**Abstract** Mineral dust is a key atmospheric aerosol agent that impacts the radiation budget and plays a significant role in cloud formation. However, studies on retrieving height-resolved microphysical properties of dust aerosols, which are crucial for understanding dust evolution, transport processes and radiative effects, from lidar measurements are still insufficient. Here, we retrieve dust aerosol microphysical properties, including the volume size distribution (VSD), total volume concentration ( $V_t$ ), effective radius ( $r_{\text{eff}}$ ), complex refractive index (CRI) and single-scattering albedo (SSA), from spectral extinction ( $\alpha$ ), backscattering ( $\beta$ ) and depolarization ( $\delta$ ) lidar measurements. We evaluate the performance of three particle scattering models, namely the spherical, spheroidal and irregular-hexahedral (IH) models, in terms of mimicking dust optical properties and deriving retrieval results when different measurement combinations are inverted. Both simulations and inversions of real lidar measurements confirm the superiority of the IH model and the significance of spectral depolarization measurements to improve the retrieval accuracy. An increase of discrepancy in depolarization ratio produced by the IH and Spheroid models is observed for  $r_{\text{eff}} > 0.5 \mu\text{m}$ , resulting in larger retrieval difference between the two non-spherical models after the inclusion of  $3\delta$ . Comparisons of the real case retrievals with Aerosol Robotic Network (AERONET) retrievals and previous in situ results indicate relatively smaller  $r_{\text{eff}}$  and larger SSA derived from the lidar retrievals. A discussion of the possible reasons is presented.

## 1 Introduction

Due to its annual emission and residence time, mineral dust dominates global aerosol by mass and impacts the Earth system in various aspects and scales (Kok et al., 2017). It directly modulates the Earth radiation budget by scattering and absorbing atmospheric radiation (Miller and Tegen, 1998), and in an indirect way by taking part in cloud formation (Ansmann et al.,

Formatted: English (US)

2019; Bangert et al., 2012; DeMott et al., 2003; Rosenfeld et al., 2001; Seifert et al., 2010). Additionally, it contributes to ecosystem dynamics and biogeochemistry during cycling processes (Miller et al., 2004; Yu et al., 2015). Moreover, the occurrence of intense dust outbreaks reduces visibility, posing potential hazards for transportation and outdoor activities. Long-term exposure to dense dust aerosols harms human health, causing respiratory issues and cardiovascular diseases (Giannadaki et al., 2014). Therefore, it is crucial to monitor and retrieve the distribution and properties of dust aerosols so as to enhance our understanding of their role in the Earth system, and their impact on human society.

The light detection and ranging (lidar) is a unique technique for obtaining vertically resolved information on dust aerosols. Optical properties measured by state-of-the-art lidars, such as lidar ratio (LR), particle linear depolarization ratio (PLDR) and fluorescence, have been used to identify and distinguish dust aerosols from others (Burton et al., 2012; Nicolae et al., 2018; Veselovskii et al., 2022). Nevertheless, quantitative retrievals of microphysical properties of dust aerosols, such as the volume size distribution (VSD) and complex refractive index (CRI) from lidar measurements remains challenging and limited. This is partly due to the shortage of applicable particle scattering models that precisely describe the backscattering properties of large non-spherical particles. It has been revealed by a number of investigators that the Lorenz–Mie theory for spherical particles is unable to reproduce the laboratory-measured flat phase function of dust particles for sideward and quasi-backward directions (Nakajima et al., 1989; Volten et al., 2001). The spheroidal model which approximates irregular dust particles as spheroids and calculates the single-scattering properties with a combination of advanced numeric methods (Dubovik et al., 2006), might also encounter difficulties in simulating backscattering due to limited computational accuracy unable to consider the impact of complex morphology of highly irregular particles, although it performs well on simulating forward and side scattering (Huang et al., 2023; Saito and Yang, 2023).

To date, only a limited number of studies have been conducted to retrieve dust aerosols from lidar measurements. The initial work by Veselovskii et al. (2010) combined the spheroidal model with regularization inversion of  $3\beta$  (backscattering coefficients at 355, 532 and 1064 nm) +  $2\alpha$  (extinction coefficients at 355 and 532 nm) measurements. The authors also examined the impact of other factors on retrievals, such as the spectral dependence of the CRI and the inclusion of depolarization at 355 nm in the inversion dataset. Müller et al. (2013) utilized both the spherical and spheroidal models to invert measurements acquired during the Saharan Mineral Dust Experiment (SAMUM) campaign, and subsequently compared the results with Aerosol Robotic Network AERONET retrievals and in situ measurements. Tesche et al. (2019) conducted case studies to investigate the effect of employing different combinations of depolarization measurements as input for the inversion of lidar optical data into dust aerosol microphysical properties. These studies highlight the significance of considering the non-sphericity of dust particles and the potential of acquiring height-resolved dust microphysical properties with lidar. However, there remains a lack of comprehensive simulation studies to more understand the limitations of different scattering models for lidar-aerosol retrieval, as well as the extent of improvement when incorporating depolarization data. The following issues are currently in need of further investigation: (1) considering that the limited sensitivity of  $(3\beta + 2\alpha)$  measurements to the size distribution of large particles has been acknowledged in spherical aerosol retrieval (Chang et al., 2022), is it still the case for non-spherical dust retrieval? Can it be ameliorated by incorporating depolarization measurements? (2) If there are other non-

spherical models applicable apart from the spheroidal model, how to evaluate their performances in terms of the capability of reproducing real lidar measurements and the accuracy and stability of the retrieval process? (3) How do different particle scattering models and combinations of input measurements influence the retrievals and consequently, what do the differences in the retrievals imply to the estimation of dust radiative effects?

Recently, a new particle scattering model, known as the Irregular–Hexahedral (IH) model, aiming to mimic light scattering of large irregular-shaped particles such as mineral dust and volcanic ash has been proposed and developed (Saito et al., 2021; Saito and Yang, 2021). Compared to the spheroidal model, the IH model utilizes more realistic shapes to represent dust morphology and exploits advanced computational methods to improve the accuracy towards 180° scattering direction by, for example, accounting for the coherent backscattering enhancement effect (CBE, Borovoi et al., 2013). However, in spite of continuous callings for implementing the IH model in more lidar applications (Castellanos et al., 2024; Haarig et al., 2022; Saito et al., 2021), there is a lack of research that applies the IH model to lidar data inversion, and compares the IH model with other applicable scattering models (such as the spherical and spheroidal models) in order to better understand its strengths and limitations in terms of lidar–aerosol retrieval.

To address these issues, we conducted comprehensive simulations and real case studies using the Basic Algorithm for Retrieval of Aerosol with Lidar (BOREAL) algorithm, which allows an investigation of different particle scattering models by using them to simulate aerosol optical properties (forward calculation) and retrieve aerosol microphysical properties (inverse process) (Chang et al., 2022). Specifically, we assess the spherical, spheroidal and IH models and particularly, we focus on the performances of the latter two non-spherical models with regards to the capability of reproducing real lidar measurements as well as the retrieval accuracy different measurement combinations are inverted. Section 2 provides a brief overview of the BOREAL algorithm, the used scattering models, the lidar system, and a summary of dust properties reported in previous literature. Section 3 presents comparisons of optical properties simulated with the scattering models. Sections 4 and 5 showcase retrievals derived by inversion of synthetic optical data and real measurements, respectively. Discussions are presented in Sect. 6, followed by conclusions in Sect. 7.

## 2 Methodology

### 2.1 BOREAL algorithm

Considering an ensemble of poly-dispersed, randomly orientated aerosol particles of which each single particle follows the independent scattering process (Mishchenko et al., 2002), the extinction coefficient ( $\alpha$ ), and the  $ij$  entry of the phase matrix ( $P_{ij}$ ) can be respectively expressed as

$$\alpha(\lambda, m) = \int_{r_{\min}}^{r_{\max}} k_{\alpha}(\lambda, m, r) \frac{dV(r)}{dr} dr, \quad (1)$$

$$P_{ij}(\lambda, m, \Theta) = \frac{1}{\sigma_{\text{sca}}(\lambda, m)} \int_{r_{\min}}^{r_{\max}} k_{ij}(\lambda, \Theta, m, r) \frac{dV(r)}{dr} dr, \quad (2)$$

**Deleted:** How accurately do the retrievals derived with different scattering models reproduce the lidar measurements?

**Deleted:** ,

**Deleted:** denoted

**Deleted:** ,

**Deleted:**  $\nu r$

**Deleted:**  $\nu r$

where  $\frac{dV(r)}{dr}$  signifies the VSD of the particle ensemble;  $k_a(\lambda, m, r)$  and  $k_{ij}(\lambda, \theta, m, r)$  are the kernels corresponding to the extinction and phase matrix elements, respectively, which are functions of the wavelength ( $\lambda$ ), the CRI consisting of the real part ( $m_R$ ) and the imaginary part ( $m_I$ ), and the particle radius ( $r$ ). In addition,  $k_{ij}$  is also a function of the scattering angle ( $\theta$ ).

The  $\sigma_{\text{sca}}$  is the scattering coefficient derived in a similar way as  $\alpha$ .

150 From Eqs. (1–2), the backscattering coefficient ( $\beta$ ), which describes the scattering intensity in the backward direction, and the particle linear depolarization ratio (PLDR,  $\delta$ ), which describes the ratio of the perpendicular-to-parallel polarization components of the backscattered light, are given by

$$\beta(\lambda, m) = \frac{\sigma_{\text{sca}}(\lambda, m) P_{11}(\lambda, m, \pi)}{4\pi}, \quad (3)$$

$$\delta(\lambda, m) = \frac{P_{11}(\lambda, m, \pi) - P_{22}(\lambda, m, \pi)}{P_{11}(\lambda, m, \pi) + P_{22}(\lambda, m, \pi)}, \quad (4)$$

155 respectively. It is well-demonstrated that  $P_{11} \geq P_{22}$  and the equality holds for spherical particles (Mishchenko et al., 2002). Therefore, the PLDR is an indicator of particle sphericity, with  $\delta = 0$  for spheres and  $0 < \delta < 1$  for non-spherical particles that are beyond the Rayleigh scattering regime.

The total volume concentration ( $V_t$ ), effective radius ( $r_{\text{eff}}$ ) and single scattering albedo (SSA,  $\omega$ ) are defined as

$$V_t = \int_{r_{\text{min}}}^{r_{\text{max}}} \frac{dV(r)}{dr} dr, \quad (5)$$

$$160 \quad r_{\text{eff}} = \frac{\int_{r_{\text{min}}}^{r_{\text{max}}} \frac{dV(r)}{dr} dr}{\int_{r_{\text{min}}}^{r_{\text{max}}} \frac{dV(r)}{dr} r dr}, \quad (6)$$

$$\omega = \frac{\sigma_{\text{sca}}(\lambda, m)}{\alpha(\lambda, m)}. \quad (7)$$

Together with VSD and CRI, they characterize the microphysical state of an aerosol particle ensemble and are referred to as the state parameters. Note that another definition of  $r_{\text{eff}}$  for non-spherical particles is (Foot, 1988)

$$r_{\text{eff}} = \frac{3 \int_0^\infty v(r) \frac{dN(r)}{dr} dr}{4 \int_0^\infty a(r) \frac{dN(r)}{dr} dr}, \quad (8)$$

165 where  $v$  and  $a$  are the volume and average projected area of a single particle. Saito and Yang (2022) pointed out that these two definitions are identical for spherical particles, while a bias of ~10-20% between Eqs. (6) and (8) will arise for non-spherical particles depending on the extent of non-sphericity if the volume-equivalent radius (i.e., the radius of the sphere with the same volume of the represented non-spherical particle) is taken as the size descriptor. Throughout this study, we adopt the Eq. (6) to calculate  $r_{\text{eff}}$ , consistent with all the studies that are selected for comparisons (Sect. 2.2.1, Sect. 6.3).

170 To effectively retrieve aerosol state parameters from lidar measurements, the BOREAL algorithm was developed. Here we recap on its inversion principle and retrieval process, while more detailed description can be found in Chang et al. (2022). The inversion is achieved by making maximum likelihood estimation (MLE) of the state parameters, which can be converted to a non-linear optimization procedure. Compared to other retrieval methods based on constrained linear inversion (e.g., Müller et

**Deleted:** ( $m = m_R - im_I$ )

**Deleted:** (

al., 1999, 2019; Veselovskii et al., 2002, 2010), this strategy allows to conveniently account for a priori constraints and simultaneously consider the uncertainties in measurements and in a priori constraints. Furthermore, VSD and CRI are retrieved simultaneously, which greatly simplifies the determination of solution space and thus improves retrieval efficiency. The relationship between the generalized measurement vector ( $\mathbf{y}$ ) and the state vector ( $\mathbf{x}$ ) that is composed of VSD representation and CRI can be expressed as,

$$\mathbf{y}_i = \mathbf{f}_i(\mathbf{x}) + \boldsymbol{\varepsilon}_i \quad (9)$$

where  $i$  from 1 to 3 denotes lidar measurements ( $i = 1$ ), virtual measurements for the smoothing constraint on VSD ( $i = 2$ ), and virtual measurements for the a priori constraint on CRI. Each measurement vector is the sum of the measurement error ( $\boldsymbol{\varepsilon}_i$ ) and the theoretical truth that is calculated from the state vector using the forward model ( $\mathbf{f}_i$ ). The forward model mapping the state vector to optical properties (i.e.,  $\mathbf{f}_1$ ) is based on the particle scattering theory and is referred to as the particle scattering model. The MLE results in the minimization of the following objective function:

$$\phi(\mathbf{x}) = \sum_{i=1}^3 [\mathbf{y}_i - \mathbf{f}_i(\mathbf{x})]^T \mathbf{C}_i^{-1} [\mathbf{y}_i - \mathbf{f}_i(\mathbf{x})] \quad (10)$$

where  $\mathbf{C}_i$  is the measurement covariance matrix corresponding to  $\mathbf{y}_i$ .

