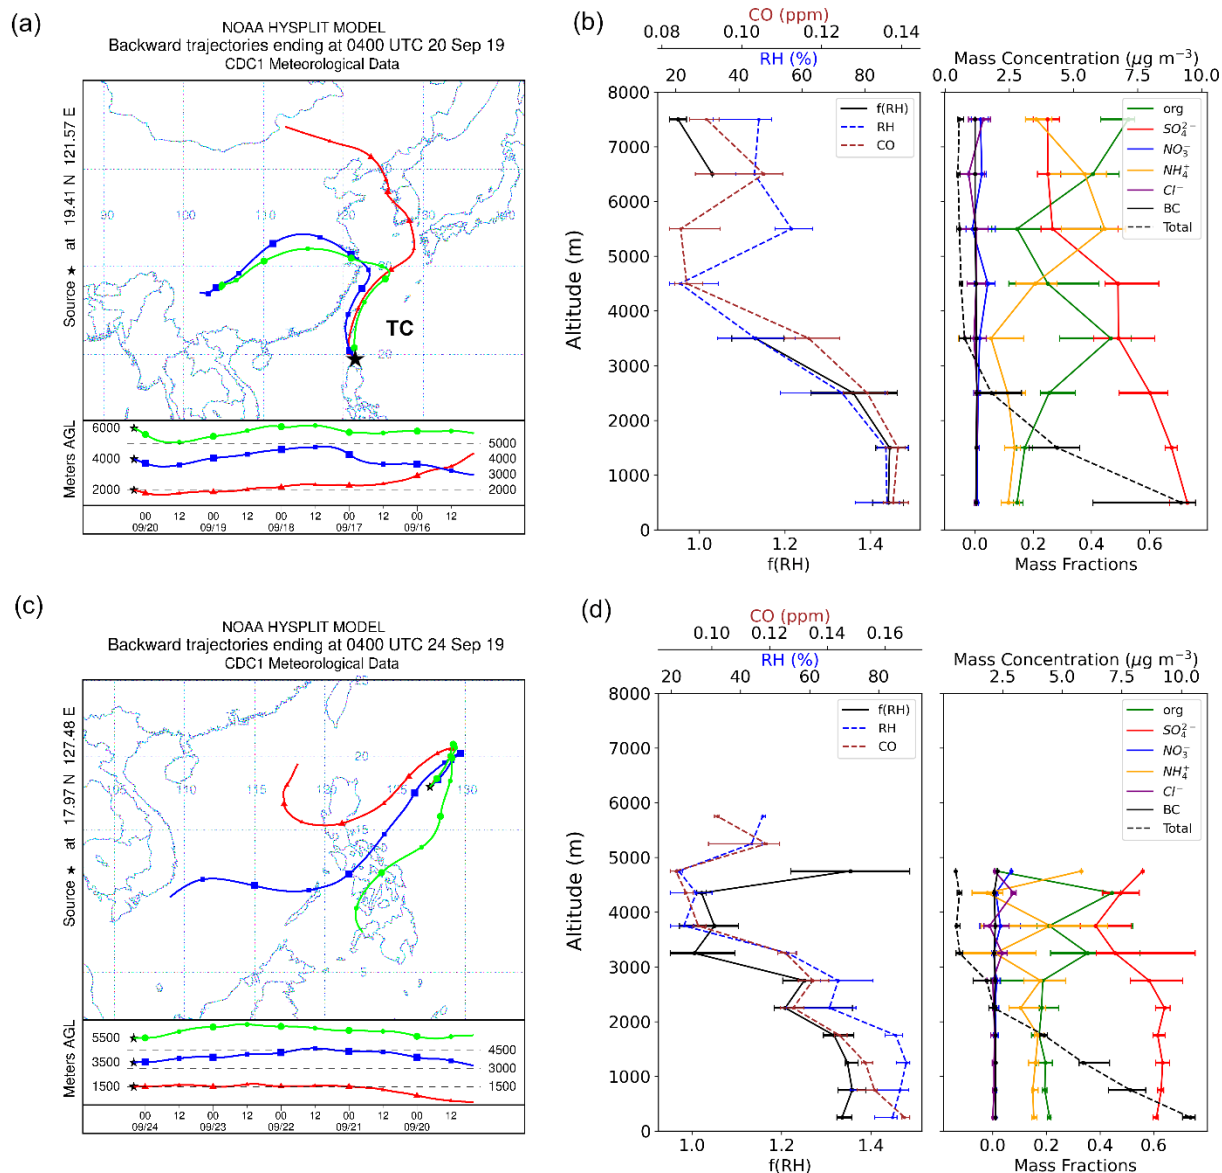

Figure 9. Case studies of (a-b) tropical cyclone-induced convection on 20 September 2019 and (c-d) shallow convection on 24 September 2019. (a) Five-day multi-level back trajectories from the average location of the aircraft from 01:20 UTC with the approximate TC center location and (b) vertical profiles (median, 25 and 75th percentiles) of (left) f(RH), relative humidity (RH), and CO mixing ratio and (right) submicrometer mass fractions of organics, sulfate, nitrate, ammonium, and black carbon and sum of mass concentrations from AMS and SP2 (dashed black line) for 1 km altitude bins, (c) five-day multi-level back trajectories from the average location of the aircraft from 02:55 to 06:02 UTC, and (d) vertical profiles of f(RH), relative humidity (RH), CO mixing ratio, and submicrometer mass fractions and sum of mass concentrations from AMS and SP2 for 0.5 km altitude bins.