For the sake of clarity and completeness, we briefly introduce the retrieval process. The state vector has a size of 10, composed of the weights of 8 log-equidistance size bins representing the VSD, one for  $m_R$  and one for  $m_I$ . The retrieval is performed for a set of predefined inversion windows,  $[r_{\min}, r_{\max}]$ . Each inversion window does not necessarily have overlapped regions with others and the union of all inversion windows covers a range of 0.05–15  $\mu\text{m}$ , where the measurements are considered to be sensitive to the state vector. For each inversion window, an individual solution to Eq. (10) is derived and the corresponding  $V_i$ ,  $r_{\text{eff}}$  and SSA are successively calculated from Eqs. (5-7). After all the individual solutions are found, the qualified ones are selected by considering the fitting error and the shape of the VSD. The statistical quantities (mean and standard deviation) of the selected individual solutions are output as the final retrieved state parameters.

In this study, apart from the spherical model used in the preliminary version (Chang et al., 2022), two non-spherical models were integrated into BOREAL (Sect. 2.3). Furthermore, BOREAL is modified to be able to take into account the spectral variability of dust  $m_I$  (Sect. 2.2.2).

## 2.2 A priori information on dust microphysical properties

This section reviews previous studies on dust microphysical properties including size, morphology and mineralogy, which rationalizes the modification of BOREAL aiming at dust retrieval and provides bases for the choice of scattering models and the setup of sensitivity study.

### 2.2.1 Size and morphology

Dust aerosols are mostly generated by wind erosion from arid and semi-arid regions (Schuttlefield et al., 2007). Particles of around 100  $\mu\text{m}$  in diameter directly lifted by wind (saltation) move in ballistic trajectories. When striking the soil bed, their

Deleted: In BOREAL, three types of measurement vectors are considered: namely the lidar-measured optical properties,  $\mathbf{y}_1$ ; the smoothing constraint on VSD,  $\mathbf{y}_2$ ; and the a priori constraint on CRI. The last two equations of Eq. (5) are proposed to reduce the underdetermination and ill-posedness of the inverse system. The state vector is retrieved by solving the following multi-term non-linear least-square problem:

$$\arg \min \{ \sum_{i=1}^3 [\mathbf{y}_i - \mathbf{f}_i(\mathbf{x})]^T \mathbf{C}_i^{-1} [\mathbf{y}_i - \mathbf{f}_i(\mathbf{x})] \}$$

Firstly, in addition to the conventional  $(3\beta + 2\alpha)$  measurements, BOREAL is capable of inverting  $3\delta$  (PLDR at 355, 532 and 1064 nm) measurements; secondly, in addition to the Sphere model, two non-spherical models – the Spheroid and IH models (detailed description in Sect. 2.2), are integrated into the BOREAL's frame; and finally, BOREAL is improved to be able to consider

Deleted: 4

Deleted: soils (Alfaro et al., 1997)

265 impacts eject dust particles ( $\sim 0.1\text{-}50\text{ }\mu\text{m}$ ) from loose soil aggregates; some saltating particles also fragment themselves into  
dust aerosols (Shao, 2008). Based on results of wind tunnel experiments, Alfaro and Gomes (2001) described dust size  
distribution at emission with three lognormal modes (geometric median diameters of 1.5 (fine mode), 6.7 (coarse mode) and  
14.2 (giant mode)  $\mu\text{m}$ , respectively) of which the fractions depend on wind friction velocity. The higher the wind speed, the  
larger amount of emission of smaller dust particles due to the increasing kinetic energy of the saltating particles. Several studies  
270 have indicated the presence of fine-mode dust by in situ measurements (Gomes et al., 1990; Kaaden et al., 2009; Kandler et  
al., 2009) or remote sensing retrievals (Eck et al., 2008). On the other hand, a study on the dynamic of dust size over southwest  
Asian by Reid et al. (2008) conversely showed no trace of the fine mode. Moreover, they concluded that the coarse mode is  
not influenced by production wind speed but rather soil properties such as geomorphology or roughness length, which was  
further supported by an emission size model inspired by the mechanism of fragmentation of brittle materials (Kok, 2011a, b).  
275 After emission, giant-mode particles are preferentially removed by gravitational settling, while the coarse-mode particles can  
steadily remain airborne and travel long distances (Tegen and Lacis, 1996). For example, particles with size 1 and 10  $\mu\text{m}$  in  
diameter will have theoretical deposition velocities of  $\sim 3 \times 10^{-5}$  and  $\sim 3 \times 10^{-3}$  m/s, respectively (Wallace and Hobbs,  
2006). However, analysis of data from in situ measurements (Maring et al., 2003; Reid et al., 2008) as well as large-scale  
closure experiments like the Saharan Aerosol Long-Range Transport and Aerosol-Cloud-Interaction Experiment  
280 (SALTRACE, Weinzierl et al., 2017) and the Chemistry-Aerosol Mediterranean Experiment/Aerosol Direct Radiative Impact  
on the regional climate in the Mediterranean region (ChArMEx/ADRIMED, Denjean et al., 2016) showed the settling rate of  
large dust particles is slower than that predicted by gravitational settling. The underlying reasons impacting the transport  
capability can be the presence of strong horizontal winds (van der Does et al., 2018), turbulence (Denjean et al., 2016; Garcia-  
Carreras et al., 2015), particle non-sphericity (Huang et al., 2020; Mallios et al., 2020) and electrostatic forces between the  
charged dust particles (Toth III et al., 2020). Furthermore, dust size distribution could be reshaped by coating through cloud  
285 processing (Wurzler et al., 2000), chemical reactions with trace gases and pollutants (Matsuki et al., 2005) and in-cloud or  
below-cloud scavenging (Mahowald et al., 2014). Thus, there is wide tempo-spatial variability of the dust size spectrum.  
Since fine-mode dust is less ubiquitous and easy to mix with anthropogenic fine-mode aerosols (e.g., Denjean et al., 2016;  
Kandler et al., 2009; Weinzierl et al., 2009), and lidar measurements are not sensitive to giant-mode dust due to the maximum  
290 wavelength of 1064 nm (Müller and Quenzel, 1985; Veselovskii et al., 2004), we summarized previous in situ measurements  
of coarse-mode dust in Table 1, where the volume median radius ( $r_v$ ), geometric standard deviation ( $S_g$ ) and  $r_{\text{eff}}$  of the  
lognormal fit are presented. The  $r_v$ ,  $S_g$  and  $r_{\text{eff}}$  in these studies show ranges of 0.78-9.97  $\mu\text{m}$ , 1.46-2.4, and 0.64-6.79  $\mu\text{m}$ ,  
respectively. The wide variations of the dust size from study to study are not only related to the differences in dust sources,  
transport and aging processes, but also attributed to the different nature of the measurement from each instrument. A further  
295 discussion of these measurements is presented in Sect. 6.2.

Table 1. Compilation of mineral dust coarse-mode volume median radius ( $r_v$ ), geometric standard deviation ( $S_g$ ) and effective radius ( $r_{\text{eff}}$ ) reported in previous studies. The marker “NA” means “not available”.

<sup>a</sup>Aerodynamic radius. <sup>b</sup>The values presented here represent the “equivalent” mode that have the same  $r_{eff}$  and effective variance with the “Mode 2 + Mode 3” in their studies. The definition of the effective variance can be found in Saito and Yang (2022).

Scanning electron microscopic images show that shapes of individual dust particles can be platelets, irregular polyhedrons or the form of aggregate (Gomes et al., 1990; Kandler et al., 2007; Reid et al., 2003). One of the major morphological parameters characterizing dust non-sphericity is the aspect ratio (AR). There are different definitions of AR adopted in dust modelling and shape measurements (e.g., Bi et al., 2010; Kandler et al., 2011; Reid et al., 2003). Huang et al. (2020) compared dozens of measurements of AR distributions after converting them to the same AR descriptor and found that the dependence of dust shape on particle size and source region is not statistically significant, while during transport, the overall non-sphericity could either increase because of the relatively higher gravitational settling of more spherical particles, or decrease due to potential coating processes.

### 2.2.2 Complex refractive index

The complex refractive index (CRI) of mineral dust mainly depends on its chemical composition and therefore is related to the mineralogy of the source soil. The hematite and goethite, which are two main mineral compositions of dust particles, are light-absorbing at ultraviolet (UV) and visible (VIS) wavelengths (Sokolik and Toon, 1999). The dust CRI is also partly influenced by the mixing states with other aerosol species such as sulfate and sea salt (Kandler et al., 2009, 2011). Here we review two representative studies of Kandler et al. (2011) and Di Biagio et al. (2019), where spectral CRIs of dust samples from various sources were provided. Kandler et al. (2011) sampled Saharan dust aerosols at a ground station (4 m above the ground) in Praia, Cape Verde, and calculated the spectral CRI based on the measured volume fractions of the chemical components using a homogeneous internal mixing rule (Quimette and Flagan, 1982). In a wavelength range of 355-2000 nm, the results (denoted K11 and summarized in Table 4 of that paper) show spectrally independent real parts ( $m_R$ ) varying in 1.56-1.58 and spectrally

Formatted: French

**Deleted:** Dust aerosols freshly emitted by windblown processes contain considerable giant particles (with diameters larger than 20  $\mu\text{m}$ ), which do not remain airborne for long due to their high settling rate. In addition, a coarse mode with a diameter range between 0.8 and 10  $\mu\text{m}$  is mainly generated from dust aggregates by saltation (Kok and Renno, 2009; Maring et al., 2003). Unlike the giant particles, these coarse-mode particles can steadily remain airborne and travel long distances, making them important constituents of mineral dust that have profound impacts on the climate (Tegen et al., 1996). Reid et al. (2008) found that the coarse-mode particle size distribution was primarily determined by the properties of soil sources rather than the wind speed. Their work also reported a global rough range of dust volume median diameter as  $\sim 3.5 \pm 30\%$   $\mu\text{m}$ . They also pointed out that short to moderate transport distances have very little effect on the size distribution of coarse mode dust. However, for long-range transported dust (older than a week or longer than 1000 km), a shift towards smaller sizes and convergence into a more uniform size are expected due to the dust scavenging mechanisms (Uematsu et al., 1983). These findings have been verified by both remote sensing retrievals (Hu, 2018) and in situ measurements (Arimoto et al., 1997). Additionally, a fine mode of dust VSD was sometimes observed (d’Almeida and Schütz, 1983; Gomes et al., 1990). Although fine-mode dust has a persistent lifetime (Tegen and Lacis, 1996) and contributes significantly to aerosol optical depth (AOD) in the UV–VIS region (Kaufman et al., 2005), it is less abundant and less ubiquitous compared to coarse-mode dust (Reid et al., 2008). Gomes et al. (1990) attributed the formation of fine-mode dust to sandblasting of loose dust aggregates, which often occurs during dust storm periods characterized by high wind speeds.

**Deleted:** The non-sphericity of dust aerosols makes their optical properties, such as backscattering, depolarization ratio and degree of linear polarization, differ from spherical particles (comprehensive discussion will be given in Sect. 3). Scanning electron microscopic (SEM) images show that depending on size and composition, dust particles present diverse and complex morphology, such as platelets, irregular polyhedrons and aggregates (Gomes et al., 1990; Kandler et al., 2007; Reid et al., 2003).

Deleted: 4

Deleted: is determined by

dependent imaginary parts ( $m_i$ ) varying in  $0.34 \times 10^{-3}$ – $1.4 \times 10^{-2}$ . Di Biagio et al. (2019) retrieved spectral CRIs for samples from global dust sources by fitting laboratory nephelometer (for scattering coefficients) and aethalometer (for absorption coefficients) measurements between 370 and 950 nm. Similarly, the results (denoted D19 and summarized in Table 4 of that paper) show spectrally independent  $m_R$  varying in 1.48–1.55 among different sources and spectrally dependent  $m_i$ . A noticeable contrast between the two studies, however, is that the K11 also shows size-dependent  $m_i$ , which is not seen in the D19. This may be because the mixing rule used for the calculation of K11 is based on size-dependent mineralogical composition, as discussed by Di Biagio et al. (2019).

The BOREAL's version depicted by Chang et al. (2022) did not consider the spectral dependence of dust  $m_i$ , which could lead to a retrieval error of 17–25% in  $V_i$  and consequently increasing retrieval uncertainty in other parameters as pointed out by Veselovskii et al. (2010). A sensitivity study on this issue will be presented in Section 3.2. To study the spectral relationship of dust  $m_i$  at lidar wavelengths, we derived the values of  $m_{i,355}$ ,  $m_{i,532}$ , and  $m_{i,1064}$  of K11 (linear interpolation for 1064 nm) and D19 (linear interpolation for 532 nm and linear extrapolation for 355 and 1064 nm). As shown in Fig. 1, the results from D19 presents a strong correlation between  $m_{i,355}$  and  $m_{i,532}$  whereas a relatively weak correlation between  $m_{i,355}$  and  $m_{i,1064}$ . We infer that this is probably because that, as shown by their study, the imaginary part in the UV and VIS is mostly dominated by iron oxide, whose spectral dependence of the imaginary part leads to the almost linear relationship between  $m_{i,355}$  and  $m_{i,532}$ ; to the contrary, the imaginary part in the Near Infrared (NIR) is affected by multiple components and thus a weaker correlation between  $m_{i,1064}$  and  $m_{i,355}$  is observed. Similarly, they pointed out that the variation among the samples, even if they are collected from the same desert region, is mostly related to difference in the iron oxide and elemental iron content. Compared to D19, K11 has higher  $m_{i,355}$  and  $m_{i,532}$ , but consistent  $m_{i,1064}$ . In particular, the results at 355 and 532 nm perfectly verify the linear relationship between these two wavelengths. According to the results shown in Fig. 1, in the modified BOREAL that takes into account the spectral dependence of dust  $m_i$ ,  $m_{i,355}$  is retrieved as a state parameter, while  $m_{i,532}$  is calculated with the fitted linear function shown in Fig. 1a. As for  $m_{i,1064}$ , it is simply fixed to 0.001 as it barely affects the measurements (see Section 3.2). The a priori mean and standard deviation are 1.5 and 0.5 for  $m_R$ , and 0.005 and 0.005 for  $m_{i,355}$ , respectively, consistent with the setting in Chang et al. (2022).