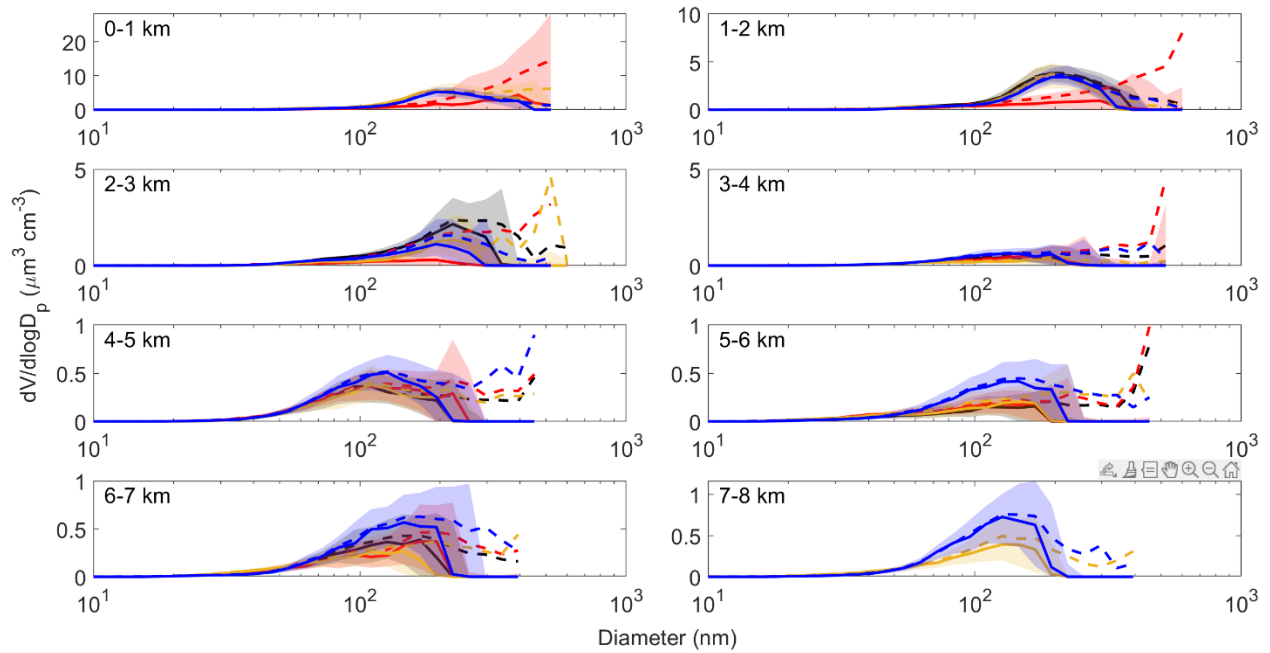

Figure 10. Median (solid line), mean (dashed line), and 25th to 75th percentiles (shaded area) of volume size distributions of submicrometer particles (FIMS) every 1 km altitude for the case study of tropical cyclone-induced convection on 20 September 2019 from 01:53 to 06:20 UTC. The colors represent four separate vertical profiles, where black was from 01:35 to 02:19 UTC, red was from 03:40 to 04:44 UTC, yellow was from 04:59 to 05:27 UTC, and blue was from 05:52 to 06:20 UTC.

The second case, the shallow cumulus case on 24 September 2019 (Hilario et al., 2025), has multi-level wind trajectories initially from the West Pacific in the northeast direction, which appear to have come from the Philippines and the general southwest direction from two days before (Fig. 9c). The most evident increase in CO (Fig. 9d) is observed between 5-5.5 km, at an altitude lower than the previous case. Both RH and f(RH) have a similar trend to CO throughout the vertical profile, which slightly follows the trend of sulfate mass fraction. This is observed especially in the lower levels (until ~2 km) where RH and f(RH) are relatively steady, even with a large decrease in total aerosol mass.

At higher altitudes, above 4.5 km, f(RH) increases to a greater degree with decreased organic mass fraction and increased sulfate mass fraction (Fig. 9d), possibly due to cloud processing. Like the first case, the VSD plots (Fig. 11) for this case show decreasing VSD magnitudes and volume weighted average diameters with increasing altitudes. The broadening of the VSDs above 3 km, concurrent with the increased decreased sulfate mass fraction, likewise suggests cloud processing. There is a known sulfate source, a power plant in western Luzon, in the Philippines that is along the path of the 1.5 km back trajectory (Fig. 9c) and may possibly contribute to sulfate in the region (Lorenzo et al., 2023). It is possible that this and other sulfate sources in the region, such as those from ships (Miller et al., 2023), are being transported vertically and affecting aerosol hygroscopicity in the areas where there is shallow convection.