Figure 1. Scatters of imaginary parts ( $m_i$ ) of the complex refractive index (CRI) at (a): 355 and 532 nm; (b): 355 and 1064 nm, derived from the results published by Kandler et al. (2011) (K11, orange) and Di Biagio et al. (2019) (D19, blue). The  $m_{i,355}$ ,  $m_{i,1064}$

for D19 are derived by linear extrapolation of the original results; the  $m_{1,532}$  for D19 and the  $m_{1,1064}$  for K11 are derived by linear interpolation of the original results. Source-resolved results for D19 are presented with different markers representing northern Africa-Sahara (NAF-S), Sahel (SAH), eastern Africa and Middle East (EAF-ME), eastern Asia (EA), North America (NAM), South America (SAM), southern Africa (SAF) and Australia (AUS). A linear fitting of all the results is also shown as red lines.

### 2.2.3 Mixture with other aerosol types

Dust particles could mix with other aerosol species internally or externally, which modifies both optical and microphysical properties from the pure dust (Kandler et al., 2009; Matsuki et al., 2005; Ryder et al., 2015; Tesche et al., 2009; Weinzierl et al., 2009, 2011; Zhang and Iwasaka, 2004). Previous studies related to dust retrieval from lidar measurements assumed the observed ensemble is a mixture of spherical and non-spherical parts which are of the same VSD and CRI but of different volume fractions. As a result, an additional state parameter, the spherical volume fraction (SVF), is introduced and retrieved (Müller et al., 2013; Tesche et al., 2019; Veselovskii et al., 2010). Nevertheless, we have discovered that retrieving SVF greatly enlarges the system underdetermination, even when the spectral PLDR is incorporated into the inversion dataset. Moreover, we encounter difficulties in determining the a priori constraints on the CRI of the aerosol mixture. Therefore, in the following simulation sections, we do not consider mixing states and assume pure dust microphysical properties. In the analysis of real dust retrievals, we believe the uncertainty due to this assumption can be reduced by focusing on cases with relatively higher possibility to be pure, which can be identified by high  $\delta_{532}$  and low fluorescence capacity (Veselovskii et al., 2022).

### 2.3. Scattering models considering particle shape

Dust non-sphericity evoked studies that model dust particles with more complex shapes rather than spheres, such as ellipsoids (Meng et al., 2010), nonsymmetric hexahedra (Bi et al., 2010), super ellipsoids (Bi et al., 2018), deformations of spheroids and ellipsoids (Gasteiger et al., 2011), and other evolved irregular shapes (Kalashnikova and Sokolik, 2002). To derive the related scattering properties for different domains of the size parameter ( $x$ ), these studies exploited combinations of computational methods such as the discrete dipole approximation (DDA, Yurkin et al., 2007), the finite-difference time domain (Yang et al., 2000), the advanced T-matrix method (Mishchenko et al., 2002), the invariant-imbedding T-matrix method (Bi et al., 2013; Johnson, 1988), the improved geometric optics method (IGOM; Yang and Liou, 1996), and physical geometric optical method (PGOM, Yang and Liou, 1997). To some extent, these studies improve the characterization of dust particles compared to simply assuming dust shape as sphere. On the other hand, however, they suffer from different limitations which impede further application to lidar observations and retrievals. For instance, in Meng et al. (2010), the model failed to consider the coherent backscattering enhancement (CBE) due to the use of IGOM, resulting in an underestimation of  $\beta$  by a factor up to of 2 (Huang et al., 2023; Zhou, 2018). Others are of high complexity and in short of complete published database so that it is difficult to apply them to remote sensing retrievals. In this study, we evaluate the performance of the following two non-spherical scattering models. The spherical model is also tested as comparison given the fact that most global aerosol models approximate dust as spherical particles (Gliß et al., 2021).

**Deleted:** Kandler et al (2009) exploited X-ray diffraction analysis to identify silicates (feldspars and clay minerals), quartz, carbonates and iron-rich materials (hematite) as the main components of Saharan dust samples. They also found that, although the change of particle size affects the relative fractions of the components, this is not a major factor affecting dust CRI. Additionally, by analyzing dust samples collected from 19 global sources, Di Biagio et al. (2019) found the average of the real part of the CRI ( $m_r$ ), varied between 1.48 and 1.55 over the spectral range of 370-950 nm, showing no clear dependence either on wavelength or on the soil source. To the contrary, they found a strong spectral dependence of the imaginary part of the CRI ( $m_i$ ), because of the existence of iron-rich materials which present strong absorption in the UV and much less absorption towards the VIS-NIR. To study the spectral relationship of dust  $m_i$  for lidar wavelengths, we extrapolated or interpolated their published results. As shown in Fig. 1, the relationship between the imaginary part at 355 nm ( $m_{i,355}$ ) and at 532 nm ( $m_{i,532}$ ) can be approximated by a linear function, whereas the imaginary part at 1064 nm ( $m_{i,1064}$ ) has a weak dependence on  $m_{i,355}$  with a value around 0.001.

**Figure 1.** Scatter plots and linear fitting of the spectral imaginary parts of CRI derived by interpolating or extrapolating the results published by Di Biagio et al. (2019): (a) imaginary parts at 355 and 532 nm; (b) imaginary parts at 355 and 1064 nm. Consolidated by these laboratory measurements, we modify the a priori constraints on CRI in BOREAL for dust retrieval in order to consider the spectral dependence of  $m_i$ . Specifically, spectrally independent  $m_R$  is retrieved with unmodified a priori constraints as used in Chang et al. (2022), while the  $m_{i,355}$  is retrieved with the a priori value of 0.005 and the a priori standard deviation of 0.005 (a detailed description about the a priori value and standard deviation can be found in Chang et al. (2022)). Then,  $m_{i,532}$  is calculated from the relationship shown in Fig. 1, and  $m_{i,1064}$  is fixed to 0.001. We believe taking account of the spectral dependence of the imaginary part of the CRI is essential in dust retrieval from lidar measurements because simulations suggest that ignoring it will lead to a retrieval error of 17-25% in  $V_i$ , as well as increases of retrieval uncertainty in other parameters (Veselovskii et al., 2010).

### 2.3.1 Spheroidal model

The spheroidal model approximates an irregular aerosol particle to a spheroid of which the shape is described by two parameters: the volume-equivalent radius,  $r_{\text{vol}}$  (the radius of the sphere having the same volume with the spheroid) and the axis ratio (the ratio of the spheroid rotational axis to the perpendicular axis). Thus, an ensemble of randomly orientated spheroids is characterized by the size and axis ratio distributions, which are thought of as independent of each other. The applicable spheroidal model was developed by Dubovik et al. (2006) and as stated by the authors, it is rationalized in remote sensing applications by the following reasons: (1) the spheroid is the simplest aspherical smooth shape with one more freedom (e.g., the length of the spinning axis) than the sphere, which means the least computational burden compared to other irregular shapes; (2) specific shape details of a single particle have insignificant influence on the bulk scattering properties of a particle ensemble due to averaging effect. To derive the optical properties, the model uses the advanced T-matrix method within the size limit and IGOM onward. The size limit depends on the axis ratio and CRI. The study of Dubovik et al. (2006) showed that the spheroidal model can well fit the laboratory measurements of dust scattering matrices (scattering angle range:  $5^\circ < \Theta < 173^\circ$ , Volten et al., 2001) and significantly improve dust retrievals from sunphotometer measurements. However, some limitations of the spheroidal model regarding to lidar applications have been found. Dubovik et al. (2006) pointed out for large particles and scattering angles greater than  $175^\circ$ , the computational accuracy deteriorates due to the limitations of IGOM. Studies found that the use of IGOM for large particles underestimates the backscattering coefficient because it ignores the CBE effect (Saito et al., 2021; Zhou, 2018). This leads to overestimation of LR, particularly at 355 nm (Haarig et al., 2022; Huang et al., 2023). Furthermore, comparisons of model-produced with lidar-measured PLDRs show that the spheroidal model fails to present the spectral variation of dust PLDR and underestimates the value at 355 nm (Haarig et al., 2022; Müller et al., 2010; Noh et al., 2017; Shin et al., 2018; Tesche et al., 2019). The database published by Dubovik et al. (2006) provides spheroidal kernels of extinction, absorption and phase matrix elements for different  $r_{\text{vol}}$ , axis ratio,  $\Theta$ ,  $m_R$  and  $m_I$ . To reduce the underdetermination of the inversion of lidar measurements, we integrate the spheroidal model into BOREAL by fixing the axis ratio distribution to that of a Feldspar sample (Volten et al., 2001) retrieved by Dubovik et al. (2006). Such strategy has been adopted in the AERONET operational dust retrieval procedure (Holben et al., 2006), as well as some lidar dust retrievals (Müller et al., 2013; Tesche et al., 2019; Veselovskii et al., 2010). Consequently, compared to spherical particles, no extra state parameters are introduced. The size descriptor of the spheroidal model in BOREAL is  $r_{\text{vol}}$ .

### 2.3.2 Irregular-Hexahedral (IH) model

The IH model approximates dust particles as hexahedrons with randomly tilted faces to produce more realistic dust shapes (e.g., sharp corners) (Saito et al., 2021). An IH particle is characterized by its maximum diameter,  $D_{\text{max}}$  (the diameter of the circumscribed sphere of the particle), and the degree of sphericity,  $\psi$  (determined by particle volume and surface area, Wadell, 1935). Assuming  $\psi$  is size-independent, the IH model defines 20 IH particles, each with its own  $\psi$ . The irregular particle

**Deleted:** In this study, three particle scattering models: the Sphere, Spheroid and IH models are adopted for simulating light-scattering by dust particles.<sup>4</sup>

The Sphere model regards an aerosol particle as a sphere of which the scattering properties are calculated with the Lorenz-Mie theory. An ensemble of spherical particles is described by its size distribution. The Sphere model is widely adopted in the fields of remote sensing (Dubovik and King, 2000; Levy et al., 2007; Müller et al., 1999), atmospheric aerosol modelling (Chin et al., 2002; Hess et al., 1998), radiative transfer calculation (Mayer and Kylling, 2005) and in situ measurements (Osborne et al., 2008). However, a number of studies have demonstrated that the Sphere model fails to accurately reproduce the scattering of dust particles whose shapes are far from spherical. An example of this is the inability of the Sphere model to represent the lidar-measured PLDR of non-spherical particles. Therefore, there is a pressing need of non-spherical models applicable to non-spherical aerosol retrieval within the community.<sup>4</sup>

**Deleted:** (Dubovik et al., 2006; Mishchenko et al., 2002)

**Deleted:** Spheroid

**Deleted:** For smaller size parameters, the Spheroid model uses the advanced T-matrix method (Mishchenko et al., 2002) to calculate the scattering properties, while for larger size parameters, the approximate geometric-optics-integral-equation method (Yang and Liou, 1996) is utilized. The Spheroid model was proposed based on the fact that a spheroid is the simplest non-spherical shape with one more characteristic (axis ratio) compared to a sphere and the scattering of electromagnetic radiation by spheroids can be accurately simulated (Mishchenko and Travis, 1994).

**Deleted:** Spheroid

**Deleted:** closely reproduce

**Deleted:** The authors further found out that exploiting the Spheroid model in dust retrieval from AERONET measurements can effectively eliminate the artifact of an abnormally high fraction of the fine-mode VSD retrieved with the Sphere model, leading to a significant reduction in fitting errors. In the AERONET operational retrieval procedure (Holben et al., 2006), when only intensity measurements are inverted, the axis ratio distribution (ARD) is fixed to the one retrieved from the laboratory measurement of Volten et al. (2001) to reduce algorithmic complexity. In this study, to avoid introducing too many unknown to the inversion system, we also fix the dust ARD as the same one employed by AERONET.

**Formatted:** Heading 3

**Deleted:** Although the Spheroid model shows superior performance to the Sphere model in mimicking the scattering of non-spherical particles, Dubovik et al. (2006) pointed out for large particles like mineral dust and large scattering angles ( $\Theta > 175^\circ$ ), the accuracy deteriorates due to the limits of the approximate geometric-optics method. In this context, the IH model was recently proposed by Saito et al. (2021). An IH particle has the shape of a hexahedron with randomly tilted faces, characterized by the maximum diameter,  $D_{\text{max}}$  (the diameter of the circumscribed sphere of the particle), and the degree of sphericity.

**Deleted:** The

ensemble is then composed of a mixture of the 20 types irregular hexahedrons and the ensemble-weighted degree of sphericity for the ensemble ( $\Psi$ ) can be determined from the  $\psi$  of each type of IH particle and the corresponding number mixing ratio.

The model provides  $\Psi$  from 0.695 (less spherical) to 0.785 (more spherical) for user's choice. To calculate the scattering properties, from small to large size parameters ( $x = 2\pi D_{\max}/\lambda$ ), the IH model exploits the Rayleigh scattering approximation ( $x \ll 1$ ), IITM, and a combination of PGOM and IGOM, respectively. The range of  $x$  varies for different  $\psi$  and CRIs. Note that the difference between the advanced T-matrix methods and IITM is that the former provides numeric exact solutions of electromagnetic scattering only for randomly orientated spheroids while the latter for more general non-spherical particles.

Compared to the spheroidal model, the IH model accounts for the CBE due to the use of PGOM and the sharp-corner characteristics of real dust particles. Thus, an improvement in backscattering calculation is expected (Saito et al., 2021; Saito and Yang, 2021).