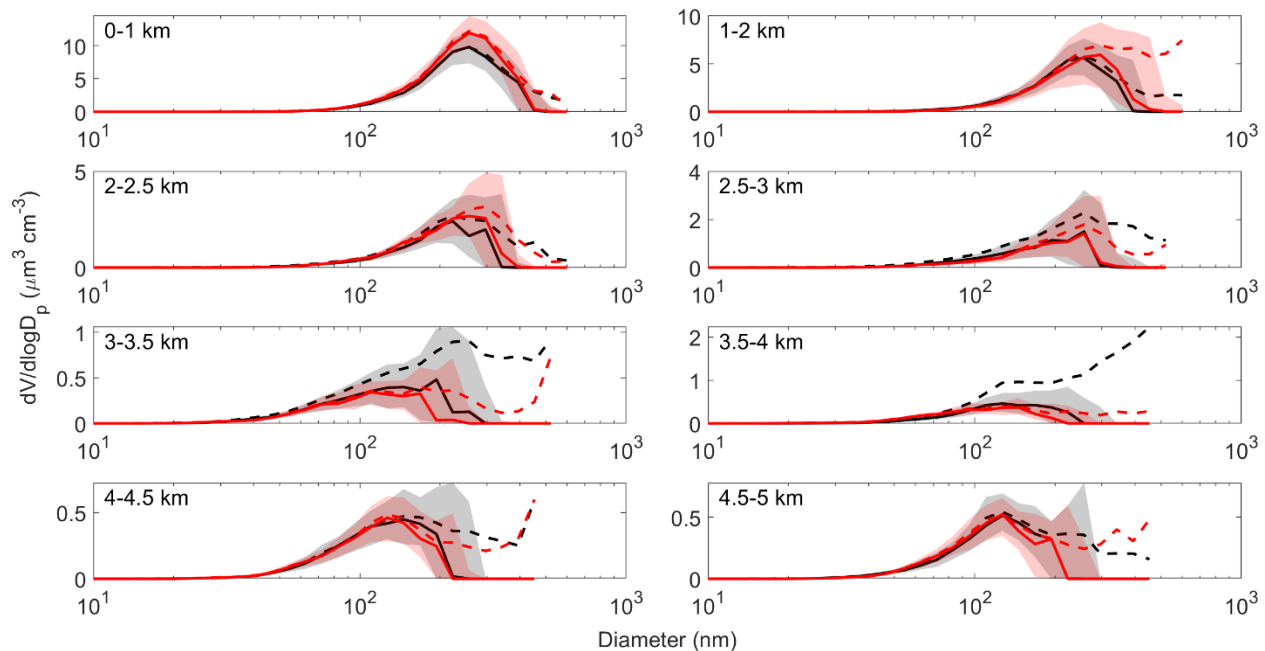

Figure 11. Median (solid line), mean (dashed line), and 25th to 75th percentiles (shaded area) of volume size distributions of submicrometer particles (FIMS) in 0.5-1 km altitude increments for the case study of shallow convection on 24 September 2019 from 02:55 to 06:02 UTC. The colors represent two separate vertical profiles, where black was from 02:55 to 04:07 UTC and red was from 05:42 to 06:02 UTC.

In summary, for both cases vertical transport in cumulus clouds correspond to higher $f(\text{RH})$ with lower organic mass fractions or increased sulfate mass fractions, at cloud outflow altitudes. At slightly higher altitudes, increasing organics with decreasing ammonium decrease $f(\text{RH})$ for the tropical cyclone case. The VSD magnitudes and the averaged diameter of the aerosol size decrease from cloud base to cloud outflow altitudes, with the VSDs broadening likely due to cloud processing. The understanding and representation of the vertical transport or aerosols due to the tropical cyclone and shallow convection and their role in aerosol-cloud interaction is further investigated as we evaluate modeled data using the two cases that we have just discussed.

3.2.3 Model Evaluation

To give regional context to the cases, we begin the discussion of model evaluation with the horizontal distribution of the modeled (~ 111 km resolution) near-surface aerosol hygroscopicity (κ : calculated from the volume fractions and κ values (Eq. 3) of the modeled submicrometer aerosol species as described in 2.3.2) and winds within the CAMP²Ex domain. We will compare the model κ values to κ from different regions around the world based on previous studies. Subsequently, we will discuss how the modeled submicrometer κ at different vertical levels compare to the κ derived from bulk $f(\text{RH})$ ($< 5 \mu\text{m}$) (Eqs. 4 and 5) as well as from κ derived from submicrometer AMS and SP2 species (Eq. 3) from the aircraft observations.

The CAM-chem modeled surface κ values (Fig. 12) in the CAMP²Ex region of interest, during the time when the three cases discussed in 3.2.1 and 3.2.2 were sampled, are within the range of globally modeled surface κ in clean

marine (0.9 – 1.0), continental (0.1 – 0.4), and continental outflow / polluted marine (0.4 – 0.6) regions from previous studies (Pringle et al., 2010). The highest modeled kappa (~1.0, Figs. 12a and 12b) is like those previously found in clean marine areas. The high kappa values are influenced by the strong winds, which can increase sea salt emissions, due to the tropical cyclone which was still developing on 16 September 2019 and more fully developed on 20 September 2019. The Pacific Ocean also is the source of high kappa (~0.9 - 1.0) for the shallow convection case on 24 September 2019 (Fig. 12c). For all three cases there was low kappa (< 0.4) in areas with low wind speeds and over land especially over Borneo and East Asia, typical of continental and continental outflow regions. For the two cases that were within the southwest monsoon (Figs. 13a and 13b) the lowest kappa values (< 0.2) were in Borneo and downwind areas including Southern Philippines and areas east of it.

The modeled surface kappa (~0.1 – 0.5) below the aircraft positions for the case studies of interest (pink lines in Fig. 12), though over the sea, are lower than in those areas most affected by the Pacific Ocean and are influenced by emissions from Borneo (Figs. 7a and 12a), East Asia (Figs. 9a and 12b) and the Philippines (Fig. 9c and 12c) based on back trajectories. Kappa, calculated from the median $f(RH)$ derived from scattering measurements, for the five air masses discussed in sections 3.1 and 3.2 (MC: -0.02, EA: 0.14, PSEA: 0.10, WP: 0.24, and Other: 0.11), all fall in the continental category even though the majority of these air masses are technically in regions with continental outflow or polluted marine regions. The CAM-chem kappa values for the aircraft positions for the case studies with vertical transport (Figs. 12b and 12c) the CAM-chem kappa values (~0.40 – 0.50) are more than double the range of calculated kappa from East Asia (0.14) and Other (0.11) air masses that are influencing the case studies. To make sense of this difference between globally modeled surface kappa values and that which is calculated from the CAMP²Ex $f(RH)$, we delve more into aerosol vertical transport and its connection to aerosol hygroscopicity and evaluate the vertical profile of the kappa calculated from the CAM-chem model outputs.

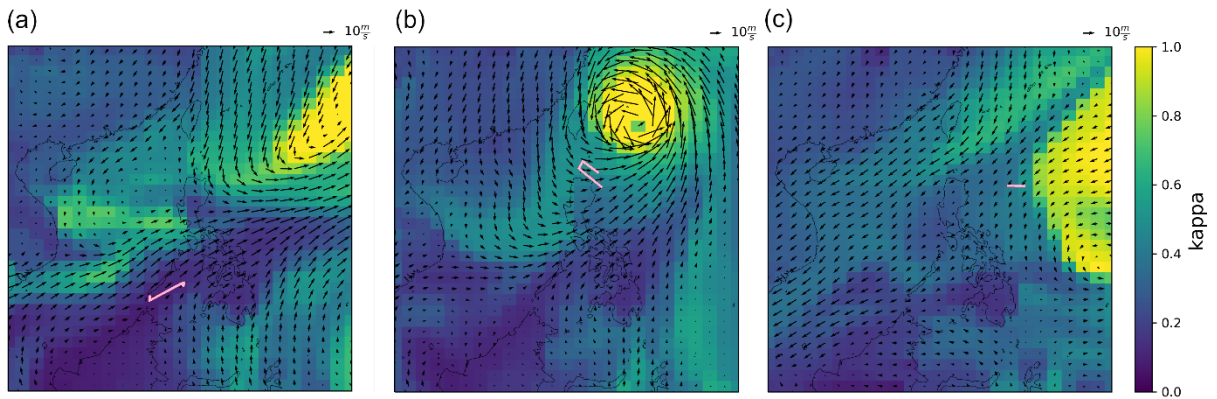

Fig. 12. Modeled kappa and winds at 957 hPa for (a) the biomass burning smoke case at 06:00 UTC on 16 September 2019, (b) the tropical cyclone-induced case at 06:00 UTC on 20 September 2019 and, (c) the shallow convection case at 06:00 UTC on 24 September 2019. The pink lines represent the aircraft locations from 02:15 to 04:22 UTC on 16 September 2019, 01:53 to 06:20 UTC on 20 September 2019 and, from 02:55 to 06:02 UTC on 24 September 2019. The approximate aircraft locations are represented by pink lines.