The database published by Saito et al. (2021) provides the same optical properties as the spheroidal model for different  $D_{\max}$ ,  $\Psi$ ,  $m_R$  and  $m_I$ . But they are cross sections rather than kernels. To derive the corresponding kernels, we integrated the cross sections at three adjacent size grids using the trapezoidal approximation (Twomey, 1977). We also noticed that the ensemble-weighted degree of sphericity acts like the integral of axis ratio distribution in the spheroidal model. Thus, due to the same reason for not increasing the underdetermination, we fix the value of  $\Psi$  to 0.71 to represent dust cases, a value employed by plentiful studies related to this model (Martikainen et al., 2025; Saito et al., 2021; Saito and Yang, 2021; Wang et al., 2024). Finally, to ensure the same size descriptor used in different scattering models throughout this study, we convert  $D_{\max}$  to  $r_{\text{vol}}$  via

$$r_{\text{vol}} = \sqrt[3]{\frac{3v(\Psi, D_{\max})}{4\pi}}, \quad (11)$$

where  $v$  is the ensemble-weighted volume for given  $\Psi$  and  $D_{\max}$ , which is provided in the look up table of the database.

## 2.4 Lidar system

In this study, BOREAL combined with different scattering models is applied to invert real dust optical properties measured by LILAS (Lille Lidar Atmospheres) – a multi-wavelength Mie-Raman-polarization-fluorescence lidar system developed by the Laboratoire d'Optique Atmosphérique, Université de Lille. LILAS exploits the Nd:YAG crystal to emit laser pulses with a repetition rate of 20 Hz and pulse energy of 90, 100, 100 mJ at 355, 532, and 1064 nm. Currently, the receiving channels are composed of: three pairs of parallel- and cross-polarized channels at 355, 532, and 1064 nm for the reception of elastic signals, two Raman channels at 387 and 530 nm and a broad band fluorescence channel centred at 466 nm. Such configuration allows simultaneous measurements of  $3\beta + 2\alpha + 3\delta$  (PLDR at 355, 532, and 1064 nm) +  $1\beta_F$  (fluorescence backscattering coefficient centred at 466 nm). Detailed descriptions of data acquisition and error analysis can be found in Hu (2018), Hu et al. (2019) and Veselovskii et al. (2020). LILAS can be transferred as an individual lidar instrument to perform measurements in field campaigns (Hu et al., 2020; Veselovskii et al., 2016), as well as make stationary routine aerosol observations at the ATOLL (Atmospheric Observation in Lille) platform where various remote sensing and in situ instruments for atmospheric monitoring have been integrated into national and international observational networks such as the European Aerosol Research Lidar

**Deleted:** with different sphericities and approximates an aerosol ensemble to being composed of the 20 IH particles with different mixing ratios. Thus, the characteristic of the whole ensemble is described by the size distribution and ensemble-weighted degree of sphericity,  $\Psi$

**Deleted:** suggested by Saito et al. (2021) and Saito and Yang (2021) ...

**Deleted:** different methods are used depending on the size parameter: the Rayleigh scattering approximation for small size parameters, the invariant-imbedding T-matrix method (Bi et al., 2013; Johnson, 1988) for moderate size parameters and a combination of the geometric-optics-integral-equation method (Yang and Liou, 1996) and physical-geometric optics method (Yang et al., 2019) for large size parameters. Note that the differences between the invariant-imbedding T-matrix and advanced T-matrix methods are that the latter provides numeric exact solutions of electromagnetic scattering only for randomly orientated spheroids while the former for more general non-spherical particles. One noticeable feature of the IH model compared to the Spheroid model is that it improves the accuracy of calculating the coherent backscattering enhancement effect. As suggested by Saito et al. (2021) and Saito and Yang (2021), in practice, we fix  $\Psi$  to 0.71 for severely irregular particles (dust) retrieval. Accordingly, compared to spherical particles, no extra state parameters are introduced. In addition, to facilitate comparison with the Sphere and Spheroid models, we convert the scattering properties from functions of  $D_{\max}$  to functions of  $r_{\text{vol}}$  via the effective volume of the IH particle ensemble which is provided by the model database.

### 3 Forward simulations

In this section, we first investigate how the optical properties simulated with the IH, spheroidal and spherical models are different from each other, as well as from some real lidar measurements. Then, we use forward simulations to figure out the sensitivity of lidar measurements to some state parameters. The VSD of a particle ensemble is assumed to be lognormal:

$$\frac{dV(r)}{dr} = \frac{1}{r} \frac{V_t}{\sqrt{2\pi \ln S_g}} \exp \left[ -\frac{(\ln r - \ln r_v)^2}{2 \ln^2 S_g} \right], \quad (12)$$

where  $r$  represents the particle radius for a spherical particle and volume-equivalent radius ( $r_{vol}$ ) for a non-spherical particle;

$r_v$  is the volume median radius,  $S_g$  the geometric standard deviation and  $V_t$  the total volume concentration. For convenience,  $V_t$  is fixed to  $1 \mu\text{m}^3/\text{cm}^3$  throughout this section. The lognormal distribution has been widely used to represent the sizes of aerosols of different kinds in the fields of modelling, remote sensing and in situ measurements (e.g., Di Biagio et al., 2019; Dubovik et al., 2002; Hess et al., 1998; Whitby, 1978).

#### 3.1 Optical properties

We focus on the comparison of extinction, backscattering and absorption properties. Figure 2 shows  $P_{11}$  and  $P_{22}$  at  $180^\circ$  as well as SSA simulated with the spheroidal, IH and spherical models for different  $r_{eff}$ ,  $m_R$  and  $m_I$  at 532 nm. The  $r_{eff}$  varies from 0.1 to 5  $\mu\text{m}$  with a fixed  $S_g$  of 1.95 (mean value of Table 1), corresponding to a  $r_v$  from 0.12 to 6.25  $\mu\text{m}$ . The range of the CRI coincides with the envelop of the measurements of Di Biagio et al. (2019), with  $m_R$  between 1.4-1.6,  $m_{I,532} = 0.004$  in the first row, and  $m_{I,532}$  between 0.001-0.007,  $m_R = 1.5$  in the second row. It can be seen that the  $P_{11}(\pi)$  for non-spherical particles is smaller than that for spherical particles and presents less variability driven by the change of CRI. This contrast between spherical and non-spherical particles is caused by the surface wave (van de Hulst, 1957), of which the revision here indicates that the used non-spherical models are physically sound. On the other hand, IH and spheroidal particles in general produce similar  $P_{11}(\pi)$ , except for  $r_{eff} > 1.5 \mu\text{m}$ , where the  $P_{11}(\pi)$  for the IH particles is slightly larger. The magnitudes of  $P_{22}$  simulated with the two non-spherical models are similar for  $r_{eff} < 0.5 \mu\text{m}$ ; however, for  $r_{eff} > 0.5 \mu\text{m}$ , the  $P_{22}(\pi)$  of the IH particles is evidently smaller, which will consequently result in larger PLDR. The simulated SSA does not show much sensitivity to particle shape, as demonstrated by previous studies (Johnson and Osborne, 2011; Mishchenko et al., 2002; Müller et al., 2010); however, it decreases with the increase of  $r_{eff}$  or  $m_I$  because that results in an increase of absorption (Bohren and Huffman, 2004; Tegen and Lacis, 1996).

#### Deleted: 2.4 A priori information on dust properties

Unlike certain aerosol species whose properties are highly variable depending on atmospheric conditions, such as hygroscopic or chemically active secondary aerosols, a number of studies have found commonalities in dust properties that could serve as a priori constraints in dust retrieval.

##### 2.4.1 Size and morphology

Dust aerosols are mostly generated by wind erosion from arid soils (Alfaro et al., 1997). Dust aerosols freshly emitted by windblown processes contain considerable giant particles (with diameters larger than 20  $\mu\text{m}$ ), which do not remain airborne for long due to their high settling rate. In addition, a coarse mode with a diameter range between 0.8 and 10  $\mu\text{m}$  is mainly generated from dust aggregates by saltation (Kok and Renno, 2009; Maring et al., 2003). Unlike the giant particles, these coarse-mode particles can steadily remain airborne and travel long distances, making them important constituents of mineral dust that have profound impacts on the climate (Tegen et al., 1996). Reid et al. (2008) found that the coarse-mode particle size distribution was primarily determined by the properties of soil sources rather than the wind speed. Their work also reported a global rough range of dust volume median diameter as  $\sim 3.5 \pm 30\%$   $\mu\text{m}$ . They also pointed out that short to moderate transport distances have very little effect on the size distribution of coarse mode dust. However, for long-range transported dust (older than a week or longer than 1000 km), a shift towards smaller sizes and convergence into a more uniform size are expected due to the dust scavenging mechanisms (Uematsu et al., 1983). These findings have been verified by both remote sensing retrievals (Hu, 2018) and in situ measurements (Arimoto et al., 1997). Additionally, a fine mode of dust VSD was sometimes observed (d'Almeida and Schütz, 1983; Gomes et al., 1990). Although fine-mode dust has a persistent lifetime (Tegen and Lacis, 1996) and contributes significantly to aerosol optical depth (AOD) in the UV-VIS region (Kaufman et al., 2005), it is less abundant and less ubiquitous compared to coarse-mode dust (Reid et al., 2008). Gomes et al. (1990) attributed the formation of fine-mode dust to sandblasting of loose dust aggregates, which often occurs during dust storm periods characterized by high wind speeds.

Deleted:  $\ln r_{eff} = \ln r_v - \frac{1}{2} \ln^2 S_g \rightarrow \rightarrow \rightarrow \rightarrow \rightarrow \rightarrow \rightarrow (9)$

**Figure 2.** Optical properties simulated with the spheroidal, IH and spherical models for different effective radii ( $r_{\text{eff}}$ ) and CRIs at 532 nm. (a)  $P_{11}$  at  $180^\circ$  (normalized to  $P_{11}(30^\circ)$ ). (b)  $P_{22}$  at  $180^\circ$  (normalized to  $P_{11}$ ). (c) SSA. The geometric standard deviation ( $S_g$ ) for generating the lognormal volume size distributions (VSDs, see Eq. (12)) is 1.95. The  $m_I$  is fixed to 0.004 and  $m_R$  varies between 1.4–1.6 in the first row, while the  $m_R$  is fixed to 1.5 and  $m_I$  varies between 0.001–0.007 in the second row. The shaded areas imply the ranges of variability due to the change of CRI, and the solid lines are means of the lower and upper bounds.

Next, we compare the lidar-related properties. The size distribution range is selected the same as that in Fig. 2, while we utilize the values from D19 for the CRI (see Fig. 1). As a comprehensive database of the sort-wave CRI of global dust samples, D19 has been used for sensitivity simulations by other studies (e.g., Ito et al., 2021). The simulated  $\alpha$ ,  $\beta$  at 532 nm, the extinction Angstrom exponent (EAE) and backscattering Angstrom exponent (BAE) over 355–532 nm are shown in Fig. 3. The solid lines and error bars represent the mean and 1 standard deviation of the spread results due to the variation of CRIs. It can be seen that the simulated extinction coefficient shows little sensitivity to CRI except at  $r_{\text{eff}} = 0.1 \mu\text{m}$ . The magnitudes of  $\alpha$  are always similar between IH and spheroidal particles, while that of spherical particles becomes lower with the increase of  $r_{\text{eff}}$ . This indicates the larger surface areas of the non-spherical particles than the spherical particles which lead to higher mass extinction efficiency (Huang et al., 2023; Ito et al., 2021; Kok et al., 2017). The simulated backscattering coefficient presents dependence on both particle shape and CRI. In particular, spherical particles show considerably larger  $\beta$  than non-spherical particles, which is in line with the contrast of  $P_{11}$  shown in Fig. 2. A weaker backscattering is expected as particles become more aspheric and sharper (Kalashnikova and Sokolik, 2002; Mishchenko et al., 2002). Nevertheless, the  $\beta$  of the spheroidal particles is quite similar to that of the more aspheric and sharper IH particles. This is because the computational method used by the spheroidal model ignores the CBE effect (Section 2.3), resulting in a systematic underestimation of  $\beta$ . The EAEs simulated with all these models always show little sensitivity to CRI, and as  $r_{\text{eff}}$  increases, they first steadily decrease to zero and then shows weak sensitivity to  $r_{\text{eff}}$ . The BAEs simulated with all these models also decrease with the increase of  $r_{\text{eff}}$ ; nevertheless, they present increasing sensitivity to CRI as  $r_{\text{eff}}$  increases.

**Deleted:** We start with the comparison of angular scattering properties. Although for lidar measurements, we are only interested in the backward direction, such comparison is necessary to expand our understanding of the differences of the selected models in simulating scattering properties of particles. It is also useful for the analyses of inversions of multi-angular measurements such as sun photometers measurements. Figure 2 shows phase matrix elements:  $P_{11}$ ,  $P_{12}$  and  $P_{22}$  with respect to the scattering angle simulated with the IH, Spheroid and Sphere models, respectively. They are generated from a particle ensemble with:  $r_g = 1.5 \mu\text{m}$ ,  $\ln S_g = 0.6$  (this leads to a  $r_{\text{eff}}$  of  $1.25 \mu\text{m}$ , a value for typical transported dust aerosols (Hu, 2018)),  $m_R = 1.5$ ,  $m_I = 0.0015$  at 532 nm. The  $P_{12}$  and  $P_{22}$  are normalized to  $P_{11}$  while the  $P_{11}$  is normalized to its value at  $30^\circ$ . The phase function ( $P_{11}$ ) in the nearly forward direction is almost the same for spherical and spheroidal particles, and around twice as large for IH particles. This is explained by the larger average projected geometric area of the IH particles compared to the spherical and spheroidal particles with the same volume-equivalent radius, since the forward peak of the phase function is dominated by diffraction whose magnitude increases with increasing projected geometric area. Except the forward direction, both magnitudes and variations of the phase functions of spheroidal and IH particles are similar, particularly for  $0 < \theta < 60^\circ$  where the values of  $P_{11}$  are almost the same. This indicates the similarity of the inversions of the photometer sky measurements using the two non-spherical models. On the other hand, the scattering intensities of the non-spherical particles are dissimilar from those of spherical particles in side and backward directions. The enhancement of intensity in the backward direction of spheres is mainly due to the so-called surface wave on the particle caused by the edge rays (van de Hulst, 1957) and is a manifest feature different from non-spherical particles. Comparison of the degree of linear polarization ( $-P_{12}/P_{11}$ ) reveals an opposite variation between the spherical and non-spherical particles, indicating the difference in the vibrational direction of the polarized component. The polarization of non-spherical particles has a lower magnitude than that of spheres. Comparison of  $P_{22}/P_{11}$ , a parameter related to the PLDR via Eq. (4), not only highlights the contrast between the spheres and non-spherical particles, but also showcases the consistency in angular variation but the difference in magnitude between the spheroidal and IH particles. The difference of  $P_{22}/P_{11}$  in the backward direction between the spheroidal and IH particles is  $\sim 40\%$ , indicating the difference of inverting PLDR measurements using the Spheroid and IH models.