The CAM-chem model (Fig. 13a) was able to represent the general trends in the observed total submicrometer mass vertical profile for the tropical cyclone-induced convection case. The observations from AMS are only for non-refractory aerosol species, however, and so sea salt and dust are not included in the total mass, possibly affecting the comparison with the model output, which accounts for both. The uniform ~ 111 km grid mesh CAM-chem and MUSICA outputs show approximate contributions by sea salt and dust to be 5 to 20% of the total mass (Figs. 13d and 13e). This could explain the higher total mass values from the model outputs compared to observations for some altitude levels, though in general even without dust and sea salt the CAM-chem model still has slightly higher aerosol total mass values (dashed lines in Fig. 13a) compared to the observations. The CAM-chem model represents the approximate aerosol total mass well for this case probably because of its large-scale nature, where wind speeds were high ($> 20 \text{ m s}^{-1}$) and where the aerosol particles are potentially from a large source (East Asia) (Figs. 9a and 13a). Together, the sum of the sulfate and ammonium mass fractions are similar for the observed (Fig. 13c) and modeled outputs close to the surface (Figs. 13d and 13e), where the model output is ammonium bisulfate and not just sulfate, but the actual mass concentrations of sulfate from the models are generally higher than the observations above 1 km (Fig. S1a). This sulfate-based compound dominates the total aerosol mass for both the observations and model outputs, as is expected based on its source air mass from East Asia, and accounts for the similar observed and modeled total mass shape profiles (Fig. S1). The organic mass fraction, on the other hand, is lower by almost half of the observed organic mass fraction due to sulfate dominating. This has a direct effect on modeled aerosol hygroscopicity (κ), as it was shown earlier that $f(\text{RH})$ decreases with an increased organic mass fraction (Fig. 4).

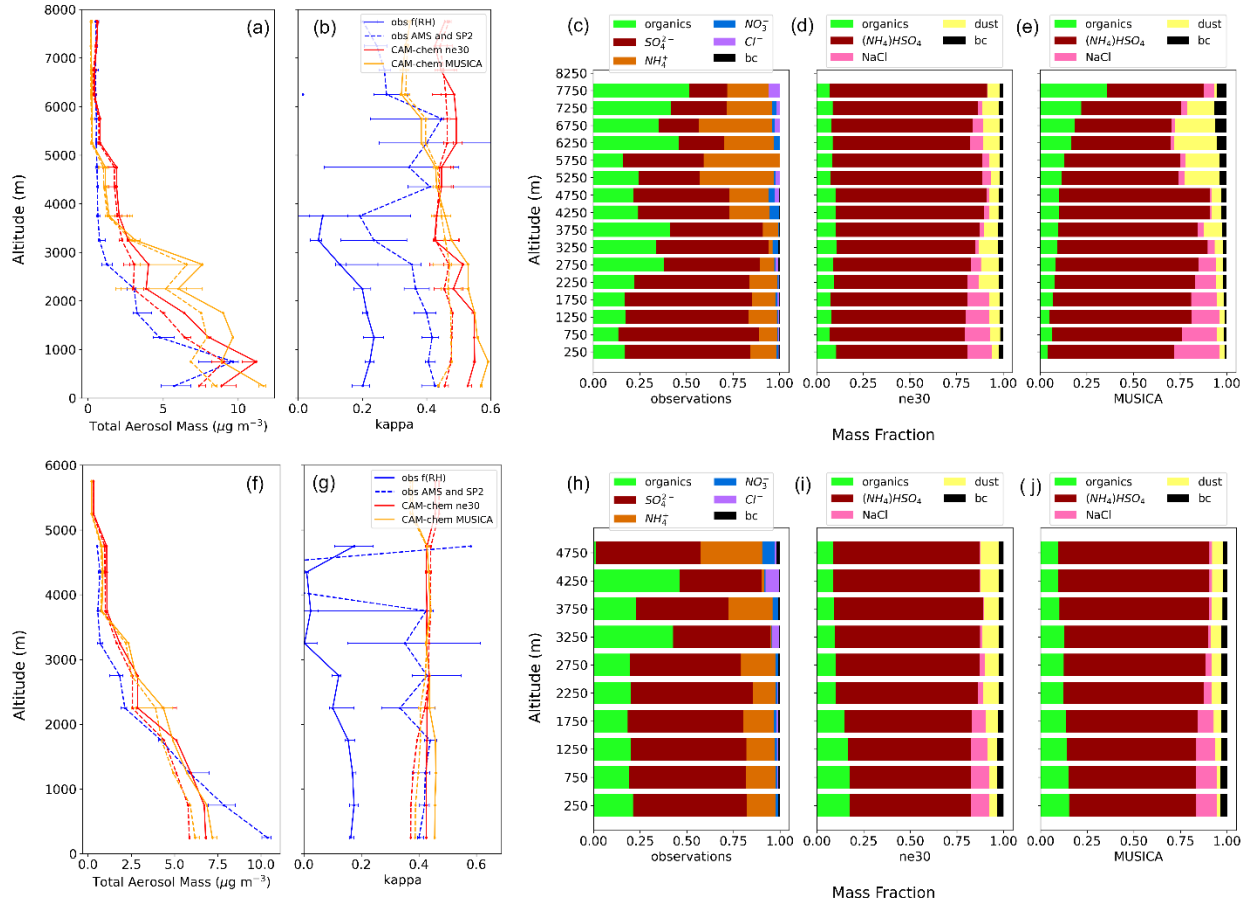

Figure 13. Vertical profiles of observed data and CAM-chem model outputs for ne30 $\sim 1^\circ$ and MUSICA 0.25° grids for (a-e) the tropical cyclone-induced convection case on 20 September 2019 and (f-j) the shallow convection case on 24 September 2019 at 500 m intervals. (a) Total observed submicrometer aerosol mass (01:53 to 06:20 UTC) from AMS (organics, SO_4^{2-} , NO_3^- , NH_4^+ , Cl^-) and SP2 (black carbon (BC)) data and CAM-chem output (06:00 UTC) (organics: primary/hydrophobic, hygroscopic, and secondary ($\text{C}_{15}\text{H}_{38}\text{O}_2$), sulfate (NH_4HSO_4), sea salt, dust (AlSiO_5), and black carbon (primary/hydrophobic and hygroscopic)) where the solid line includes all the CAM-chem species and the dashed line excludes dust and sea salt and (b) calculated kappa from observed f(RH) (solid line, $< 5 \mu\text{m}$) and from AMS and SP2 (dashed line, submicrometer) data and using ZSR mixing rule for all CAM-chem aerosol species (solid line, submicrometer) and excluding dust and sea salt (dashed line). The lines correspond to the median values of data in the given altitude intervals and the bars correspond to the 25th and 75th percentile values. Submicrometer median mass fractions at 500 m intervals of (c) observational data (01:53 to 06:20 UTC) and (d-e) corresponding CAM-chem model outputs (06:00 UTC) for (d) ne30 $\sim 1^\circ$ and (e) MUSICA 0.25° grids for the tropical cyclone-induced convection case on 20 September 2019. CAM-chem outputs were combined into five main categories: organics (primary/hydrophobic, hygroscopic, and secondary ($\text{C}_{15}\text{H}_{38}\text{O}_2$)); sulfate (NH_4HSO_4); sea salt; dust (AlSiO_5); and black carbon (primary/hydrophobic and hygroscopic). (f) Total observed submicrometer aerosol mass (02:55 to 06:02 UTC) from AMS and SP2 data and (06:00 UTC) CAM-chem output and (g) calculated kappa from observed f(RH) and from AMS and SP2 data. Submicrometer median mass fractions of (h) observational data (02:55 to 06:02 UTC) and (i-j) corresponding CAM-chem model outputs (06:00 UTC) for the shallow convection case on 24 September 2019.

Median modeled kappa for the tropical cyclone-induced convection case is more than twice in magnitude compared to the median derived kappa from f(RH) (Fig. 13b), though they have a similar vertical profile shape. It has been noted

from previous studies that the conversion of observed $f(RH)$ to κ (Brock et al., 2016b) may be associated with up to 40% uncertainty (van Dierenhoven et al., 2022), though this does not change that the κ from CAM-chem is still approximately twice the calculated observed κ . We note that additional uncertainties as a result of the conversion from Brock et al. (2016b) could also be contributing to the discrepancy. Brock et al. (2016b) used submicrometer measurements in the southeast U.S. while CAMP²Ex $f(RH)$ was calculated for particles less than 5 μm . κ calculated from $f(RH)$ represents larger particles ($< 5 \mu m$) compared to the κ calculated from CAM-chem ($< 0.48 \mu m$), and the difference in size of the particles could be contributing to this disparity in κ .

We compare more similar sized particles, κ derived from AMS and SP2 measurements ($< 0.70 \mu m$) with κ calculated from CAM-chem (Fig. 13b), and find that the κ derived from the AMS and SP2 is still lower than that computed from CAM-chem outputs. The κ from AMS and SP2 is approximately twice (100% larger than) the κ from $f(RH)$, probably due to more than just particle size differences. Based on Mie theory and studies comparing $f(RH)$ of PM_{10} and PM_{10} particles (Zieger et al., 2013; Titos et al., 2021), CAMP²Ex $f(RH)$ would be larger if it were measuring just submicrometer particles due to the increased scattering efficiency for accumulation mode particles compared to coarse particles. Though, based on Fig. 3 of Titos et al. (2021), the difference in $f(RH)$ in marine sites would only be ~ 0.1 (given median observed SAE) and that would translate to ~ 20 to 40% increase in κ . Thus, although size plays a role, composition is also contributing to the difference in the calculated κ values between observations and the model. Examples of past studies in the region with low κ values suggest that both the size and compositional effect together are important. Lab experiments of tropical peat burning showed that smaller (70 nm) primary organic particles (POA) became more oxidized faster compared to larger particles (150 nm) and κ for oxidized POA (100 nm) was 0.16 (Chen et al., 2022). Ground measurements of aerosol particles (56 nm – 100 nm) in Quezon City in the Philippines, which were dominated by elemental carbon, yielded κ values less than 0.10 (AzadiAghdam et al., 2019).