**Figure 3.** Lidar-related optical properties simulated with the spheroidal (blue), IH (orange) and spherical (green) models as functions of  $r_{\text{eff}}$  for varying CRIs. (a) Extinction ( $\alpha$ , dashed lines) and backscattering ( $\beta$ , solid lines) coefficients at 532 nm. (b) Extinction Angstrom exponent over 355-532 nm ( $EAE_{355-532}$ ). (c) Backscattering Angstrom exponent over 355-532 nm ( $BAE_{355-532}$ ). The  $S_v$  of the VSDs is the same as that in Fig. 2, while the CRIs are set to the results of 19 global samples reported in Di Biagio et al. (2019) (also see Fig. 1). The markers and error bars represent the mean and 1 standard deviation of the spread results due to the variation of the CRIs, respectively.

Figure 4 displays spectral LR and PLDRs simulated with the spheroidal and IH models. The particle microphysical properties for the simulation are the same as those in Fig. 3. It can be seen that the LR for the two particle types only show divergence at 355 and 532 nm for  $r_{\text{eff}} > 1 \mu\text{m}$ , where the spheroidal particles have a larger LR. However, the LR variations against wavelength and particle size produced by the two non-spherical models are always consistent. For  $r_{\text{eff}}$  between 0.4-1  $\mu\text{m}$ , the LR slightly increase as the wavelength changes from 355 to 532 nm, while an obvious increase of the LR is observed as the wavelength increases from 532 to 1064 nm. By contrast, for  $r_{\text{eff}} > 1 \mu\text{m}$ , the LR presents a clear decreasing trend with the increase of the wavelength and at the same time, are more affected by CRI. Furthermore, although it is not shown here, spherical particles have apparently lower LR than the non-spherical particles due to their stronger backscattering, as we have seen in Fig. 3a. The simulated PLDRs show strong size dependence varying with wavelength, indicating spectral PLDR contains useful information for particle size retrieval (Mishchenko et al., 2002). The influence of particle shape on PLDR seems to depend on the effective size parameter,  $x_{\text{eff}} = 2\pi r_{\text{eff}}/\lambda$ : the PLDR of IH particles is obviously larger than that of spheroidal particles when  $x_{\text{eff}}$  is greater than 5. The higher PLDR produced by the IH particles could result from the more irregular shape with asymmetric surfaces that cause more complex inner reflections and thus more significant change of the polarization state between the incident and backscattered light (Liou, 2002). However, when  $x_{\text{eff}}$  is less than 5, the sensitivity of PLDR to surface deformation disappears and the PLDRs of both types of particles rapidly decrease with the decrease of  $x_{\text{eff}}$ , consistent with the variations of  $P_{22}(\pi)$  shown in Fig. 2b, 2d and the simulations of Gasteiger et al. (2011). The spectral variation of PLDR when  $r_{\text{eff}} > 1 \mu\text{m}$  is another significant contrast between the two models: as the wavelength increases, the spheroidal-produced PLDR monotonically increases; whereas the IH-produced PLDR peaks at 532 nm, or monotonically decreases. Furthermore, this simulation suggests that PLDR is more sensitive to particle size than CRI: the influence of CRI on PLDR emerges only if  $r_{\text{eff}} > 1 \mu\text{m}$  at 355 nm for both types of the particles.

**Deleted:** The PLDRs produced by the two non-spherical models start to deviate from each other at  $\sim 5$ , after which the spheroidal particles present obviously smaller values.

**Figure 4.** LRs and PLDRs simulated with the spheroidal and IH models at (a) 355 nm, (b) 532 nm, and (c) 1064 nm. The VSDs and CRIs for the calculation are the same as those in Fig. 3.

We compared model-simulated optical properties with some real lidar measurements which are compiled in Table 2. In particular, it shows the comparison between two triple-wavelength LR and PLDR measurements of Saharan dust (Gebauer et al., 2024; Haerig et al., 2022). The two measurements present consistent spectral variation of PLDR between 355 and 1064 nm, and spectral variation of LR between 532 and 1064 nm, verifying the same Saharan source. However, the measurement by Gebauer et al. (2024) shows an overall smaller spectral PLDR and a larger  $LR_{355}$  than that by Haerig et al. (2022), indicating the dust was polluted (Gebauer et al., 2024). Combining all these measurements, the measured EAEs vary in an overall range of  $\pm 0.3$ , showing no clear dependence on dust sources and transport processes. They can be reproduced by all the scattering models for  $r_{\text{eff}} > 0.4 \mu\text{m}$ . The measured BAE varies in a larger range between  $-0.95$  and  $0.6$  probably due to the variations of CRI. Except the polluted Saharan dust case, the measurements reveal a source dependence of dust BAE: Saharan dust has a systematically higher BAE than Asian dust, which might result from difference in CRI induced by different mineralogic components in the source soil. In spite of the large range of the measured BAE, it can only be reproduced by the IH particles when  $r_{\text{eff}}$  is greater than  $1 \mu\text{m}$ .

The measurements of LR generally decrease from 355 to 532 nm (except for the Saharan transported dust), and increase from 532 to 1064 nm. Such a spectral variation is well described by both spheroidal and IH models for the  $r_{\text{eff}}$  range  $0.4$ – $1 \mu\text{m}$ . When  $r_{\text{eff}} \geq 2 \mu\text{m}$ , the spheroidal model produces  $LR_{355}$  too high whereas the IH model produces more reasonable values compared with the measurements. On the other hand, both spheroidal and IH models can well reproduce the measured  $LR_{355}$  when  $r_{\text{eff}} > 0.4 \mu\text{m}$ . The measurements of PLDRs for Saharan and Middle East dust can be reproduced by spheroidal particles with  $r_{\text{eff}}$  between  $0.4$ – $1 \mu\text{m}$ , whereas cannot be well reproduced by IH particles in this size range because the simulated values are either too high at 355 nm or too low at 532 nm. On the other hand, only the IH particles can reproduce the measurements of PLDRs for USA and East Asia dust, of which the magnitudes and spectral variations are apparently distinct from those for Saharan and Middle East dust, probably because of the differences in dust purity and the fraction of larger particles (Gebauer et al., 2024; Hu et al., 2020).

**Table 2.** Summary of representative lidar measurements of dust optical properties, including lidar ratio (LR), particle linear depolarization ratio (PLDR), extinction Angstrom exponent (EAE, over 355 to 532 nm) and backscattering Angstrom exponent (BAE, over 355 to 532 nm).

The above simulations illustrate the distinctions and resemblances among the spherical, spheroidal and IH models in generating particle scattering properties. The backscattering coefficient is the most prominent contrast between the spherical and non-spherical models, whereas the main difference between the two non-spherical models is observed in the PLDR. They indicate that the IH model might be the preferable one in terms of mimicking optical properties more consistent with real lidar measurements. A further discussing is presented in section 6.

### 3.2 Influence of ignoring spectral dependence of $m_i$

Recall that in Section 2.2.2, in order to account for the spectral dependence of dust imaginary refractive index, we use the derived regression relation to link  $m_{i,355}$  and  $m_{i,532}$  and fix  $m_{i,1064}$  to 0.001. Following from this consideration arise two questions: (1) what will be the influence if we ignore the  $m_i$  spectral dependency? (2) Since a visible dispersion of  $m_{i,1064}$  ( $2 \times 10^{-4}$ - $2 \times 10^{-3}$ ) is observed in Fig. 1b, is  $m_{i,1064} = 0.001$  a reasonable assumption for the retrieval? To this end, we calculated the difference in optical properties due to different treatments of  $m_i$ . The same microphysical properties as those in Figs. 3-4 are used for the calculation. As illustrated in Fig. 5, the solid lines represent the variations in  $\alpha$ ,  $\beta$ ,  $\delta$  after setting  $m_{i,\lambda} = m_{i,355}$  ( $\lambda = 532$  or  $1064$  nm), namely, dismissing the spectral dependence, while the dashed lines represent the variations after setting  $m_{i,1064} = 0.001$ . For comparison, we set measurement uncertainties as the one third of the estimated maximum measurement errors for LILAS (Hu et al., 2019). It can be seen that at 532 nm, the variability of  $\alpha$  is much smaller than the corresponding measurement uncertainty all the time, which means that ignoring the spectral dependence of  $m_i$  has no influence on  $\alpha_{532}$ . Nevertheless, the variation in  $\beta$  rapidly increases as  $r_{\text{eff}}$  grows and exceeds the measurement uncertainty for  $r_{\text{eff}} > 0.2$   $\mu\text{m}$  (at 532 nm) and  $r_{\text{eff}} > 0.4$   $\mu\text{m}$  (at 1064 nm), respectively. The influence on  $\delta$  is only significant for  $r_{\text{eff}} > 3$   $\mu\text{m}$  at 532 nm, and  $r_{\text{eff}} > 4$   $\mu\text{m}$  at 1064 for both spheroidal and IH models. On the other hand, the assumption of  $m_{i,1064} = 0.001$  makes no

Figure 2. Normalized phase matrix elements: (a)  $P_{11}/P_{11}(30^\circ)$ , (b)  $-P_{12}/P_{11}$  with respect to the scattering angle. The calculation is done for 532 nm wavelength and a monomodal VSD with  $\omega = 1.5$ ,  $m = 0.6$ , and  $m = 1.5 - i0.0015$  using the IH, Spheroid and Sphere models, respectively.

Figure 3 illustrates the variation of SSA with respect to the effective radius ( $r_{\text{eff}}$ ) and the effective size parameter,  $x_{\text{eff}}$ , for different CRIs simulated with the three scattering models at 532 nm, respectively. The of the monomodal VSD is 0.6. The SSA displays distinct patterns for different size regions. For small  $r_{\text{eff}}$ , SSA is a monotonically increasing function of because according to the Rayleigh approximation, as  $r_{\text{eff}}$  grows, the scattering efficiency increases much faster than the absorption efficiency for a fixed CRI. As  $r_{\text{eff}}$  rises, the upper bound of the Rayleigh region shifts towards the right from  $\sim 0.02 \mu\text{m}$  ( $\sim 0.3$ ) to  $\sim 0.07 \mu\text{m}$  ( $\sim 0.8$ ). Beyond the Rayleigh region and with the continuous increase of particle size, the SSA reaches the maximum, stays, and subsequently decreases. However, note that it should be always greater than 0.5 as  $r_{\text{eff}}$  approaches to the geometric optics region due to the presence of the ray-tracing scattering cross section (Mishchenko et al., 2002). The SSA shows strong sensitivity to  $r_{\text{eff}}$ , a main contributor to the absorption efficiency factor, while it only presents limited sensitivity to  $x_{\text{eff}}$  in the Rayleigh region. On the other hand, the SSA is little sensitive to particle shape for particles with the same size, except for  $> 0.6 \mu\text{m}$  ( $> 7$ ) and  $> 0.001$  where spheres produce lower SSA than spheroids and IH particles. This is consistent with the study by Saito and Yang (2003).

change of  $\delta_{1064}$ ; however, the variation of  $\beta_{1064}$  exceeds the measurement uncertainty for  $r_{\text{eff}} > 3 \mu\text{m}$  for the spherical and spheroidal models and  $r_{\text{eff}} > 4 \mu\text{m}$  for the IH model, respectively.

**Figure 5.** Variations of optical properties due to different treatments of the imaginary part of CRI, simulated with the spheroidal (a, d), IH (b, e) and spherical (c, f) models. (a-c) Variations of  $\alpha_{532}$ ,  $\beta_{532}$ , and  $\delta_{532}$  if we use  $m_{1,532} = m_{1,355}$  rather than the exact value. (d-f, solid lines with circle markers) Variations of  $\beta_{1064}$  and  $\delta_{1064}$  if we use  $m_{1,1064} = m_{1,355}$  rather than the exact value. (d-f, dashed lines with triangle markers) Variations of  $\beta_{1064}$  and  $\delta_{1064}$  if we use  $m_{1,1064} = 0.001$  rather than the exact value. The microphysical properties used for the calculation are same as those in Figs 3-4. The measurement uncertainty of each optical property is taken as the one third of the estimated maximum error for LILAS (Hu et al., 2019) and shown in the legend.

This simulation demonstrates that on the one hand, it is necessary to consider the spectral dependency of  $m_i$  in mineral dust retrievals and on the other hand, the treatment presented in Section 2.2.2 is rational. Correspondingly, the retrieval of dust spectral imaginary part is converted to the retrieval of the monochromatic value at 355 nm. Hereinafter, unless explicitly stated, the imaginary part exclusively refers to  $m_{1,355}$ , and we omit the subscript indicating the wavelength for simplicity.