The over and under-represented mass of sulfates and organics, respectively (Fig. 13b), by the model may be causing the higher κ in the model. Based on the discussion in section 3.1.2 on air masses coming from East Asia (Fig. 4c), as is the case for this event, an organic mass fraction that is lower by half can increase the $f(RH)$ ($f(RH) = (-0.81 * \text{organic mass fraction}) + 1.56$) and therefore the derived κ by $\sim 70\%$. Organics, especially secondary organic aerosols have been underpredicted by CAM-chem in urban and urban outflow regions (Schwantes et al., 2022). This is consistent with the observations for this case, which is influenced by urban outflow from East Asia and thus affecting the calculated κ from the model. CO (Fig. S1) is also underrepresented by the model potentially due to emissions inventories (Hua et al., 2024).

For the case of shallow convection, the shape of the vertical profile of the CAM-chem model output total mass concentration is similar to the observed total mass concentration profile (Fig. 13f), though it underestimates the observed total concentration by approximately 2 to 4.5 $\mu g m^{-3}$ below 1 km altitude, and then overestimates concentrations by approximately 0.5 to 2 $\mu g m^{-3}$ above 1 km. This is due to the model underestimating organics and sulfate close to the surface, while sulfate is overestimated above 1 km (Fig. S1b). The effect of this is seen in the

model-derived kappa, which is, like the previous case, higher than the calculated kappa from observations, though to a lesser degree (Fig. 13g). Unlike the case of the tropical cyclone-induced convection, the modeled kappa is relatively unchanging in shape compared to the kappa derived from observations. This is likely due to the differences in the compositional profile at the higher altitudes, even if the total mass is similar. The model is not able to represent the increase and decrease in organic mass fraction from 3.5 to 4.5 km (Fig. 13h) and dominance of sulfate above 4.5 km. At those altitudes the observations become dominated by sulfate, ammonium, and nitrate (Fig. 13h), even with losses due to scavenging and activation as shown by decreased aerosol mass with altitude, probably due to the in-cloud production of sulfate as discussed in section 3.2.2. The mass fraction profiles from the model (Figs. 13i and 13j) appear to have a steadily decreasing (increasing) organic and sea salt (sulfate and dust) mass fraction with height. This case is a smaller scale event with smaller surface winds associated with it (Fig. 12b) compared to the tropical cyclone case. With weak forcing, it is likely that the CAM cumulus parameterizations does not predict the convection observed in the shallow convection case affecting modeled aerosol mass vertical distribution and, consequently, kappa in both the uniform $\sim 111^\circ$ global model and the regionally refined simulations. This is similar to a model evaluation study (i.e. GEOS and GOCART) of CAMP²Ex aerosol extinction data, which recommended an improvement of shallow convection schemes to improve the representation of vertical transport (Collow et al., 2022). In fact, the CO increase above 5 km, that that we used to identify convection, is not captured by CAM-chem (Fig. S2). What is consistent though is that for both the observations and model output of this shallow convection case, the relative magnitude of the model kappa is lower than that of the tropical cyclone case.

4. Conclusion

This study reports on low PM₅ ($D_p < 5 \mu\text{m}$) aerosol hygroscopicity measured during CAMP²Ex 2019 in Southeast Asia due to organics from biomass burning. Aging and vertical transport changes the hygroscopicity of particles affecting clouds in the region. Comparisons with a global atmospheric chemistry model reveal discrepancies between observed and modeled aerosol concentrations and hygroscopicity, emphasizing the need to improve emissions inventories and shallow cloud parameterizations. Notable results of this work, following the study goals raised at the end of Section 1 are as follows:

The generally low median $f(\text{RH})$ (1.24 with Q1 and Q3 of 1.05 and 1.43, respectively) of aerosol particles ($< 5 \mu\text{m}$) in Southeast Asia during the CAMP²Ex campaign from 24 August to 5 October in 2019 is linked to the dominating regional effect of biomass burning from the Maritime Continent. Measurements of $f(\text{RH})$ in other polluted marine environments around the world for PM₁₀ ($< 10 \mu\text{m}$) and PM₁ ($< 1 \mu\text{m}$) particles have higher ranges (median of $\sim 1.7 - 2.0$) of $f(\text{RH})$ values (Titos et al., 2021). The median $f(\text{RH})$ of air masses from the Maritime Continent was exceptionally low (1.05 with Q1 and Q3 of 0.94 and 1.20, respectively) for polluted marine environments and are more similar to those with biomass burning (Gomez et al., 2018). The air masses with the highest $f(\text{RH})$ from CAMP²Ex are generally from the West Pacific, in the northernmost regions of the Philippines and farthest away from the Maritime Continent. Their median $f(\text{RH})$ (1.49 with Q1 and Q3 of 1.26 and 1.73, respectively) is also lower than what has been associated with typical polluted marine environments.