### 3.3 Sensitivities of depolarization measurements

One of the objectives of this study is to figure out how the inclusion of spectral depolarization measurements influence the retrieval accuracy. To this end, we study their sensitivities to  $r_{\text{eff}}$  and CRI (note that the PLDR is independent of  $V_i$ ) using the error-normalized Jacobian (ENJ) matrix (Rodgers, 2000; Xu and Wang, 2015) which is defined as

$$\mathbf{J} = \mathbf{S}_\epsilon^{-\frac{1}{2}} \mathbf{J} \mathbf{S}_{a_1}^{\frac{1}{2}} \quad (13)$$

where  $\mathbf{J}$  is the measurement Jacobian matrix for a specific state,  $\mathbf{S}_e$  the measurement covariance and  $\mathbf{S}_a$  the a priori covariance of the state. The ENJ provides a direct comparison between measurement uncertainty and variability due to perturbations of the state vector. Accordingly, it is a measure of measurement sensitivity and tells whether the change of a state parameter is “detectable” by a measurement ( $\{\mathbf{f}\}_{ij} > 1$ ) or submerged by noise ( $\{\mathbf{f}\}_{ij} < 1$ ). In this study, the uncertainty of  $\delta$  measurements is 5% for all three lidar wavelengths (i.e., one third of the estimated maximum error of  $\delta$  for LILAS, cf. Hu et al. (2019)). In practice, we set the a priori uncertainties of  $r_{\text{eff}}$ ,  $m_R$  and  $m_I$  to 20%, 0.02 and 0.004, respectively.

Figure 6 displays the ENJ elements about spectral PLDR to  $r_{\text{eff}}$ ,  $m_R$  and  $m_I$  for the IH model (top row) and the spheroidal model (bottom row). The CRI used to generate  $\partial\delta/\partial r_{\text{eff}}$  is  $1.52 - 0.0035i$  (the mean value of D19), of which the real part is also used to generate  $\partial\delta/\partial m_I$  and the imaginary part is also used to generate  $\partial\delta/\partial m_R$ . Furthermore, two effective radii,  $r_{\text{eff}} = 0.5 \mu\text{m}$  (possible lower limit to allow both the IH and spheroidal models to reproduce most real lidar measurements) and  $r_{\text{eff}} = 2 \mu\text{m}$  (near the median value in Table 1), are used to generate  $\partial\delta/\partial m_R$  and  $\partial\delta/\partial m_I$  to capture their behaviours under different sizes. It can be seen that both non-spherical models share some common features. The sensitivity of  $\delta$  to  $r_{\text{eff}}$  decreases from positive to negative as  $r_{\text{eff}}$  increases and  $\delta_{1064}$  shows the highest sensitivity in both models when  $r_{\text{eff}} > 0.2 \mu\text{m}$ . However, compared to the IH model, the PLDR sensitivity to  $r_{\text{eff}}$  decreases faster with particle size for spheroidal particles. The sensitivity of  $\delta$  to  $m_R$  decreases with the increase of  $r_{\text{eff}}$ , the increase of  $m_R$ , and the decrease of  $\lambda$ . The sensitivity of  $\delta$  to  $m_I$  is overall negative and its magnitude increases with the increase of  $r_{\text{eff}}$  and the decrease of  $\lambda$ , but it shows opposite variations with  $m_I$  in different models. Also note that the  $m_I$  here refers to  $m_{I,355}$  of which  $\delta_{1064}$  is independent. The general findings from Fig. 6 are (1)  $\delta_{1064}$  might be essential for size retrievals, while (2)  $\delta_{355}$  could be helpful in imaginary refractive index retrieval. In addition, we point out that the accuracies of some state parameters, to which the incorporated  $\delta$  measurements do not have much sensitivity, can still be improved as a part of the integral retrieval. This will be further demonstrated in the next section.

**Figure 6.** Error-Normalized Jacobian (ENJ, see Eq. (13)) elements about (a, d)  $\partial\delta/\partial r_{\text{eff}}$ , (b, e)  $\partial\delta/\partial m_R$  and (c, f)  $\partial\delta/\partial m_I$  for (a-c) the IH model and (d-f) the spheroidal model. The  $S_g$  used for VSD generation is 1.95, same as those used in Figs 2-5; the CRI in panels (a), (d) is  $1.52 - 0.0035i$  (the mean value of D19); the  $m_I$  in panels (b), (e) is 0.0035; the  $m_R$  in panels (c), (f) is 1.52.

#### 4 Retrieval simulations

If we assume the observations are of enough accuracy, the quality of aerosol microphysical property retrieval depends not only on the accuracy of the forward model (namely, how well the particle scattering model can reproduce the lidar measurements in this study) but also on the performance of inversion procedure. In this section, we assess the latter, which is related to the sensitivity of the measurement to the state parameter under different scattering models, and can be investigated through simulation study. That is, synthetic measurements are generated from a set of pre-defined aerosol state parameters and then inverted back into these state parameters. The performance of the inversion procedure can be evaluated by comparing the “retrieved” with the “true” values (i.e., retrieval errors). Moreover, we use the fitting error as a metric to quantify how well the measurements are reproduced by a retrieval, which is defined as

$$\varepsilon_{\text{fit}} = \sqrt{\frac{1}{n} \sum_{i=1}^n \left( \frac{y_i - \hat{y}_i}{y_i} \right)^2} \times 100\%, \quad (14)$$

where  $y$  and  $\hat{y}$  denote the exact measurement and the measurement recalculated from the retrieval;  $n$  is the number of inverted measurements in the retrieval. For example, if  $(3\beta + 2\alpha + 3\delta)$  data are inverted, then  $n$  is 8.

We noticed in Sect. 3 that there is a difference between the in-situ-measured particle size and model-simulated particle size for fitting the ranges of real lidar measurements (not all, but some of the measurements). Thus, we test the  $r_{\text{eff}}$  from 0.1 to 5  $\mu\text{m}$  in order to cover the ranges of both in situ and model-simulated results. The geometric standard deviation is fixed to  $S_g =$

1.95, keeping the setting in Sect. 3. The  $V_i$  is normalized to 1 as many previous studies did (Müller et al., 2019; Veselovskii et al., 2002, 2004). For CRI,  $m_R$  varies between 1.4-1.6, and  $m_I$  between 0.001-0.009, based on D19; in addition, the mean value of D19 is also included. Table 3 lists the setup of the microphysical properties for the simulation.

**Table 3. Aerosol microphysical properties (state parameters) setup for the retrieval simulation.**

State parameter	Values
$r_{\text{eff}}$ (μm)	From 0.1 to 0.9 with a step of 0.2; from 1 to 5 with a step of 0.5.
$S_g$	1.95
$m_R$	1.4, 1.45, 1.5, 1.52*, 1.55, 1.6
$m_I$	0.001, 0.003, 0.0035*, 0.005, 0.007, 0.009

\* mean value of the D19 results

We stress that such simulations cannot decide which non-spherical model derives a better result that is closer to the “true state” by using them to invert the same synthetic measurements. This is because first, the generated measurements contain modelling errors thus do not represent the “real” measurements; second, using a model to invert the synthetic measurements that are generated by another scattering model certainly will lead to a worse result due to the difference between the two models in simulating optical properties. The point here is, for different scattering models, to evaluate their retrieval sensitivities when the underlying microphysical properties change and to check if the retrieval will be improved by incorporating different types of measurements (particularly the depolarization measurements) due to an improvement of information contents. From such simulations, we expect to better understand the part of the retrieval uncertainty related to model sensitivity, other than the part due to the model correctness.

4.1 Retrievals from error-free synthetic measurements

In this section, we invert synthetic measurements without measurement errors included (error-free). We focus on the comparison of the results derived from  $(3\beta + 2\alpha + n\delta)$  measurements, where  $n$  varies from 0 to 3 so as to evaluate the influence of different depolarization measurements on the retrieval. Figure 7 shows the retrieval errors of  $V_i$ ,  $r_{\text{eff}}$ ,  $m_R$  and  $m_I$  for the  $r_{\text{eff}}$  values in Table 3 and the CRI of 1.4 – 0.001*i*. The optical data are simulated and inverted by the IH model. Overall, the  $V_i$  and  $r_{\text{eff}}$  (for  $r_{\text{eff}} > 0.3 \mu\text{m}$ ) are underestimated whereas the  $m_R$  and  $m_I$  overestimated and this trend exacerbates with the increase of particle size. This could result from the retrieval process of BOREAL. As described by Chang et al. (2022), the initial guess for the VSD is a uniform distribution with a  $V_i$  usually smaller than the truth. During the iteration, the state vector (composed of VSD bin and CRI) should gradually converge, making  $V_i$  increase to the exact value. However, as particles become bigger,  $(3\beta + 2\alpha)$  measurements lose the sensitivity to the state parameters rapidly because of the fast decreases of the magnitudes (see Fig. 3), which, in turn, increases the underdetermination of the system. As a result,  $V_i$  often stops at an underestimated value and the consequent effect is compensated for by biases of other state parameters (e.g.,  $r_{\text{eff}}$ ,  $m_R$  and  $m_I$ ). As discussed in other studies, this is one of the main challenges of retrieving coarse aerosol particles from the conventional  $(3\beta + 2\alpha)$  data set (cf. Burton et al., 2016; Müller et al., 2019; Veselovskii et al., 2002). On the other hand, it reveals BOREAL fails to provide

Deleted: we study the performance of BOREAL in dust aerosol retrieval by inverting synthetic optical data calculated from predefined aerosol models in order to address the following questions. Namely, (1) given the state parameters of dust aerosols according to our a priori knowledge, are the scattering models capable of reproducing the ranges of real lidar measurements? (2) When different optical datasets (i.e.,  $3\beta + 2\alpha$  or  $3\beta + 2\alpha + 3\delta$ ) are considered, how large is the spread of retrievals derived with the three scattering models (IH, Spheroid, Sphere)? (3) How dose measurement noise influence the retrieval accuracy?

effective constraints on large particles when measurement sensitivity gets weak, which is a crucial point to improve in future studies. The incorporation of  $\delta$  largely improves the retrieval accuracy, especially for the  $r_{\text{eff}}$  in 0.5-2  $\mu\text{m}$  where the  $\delta$  shows higher sensitivity to  $r_{\text{eff}}$  as indicated in Fig. 6. The results also highlight the significance of  $\delta_{1064}$  to the retrieval accuracy: the inversions including  $\delta_{1064}$  are in the cluster with the best quality. Indeed, compared to other wavelengths, PLDR at 1064 nm shows the highest sensitivity to  $r_{\text{eff}}$  and  $m_R$ , as indicated by Fig. 6. However, as  $r_{\text{eff}} > 2 \mu\text{m}$ , the accuracies of  $\delta$ -included retrievals also decrease due to the decrease of  $\delta$  sensitivity, but they are still better than those of the non- $\delta$ -included retrievals.

**Figure 7.** Retrieval errors  $\epsilon$  of (a)  $V_2$ , (b)  $r_{\text{eff}}$ , (c)  $m_R$  and (d)  $m_I$  when inverting  $(3\beta + 2\alpha + n\delta)$  synthetic measurements. The legends denote the number and wavelengths of the included  $\delta$  where “None” means no  $\delta$  is included. The true  $r_{\text{eff}}$  varies from 0.1 to 5  $\mu\text{m}$  and true CRI is  $1.4 - 0.001i$ . The synthetic measurements are generated and inverted by the IH model.

Figure 8 is same as Fig. 7 except that the optical data are simulated and inverted by the spheroidal model. Some common features shared with Fig. 7 can be extracted. For instance, the envelopes of retrieval errors show the same trend of variation with  $r_{\text{eff}}$ ; the retrievals have the best accuracy when  $\delta_{1064}$  is incorporated into the inversion set. Nevertheless, the most distinctive feature compared to the IH model is that for the spheroidal model, the incorporation of  $\delta_{355}$  nearly makes no difference to the retrieval.

**Figure 8.** Same as Fig. 7 but the synthetic measurements are generated and inverted by the spheroidal model.

We zoom in to check the retrieved VSDs at two effective radii,  $r_{\text{eff}} = 0.5$  and 2  $\mu\text{m}$ . The reason for selecting these  $r_{\text{eff}}$  values has been mentioned in Section 3.3. The results for the IH model and the spheroidal model are shown in Figs. 9-10, respectively.

For both scattering models, the monomodal shape of the VSD is successfully retrieved. It can be seen that the VSD retrieval deteriorates as  $r_{\text{eff}}$  increases from 0.5 to 2  $\mu\text{m}$  and a conspicuous improvement of accuracy is observed for the IH model when

$\delta_{1064}$  is incorporated. The underestimates of  $V_i$  are mainly caused by the underestimates of  $S_k$  and the maximum VSD, while the underestimates of  $r_{\text{eff}}$  are mainly due to the underestimates of  $S_k$  and  $r_v$ .

Figure 9. VSD retrievals from  $(3\beta + 2\alpha + n\delta)$  inversions at (a)  $r_{\text{eff}} = 0.5 \mu\text{m}$ , (b)  $r_{\text{eff}} = 2 \mu\text{m}$ . The CRI is  $1.4 - 0.001i$ . The synthetic measurements are generated and inverted by the IH model.

Figure 10. Same as Fig. 9 but the synthetic measurements are generated and inverted by the spheroidal model.

Figure 11 displays variations of retrieval errors with respect to CRI when  $r_{\text{eff}}$  is  $2 \mu\text{m}$  for the IH model (the synthetic measurements are generated and inverted by the IH model). Here we focus on some representative features. Firstly, as  $m_R$  or  $m_I$  increases, the accuracy of non- $\delta$  (i.e.,  $3\beta + 2\alpha$ ) inversion is gradually improved. This is because as the true CRI becomes larger (e.g.,  $1.6 - 0.009i$ ), it is less likely to retrieve a highly overestimated CRI because of the a priori constraint ( $m_{R,a} = 1.5$ ,  $m_{I,a} = 0.005$ ). This also leads to improvement in  $V_i$  and  $r_{\text{eff}}$  retrievals due to the compensation effect. When different  $\delta$  measurements are considered, difference between the retrievals with and without  $\delta_{1064}$  included becomes smaller as  $m_R$  or  $m_I$  increases. However, it is clear that the inversions with  $\delta_{1064}$  included receive the best accuracy when both  $m_R$  and  $m_I$  are low (e.g.,  $m_R = 1.4$ ,  $m_I = 0.001$ ), and compared to the  $(3\beta + 2\alpha)$  inversion, conspicuous retrieval improvement is found for any  $\delta$ -included inversions as long as  $m_R > 1.5$  and  $m_I = 0.009$  do not simultaneously happen. Similarly, Fig. 12 shows the results for the spheroidal model. The results show a larger dispersion and variability as CRI changes. Compared to the IH model, the contribution of  $\delta_{1064}$  to retrieval accuracy is less significant, especially in terms of the  $m_I$  retrieval. However, it can still be identified when the true CRI is  $1.4 - 0.001i$ . Another noticeable feature for the spheroidal model is that as  $m_R$  or  $m_I$  increases,

accuracies of the inversions only including  $\delta_{355}$  are significantly improved and even are better than the inversions only including  $\delta_{1064}$  when  $m_R > 1.5$ . This might explain the somewhat contradict finding by Tesche et al. (2019) that  $\delta_{355}$  brings more retrieval improvement than  $\delta_{1064}$  because they utilized the spheroidal model and all the retrievals in their study show  $m_R$  greater than 1.5. A further discussion is presented in Sect. 6.2.

For both IH and spheroidal models, a retrieval is often of higher accuracy by only including  $\delta_{1064}$  rather than  $\delta_{355} + \delta_{532} + \delta_{1064}$ , which is contrary to the intuition that the more incorporated measurements, the better the retrieval accuracy. The explanation here could be that due to the limited sensitivity of  $\delta_{355}$  or  $\delta_{532}$  to the particles with  $r_{\text{eff}} = 2 \mu\text{m}$ , the incorporation of  $\delta_{355}$  or  $\delta_{532}$  in fact contributes more to the ill-posedness than the information contents (Twomey, 1977). Furthermore, we notice a sudden rise of retrieval error happens to the spheroidal model for two cases: (1)  $(3\beta + 2\alpha)$  inversion when the true CRI is  $1.6 - 0.005i$ ; (2)  $(3\beta + 2\alpha + \delta_{532})$  inversion when the true CRI is  $1.6 - 0.009i$ . We found that their low retrieval qualities are accompanied by fitting errors (Eq. 14) greater than 5%, which are large comparing to most of the cases where the fitting errors do not exceed 2%. The reason is still unknown, but it implies potential instability of the spheroidal model in the inversion of lidar measurements.

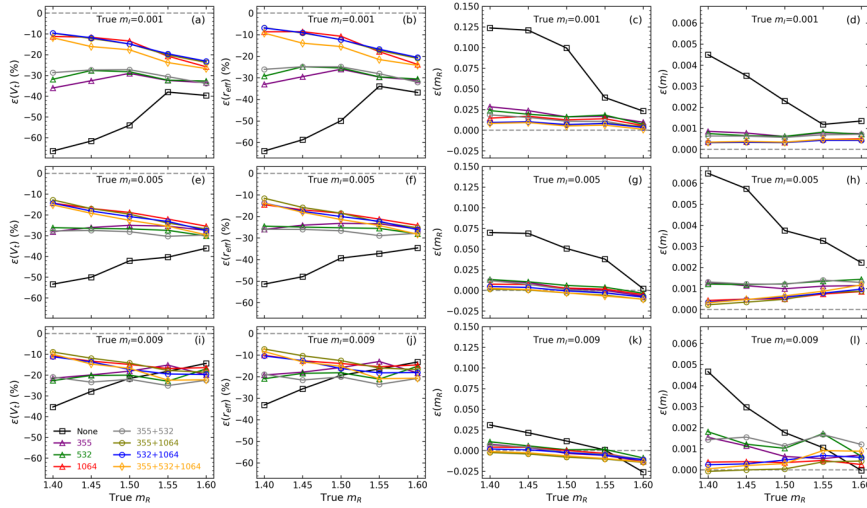

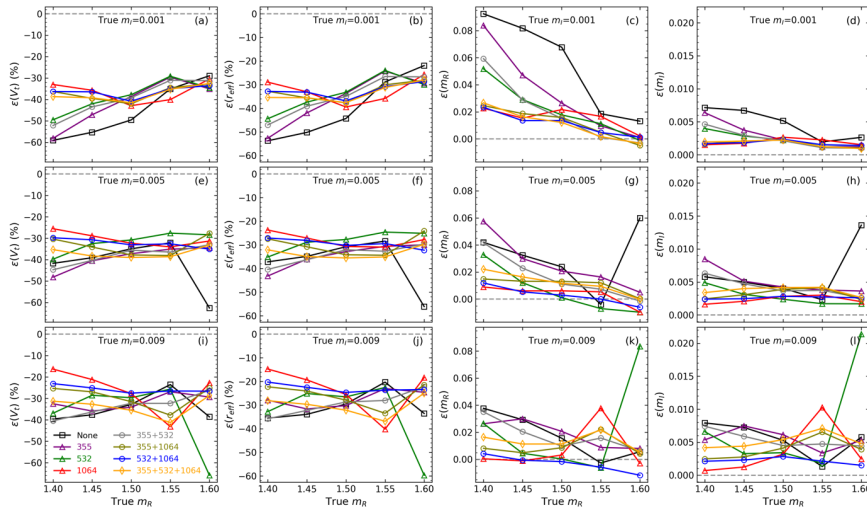

Figure 11. Variations of retrieval errors against the true  $m_R$  (x-axis) and  $m_I$  (rows) when the true  $r_{\text{eff}}$  is  $2 \mu\text{m}$ . The  $(3\beta + 2\alpha + n\delta)$  synthetic measurements are generated and inverted by the IH model.

**Figure 12.** Same as Fig. 11 but the synthetic measurements are generated and inverted by the spheroidal model.

As the  $r_{\text{eff}}$  gets lower (see Figs. S1-S2 for the case of true  $r_{\text{eff}} = 0.5 \mu\text{m}$ ), the variations of the retrievals against CRI generally keep the same trend for both IH and spheroidal models. However, it is noteworthy that due to the increase of sensitivity, there is a much improvement of retrieval accuracy in the non- $\delta$  inversion. In addition, for the IH model, the accuracies of  $m_I$  retrieved from  $\delta$ -included inversions visibly decrease probably because of the reduction of  $\delta$  sensitivity to  $m_I$  as seen in Fig. 6c.

To have an overall point of view on these retrieval results, we grouped them by the  $r_{\text{eff}}$  range as Group 1 where  $0.5 \mu\text{m} \leq r_{\text{eff}} < 1 \mu\text{m}$ , allowing the scattering models to reproduce real lidar measurements for the submicron meter range (Figs. 3-4 and Table 2); Group 2 where  $1 \mu\text{m} \leq r_{\text{eff}} \leq 2 \mu\text{m}$ , consistent with the  $r_{\text{eff}}$  ranges derived from most in situ results in Table 1 and lidar measurements are still sensitive to the state parameters to some extent; and Group 3 where  $2 \mu\text{m} < r_{\text{eff, true}} \leq 5 \mu\text{m}$ , including the rest of the dataset. Tables 4-5 summarize the means  $\pm$  standard deviations of the grouped retrieval errors when the  $(3\beta + 2\alpha + n\delta)$  measurements are inverted with the IH (Table 4) and spheroidal (Table 5) model, respectively. We also list the results derived by inverting  $(3\beta + 2\alpha)$  with the spherical model in order to quantify the retrieval bias as ignoring particle non-sphericity. It can be clearly seen that the increase of particle size leads to an overall reduction of retrieval accuracy. Consistent with previous single-case comparisons, non- $\delta$  inversions result in underestimation of  $V_I$  and  $r_{\text{eff}}$ , and overestimation of  $m_R$  and  $m_I$  due to the underdetermination and compensation effect. The incorporation of  $\delta_{1064}$  largely improves the retrieval accuracy for all state parameters, especially for Group 2 and Group 3. Statistical results suggest that combining  $\delta_{1064}$  with  $\delta_{355}$  or  $\delta_{532}$  could additionally improve the CRI retrieval for Group 1 and Group 2, while such improvement cannot be achieved by singly using  $\delta_{355}$  or  $\delta_{532}$ . Compared to the spheroidal model, the  $\delta$  measurements represented by the IH model bring greater retrieval

improvement, especially for CRI when  $r_{\text{eff}}$  belongs to Group 2. Finally, ignoring particle non-sphericity (i.e., inverting the synthetic measurements by the spherical model) severely underestimates  $m_R$  and overestimates  $m_I$ , which also leads to the largest retrieval bias for  $V_i$  and  $r_{\text{eff}}$  (both are underestimated). This is because the spherical assumption offsets  $\beta$  to higher values which have to be reduced by increasing  $m_I$  or decreasing  $m_R$  (see Figs. 2-3). Such a behaviour has been widely observed in previous studies (Müller et al., 2013; Veselovskii et al., 2010).

**Table 4. Means  $\pm$  standard deviations of the retrieval errors for all the cases in Table 3 when different combinations of  $\delta$  measurements are added to the  $(3\beta + 2\alpha)$  inversion (“None” means non- $\delta$  inversion and “All” means  $(3\beta + 2\alpha + 3\delta)$  inversion). The results are separated into Group 1 ( $0.5 \mu\text{m} \leq r_{\text{eff,true}} < 1 \mu\text{m}$ ), Group 2 ( $1 \mu\text{m} \leq r_{\text{eff,true}} \leq 2 \mu\text{m}$ ) and Group 3 ( $2 \mu\text{m} < r_{\text{eff,true}} \leq 5 \mu\text{m}$ ). The synthetic measurements are generated and inverted by the IH model except for the column “Spherical”, where the  $(3\beta + 2\alpha)$  data are generated by the IH model but inverted by the spherical model.**

## 4.2 Influence of measurement noise

In this section, we investigate how well these scattering model work when inverting noise-contaminated measurements by adding simulated random noise to the synthetic measurements. We take the magnitudes of the maximum measurement errors of LILAS as references, which are 10% for  $\alpha_{355}$ ,  $\alpha_{532}$ ,  $\beta_{355}$ ,  $\beta_{532}$ ; 15% for  $\delta_{355}$ ,  $\delta_{532}$ ,  $\delta_{1064}$ ; and 20% for  $\beta_{1064}$  (Hu et al., 2019). We assume the independent Gaussian error for each measurement; thus, the corresponding standard deviations are 3.3% for

$\alpha_{355}, \alpha_{532}, \beta_{355}, \beta_{532}$ ; 5% for  $\delta_{355}, \delta_{532}, \delta_{1064}$ ; and 6.7% for  $\beta_{1064}$ . According to the results presented in Sect. 4.1, we dismiss the cases where  $r_{\text{eff}} > 2 \mu\text{m}$  and the inversions using the spherical model as they do not have satisfying retrieval accuracy even for error-free measurements. Instead, we present the noise test results of two single but representative cases: (1)  $r_{\text{eff}} = 0.5 \mu\text{m}, m_R = 1.52, m_I = 0.0035$ ; (2)  $r_{\text{eff}} = 2 \mu\text{m}, m_R = 1.52, m_I = 0.0035$ . The span of  $r_{\text{eff}}$  covers the range allowing the scattering models to reproduce most real measurements in Table 2 (Figs. 3-4), and the range of most in situ measurements in Table 1. The selected  $m_R$  and  $m_I$  correspond to mean values of D19.

For each case and every possible  $\delta$  combination as the input, Figs. 13 (for the IH model) and 14 (for the spheroidal model) show the standard deviations (STDs) of the retrieval errors derived from 1000 inversions of the noise-contaminated measurements. The STDs of  $\epsilon(V_I) \pm \epsilon(r_{\text{eff}}) \pm \epsilon(m_R)$  for both models are comparable, but the spheroidal model shows a generally larger STD of  $\epsilon(m_I)$ , particularly for  $r_{\text{eff}} = 2 \mu\text{m}$ . Recall that we have demonstrated in Section 4.1 that compared to the IH model, the spheroidal model either does not receive a significant retrieval improvement after the incorporation of  $\delta$  measurements, especially for the  $m_I$  retrieval. In this regard, we believe that the IH model works better in the retrieval process. In addition, for the IH model and  $r_{\text{eff}} = 2 \mu\text{m}$ , measurement noise causes a larger retrieval dispersion if only  $\delta_{1064}$  is included, while a combination of  $\delta$  at other wavelengths can effectively reduce the retrieval dispersion. This could be related to the alteration of system ill-posedness due to changes of the measurement set and state parameters (Rodgers, 2000; Twomey, 1977). However, a clear suggestion is that it is important to combine measurements of both high and low sensitivities to suppress the influence of measurement noise. In this regard, we suggest using the IH model to invert at least  $(3\beta + 2\alpha + 2\delta)$  lidar measurements with one of the  $\delta$  at 1064 nm in real applications.

**Figure 13.** Standard deviations (STDs) of the retrieval errors for two single case retrievals: (a-d)  $r_{\text{eff}} = 0.5 \mu\text{m}, m_R = 1.52, m_I = 0.0035$ ; (e-h)  $r_{\text{eff}} = 2 \mu\text{m}, m_R = 1.52, m_I = 0.0035$ , derived by inverting error-free synthetic measurements perturbed with random noise for 1000 times. The measurement noise is assumed to be Gaussian and independent of each other, of which the standard deviation is: 3.3% for  $\alpha_{355}, \alpha_{532}, \beta_{355}, \beta_{532}$ ; 5% for  $\delta_{355}, \delta_{532}, \delta_{1064}$ ; and 6.7% for  $\beta_{1064}$ . The related scattering model is the IH model.

Figure 14. Same as Fig. 13 but it is related to the spheroidal model.

## 5 Applications to real dust observations

In this section, different configurations (i.e., scattering model and inverted dataset) are applied to the retrievals of two representative dust cases observed by LILAS. In the first case, dust was freshly emitted with aging no more than 2 days; the second case concerns a transported dust layer with aging of around one week.