Throughout CAMP²Ex, submicrometer organic matter is the main aerosol component associated with biomass burning and the low $f(RH)$ values. Organics are a major feature of total aerosol mass, especially in air masses traced back to the Maritime Continent. Biomass burning smoke is spread out in the region increasing AOD downwind of the MC (Fig. 2 in Reid et al. (2023)) and is corroborated by cases of sub-1 $f(RH)$ and submicrometer reflective particles with elevated organic mass fractions that are present in all the air masses. Based on clustering analysis using optical properties, majority of the particles sampled during the campaign appear to be a mixture of both organic and elemental carbon. Organics dominate in terms of mass fraction due to the smoldering-type burning in peat fire (Reid et al., 2023) from the Maritime Continent, which is known to produce more organics than elemental carbon (Reid et al., 2005). This is consistent with what Miller et al. (2023) observed where the highest median levels of organic and elemental carbon mass during CAMP²Ex were due to biomass burning from the Maritime Continent. Without organics, the baseline $f(RH)$ (1.38 – 1.55, Fig. 4), is still lower than measurements from other areas (i.e. 2.19 from SEAC⁴RS in and around the U.S.) (Shingler et al., 2016a) probably due to the presence of elemental carbon, which is the second most dominant aerosol type during the campaign.

Farther away from the Maritime Continent, the organic particles have aged and become more oxidized as they interacted with the other air masses. The West Pacific is a remote region in northern Philippines and is downwind of biomass burning from MC, resulting in a combined marine and polluted aerosol. The oldest biomass burning aerosols were observed there. The organic oxidation values of the aerosol particles in the air mass from the West Pacific are close to the threshold of maximum oxidation that has been observed in previous studies (Cubison et al., 2011). Vertical transport decreases and increases hygroscopicity at cloud level with increased organic and sulfate mass fractions, respectively, in the West Pacific. These aerosol constituents are thought to be transported from the MC and the Philippines and their surrounding oceans, where natural and industrial sources are significant (Miller et al., 2023), and then cloud processed.

Evaluation of the global chemical transport CAM-chem model at two output grids (~111 km and 25 km) against two convective cases from CAMP²Ex show the underrepresentation of organics in general and a higher derived aerosol hygroscopicity (κ), which may be linked to the possible overestimation of aerosol hygroscopicity from biomass burning based on studies of aerosol optical depth and extinction in the area (Collow et al., 2022; Edwards et al., 2022). CAM-chem overestimates sulfate in the tropical cyclone induced convection case, consistent with results from an assessment of the NAAPS reanalysis product on the positive bias of sulfate from East Asia (Edwards et al., 2022). The vertical representation of the aerosol composition for the larger scale convection case due to a tropical cyclone is better than that for the shallow convection case. Cloud processing and increased hygroscopicity are not captured by the model for the shallow convection case, irrespective of model grid size. The representation of shallow convection in the area by global models remains challenging, based on other model-evaluation studies (Collow et al., 2022). Past studies on biomass burning aerosol effects on convection in Southeast Asia using a cloud-scale model emphasized the importance of aerosol composition and absorptive properties, and their effect on atmospheric stability, in the understanding of aerosol-cloud interactions (Hodzic and Duvel, 2018). It is thus ideal that cloud-scale models be

evaluated using the dataset from CAMP²Ex, where the invigoration of shallow clouds has been observed (Reid et al., 2023).

The implications of the low aerosol hygroscopicity in the region and its effects on clouds and climate are just beginning to be unraveled. The mixing and aging of organic and elemental carbon from biomass burning smoke in the Maritime Continent with background and transported sources influences hygroscopicity observations and modeling uncertainties and can be the topic of future work. Improvements in harmonization in terms of aerosol particle sizes and composition, along with updated emissions inventories, will be helpful moving forward both for the observations and modeling of aerosol hygroscopicity. These suggestions can hopefully improve shallow cumulus representation, which is still the biggest source of differences in model sensitivity in the understanding of climate change (Bony and Dufresne, 2005), in the region and globally. Emerging endeavors to implement higher resolution schemes in a large domain (Pfister et al., 2020; Radtke et al., 2021) to capture both fine scale aerosol-cloud processes along with improved observations in Southeast Asia hold promise.

Data availability. CAMP²Ex data can be found at <https://doi.org/10.5067/Suborbital/CAMP2EX2018/DATA001>. CAM-chem model outputs can be found at <https://doi.org/10.6084/m9.figshare.26755936.v1>.

Author contributions. LDZ, ECC, JPDG, GSD, RF, MRAH, MS, JW, QX, and AS carried out various aspects of the data collection. ST and JZ conducted the CAM-chem model simulations. GRL, LDZ, AFA, MB, ECC, RF, MRAH, MS, JW, QX, and AS performed analysis and interpretation of the data. GRL and AS prepared the manuscript with contributions from the coauthors.