### 5.1 Case 1: Fresh dust on 14 April 2019, Kashi

The first case is from the Dust Aerosol Observation (DAO) campaign where intensive field measurements were taken at Kashi (39.50° N, 75.93° E) located on the western edge of the Taklamakan desert, one of the main sources of dust in Asia (Hu et al., 2020). On 15 April 2019, LILAS detected continuous aerosol layers extending from the boundary layer (BL) to around 3.5 km (Fig. 15), resulting in an obvious increase of daily AOD and decrease of EAE. Back trajectory analysis and satellite observations indicate the aerosol layers are related to a dust activity in the Taklamakan desert during 13-15 April (Hu et al., 2020). Figure 16 displays the time-averaged optical profiles between 18:00 and 20:00 UTC, 15 April. Below 2.3 km, all the optical properties are stable and a well-mixed structure can be identified: the PLDR is larger than 0.3 at all wavelengths and shows a typical dust-type spectral variation (Haarig et al., 2022; Hu et al., 2020), indicating the presence of homogeneous pure dust. Between 2.3 and 2.8 km, the decrease of PLDR and increase of EAE suggest an increase of fine-mode particles, and the variation of LR implies an alteration of aerosol components, although the extinction and backscattering coefficients are still stable. Above 2.8 km, the extinction and backscattering decline rapidly due to the decrease of aerosol loading.

**Deleted:** 4.1 Reproduction of lidar measurements and strategy of retrieval simulations

We define three VSDs to represent the size distributions of transported dust (TD), fresh dust (FD) and bimodal dust (BD, a mixture of fine-mode and coarse-mode dust). For CRI, three real parts and three imaginary parts are defined. The spectral dependence of the imaginary part is considered as described in Sect. 2.4.2.

Hereinafter, unless explicitly stated, the imaginary part of CRI presented and discussed always refers to the monochromatic value at 355 nm, and for simplicity, the subscript “355” is omitted. Complete parameterization of the aerosol models is shown in Table 1, which leads to 27 sets of state parameters in total.

**Table 1. Aerosol model setup for the retrieval simulation** (subscript “f” for fine mode, “c” for coarse mode). The “Index of ( $m_R$ ,  $m_{L355}$ )” shows the CRI values corresponding to the x-axes in Figs. 11, 13, and 14. Lognormal VSD (Eq. 6)

**Deleted:** BOREAL a

**Deleted:** we apply BOREAL algorithm to real lidar measurements obtained during two dust episodes to evaluate its performance under different configurations, specifically using different scattering models (Sphere, Spheroid or IH model) and input datasets. We only focus on pure dust observations which can be identified by analysing depolarization and fluorescence measurements of LILAS (Veselovskii et al., 2022)

**Deleted:** by LILAS and sun-sky photometers to study the mineral dust aerosol freshly emitted from the Taklamakan desert –

**Deleted:** a dust activity was detected by LILAS at Kashi (39.50° N, 75.93° E) located on the western edge of the Taklamakan desert

**Deleted:** revealed

**Deleted:** it originated from the Taklamakan desert 1 or 2 days ago

**Deleted:** Figure 16 is the range-corrected backscattered signals at 1064 nm since 15 April 2019, 12:00 UTC. A continuous aerosol layer extending from the boundary layer (BL) to around 3.5 km is notable. Furthermore, clouds were continuously present during the period.

**Deleted:** 17

**Deleted:** The profiles indicate the particles were evenly distributed below 2.2 km with LR and PLDR values typical for pure dust.

Figure 15. LILAS range-corrected backscattered signals at 1064 nm between 12:00 UTC, 15 April 2019 and 00:00 UTC, 16 April 2019, at Kashi, China.

Figure 16. Optical profiles at 355, 532, and 1064 nm, averaged for the period 18:00–20:00 UTC, 15 April 2019, at Kashi. This figure is adapted from Fig. 10 in Hu et al. (2020). The variations of  $\delta$ , LR and AE above 2.3 km indicate the alteration of aerosol components and the rapid declinations of  $\alpha$  and  $\beta$  above 2.8 km mark the upper boundary of the aerosol layer.

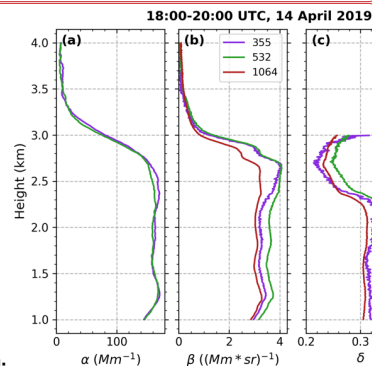

We averaged the optical properties every 200 m for the layer below 3 km and inverted the averaged optical properties with the IH, spheroidal and spherical models, respectively. The  $(3\beta + 2\alpha)$  and  $(3\beta + 2\alpha + 3\delta)$  data are inverted and the corresponding retrieved microphysical properties ( $V_t$ ,  $r_{\text{eff}}$ ,  $m_R$ ,  $m_i$ ) are shown in Fig. 17. The decrease followed by an increase of  $r_{\text{eff}}$  above 2.3 km, which is only reflected by  $(3\beta + 2\alpha + 3\delta)$  inversion, agrees with the variations of the  $\delta$  and EAE shown in Fig. 16. The stand-alone lidar observations cannot verify the exact involved aerosol species in that layer. Hu et al. (2020) pointed out the high possibility of the presence of anthropogenic aerosols that were lifted by convection and remained at higher altitudes as bigger dust particles settled down. Given that BOREAL is only developed for pure dust retrieval (Section 2.2.3) at the current stage, retrieval accuracy for this layer is therefore not guaranteed. For the retrievals below 2.2 km, when inverting  $(3\beta + 2\alpha + 3\delta)$  measurements, the two non-spherical models derive apparently distinct results so as to fit the input measurements: the spheroidal model derives smaller  $m_R$  and  $m_i$ , as well as larger  $V_t$  and  $r_{\text{eff}}$ . The influence of ruling out  $3\delta$  on the retrievals agrees

with what we saw in Section 4: on the one hand, the spheroidal-derived  $m_R$  and  $m_1$  become larger, accompanied by decreasing  $V_t$  and  $r_{eff}$ ; on the other hand, the IH-derived result barely changes since the  $m_R$  is retrieved close to 1.6 from the  $(3\beta + 2\alpha + 3\delta)$  inversion. Compared to the inversion of  $(3\beta + 2\alpha)$  using the non-spherical models, using the spherical model derives similar  $V_t$  and  $r_{eff}$  but evidently lower  $m_R$  and higher  $m_1$ . We also observed such a behaviour when  $m_R$  is set to 1.6 in the simulation (not shown here). In a word, the variations of the inversions caused by different scattering models and input measurements are in line with our simulation results, indicating the results from  $(3\beta + 2\alpha + 3\delta)$  inversion are least affected by retrieval uncertainty.

**Figure 17.** Profiles of (a)  $V_t$ , (b)  $r_{eff}$ , (c)  $m_R$  and (d)  $m_{1,355}$  retrieved from the averaged optical data in Fig. 17 with different retrieval configurations: inversion of  $(3\beta + 2\alpha + 3\delta)$  with the IH model (3+2+3, IH), inversion of  $(3\beta + 2\alpha + 3\delta)$  with the Spheroid model (3+2+3, Sphd), inversion of  $(3\beta + 2\alpha)$  with the IH model (3+2, IH), inversion of  $(3\beta + 2\alpha)$  with the Spheroid model (3+2, Sphd) and inversion of  $(3\beta + 2\alpha)$  with the Sphere (Sph) model (3+2, Sph).

Figure 18 displays for different configurations the retrieved VSDs, SSAs and the comparisons between the real and reproduced measurements in the layer 1.5–2 km. The selected layer is far from the polluted layer and thus is attributed to purer dust. All retrieval configurations derive monomodal VSD located in the coarse mode range, except for the spherical model which obtains a second mode at 0.4–0.5  $\mu\text{m}$ . When inverting the  $(3\beta + 2\alpha + 3\delta)$  measurements, the IH-derived VSD has a similar volume median radius ( $r_v \sim 1.3$ –1.7  $\mu\text{m}$ ) to the spheroidal-derived VSD but a larger  $S_g$ , resulting in a smaller  $r_{eff}$ . Because of the implemented spectral relationship of dust  $m_1$ , the retrieved SSAs present a typical spectral dependency of dust aerosols (e.g., Di Biagio et al., 2019) and the highest SSA corresponds to the lowest  $m_1$  retrieved with the configuration  $(3\beta + 2\alpha + 3\delta)$ , spheroidal). The error bars attached to the real measurements represent the corresponding maximum measurement errors. For all retrieval configurations, difference between real and reproduced measurements is within the corresponding error bar as long as this measurement is incorporated into the inversion dataset. The inversion of  $(3\beta + 2\alpha + 3\delta)$  enable both IH and spheroidal models to reproduce the spectral variation of the measured PLDR. However, when it comes to the  $(3\beta + 2\alpha)$  inversion, the spheroidal model underestimates  $\delta$  for all wavelengths while the IH model performs much better: only a little overestimate of  $\delta_{355}$  is observed.

**Deleted:** Figure 18 shows the profiles of  $V_t$ ,  $r_{eff}$ ,  $m_R$  and  $m_{1,355}$  for Case 1 retrieved with different retrieval configurations. The profiles of microphysical properties are stable below 2.2 km and present more variability above 2.2 km. In particular, the decline of  $r_{eff}$  above 2.2 km, retrieved from  $(3\beta + 2\alpha + 3\delta)$  measurements, supports the conclusion drawn by Hu et al. (2020) that a lifted fine-mode anthropogenic aerosol layer was above the well-mixed dust layer due to convection. Different heights and retrieval configurations result in ranges of 35–85  $\mu\text{m}^3/\text{cm}^3$  for  $V_t$ , 0.4–1.3  $\mu\text{m}$  for  $r_{eff}$ , 1.45–1.68 for  $m_R$  and 0.0015–0.012 for  $m_{1,355}$ .

**Deleted:** 8

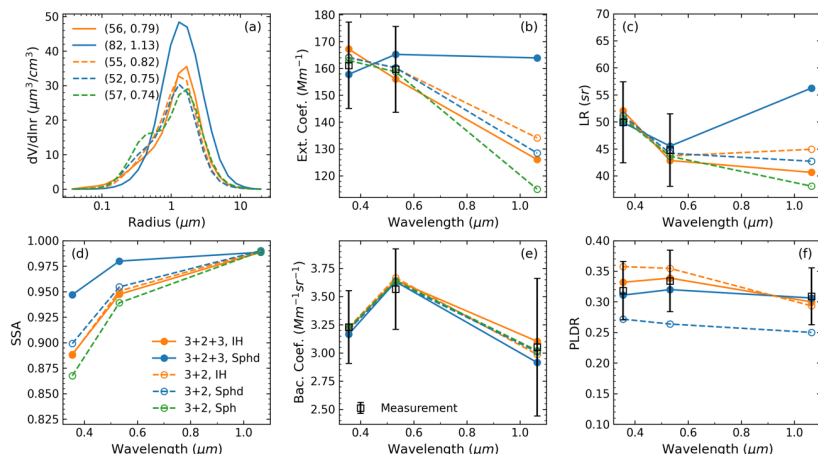

**Deleted:** 9

**Deleted:** more retrieval results for a layer averaged between 2 and 2.2 km, showing the VSD,  $m_R$ , spectral  $m_1$  and SSA, as well as the comparisons between the measured and recalculated optical properties (i.e., measurement fitting)

**Deleted:** accompanied by  $m_R$  in 1.45–1.58,  $m_{1,355}$  in 0.002–0.009, and  $\omega_{355}$  in 0.87–0.94

**Deleted:** The UV-enhanced imaginary part, and correspondingly,

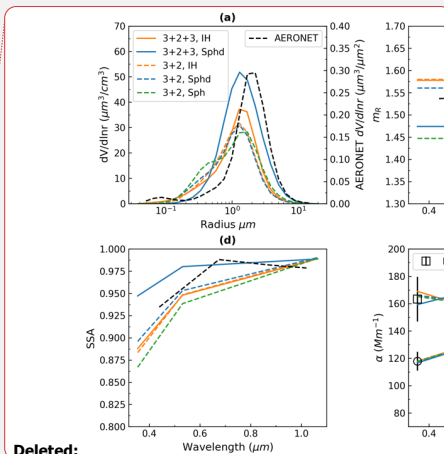

**Deleted:** the UV-declined SSA are the consequences of considering the spectral dependence of dust aerosols. When the  $(3\beta + 2\alpha)$  measurement are inverted, the 3 scattering models lead to similar  $V_t$  and  $r_{eff}$ , however, the Sphere model results in lower  $m_R$  and higher  $m_1$ . With the inclusion of  $3\delta$  measurements,  $V_t$ ,  $r_{eff}$  increase while  $m_R$ ,  $m_1$  decrease for both IH and Spheroid models; however, compared with the IH model, the Spheroid model derives higher  $V_t$  and  $r_{eff}$ , while lower  $m_R$  and  $m_1$ . Compared to the measurement error bars, all the scattering models are able to well fit the measurements. The AERONET level 2.0 retrieval at 15 April 2019, 3:50 UTC, Kashi, is also displayed for comparison. Compared to the BOREAL retrievals, the AERONET retrieval derives a coarse-mode-predominating VSD with larger coarse-mode  $r_{eff}$  and a wavelength-independent  $m_R$  of  $\sim 1.54$ . Moreover, the spectral variations of  $m_1$  and SSA retrieved by AERONET are consistent with those retrieved by BOREAL.

**Figure 18.** Retrievals and reproduced measurements for the layer between 1.5 and 2 km in Case 1. The retrievals include (a) VSD, and (d) SSA. The reproduced measurements include (b) extinction coefficient, (c) LR, (e) backscattering coefficient and (f) PLDR. The legend in (a) refers to the  $(V_s, r_{cn})$  ( $\mu\text{m}^3/\text{cm}^3, \mu\text{m}$ ) retrieved with the corresponding configuration.

## 5.2 Case 2: Transported dust on 21 March 2022, Lille

An increase of aerosol activity above the BL was observed by LILAS operated at ATOLL/Lille since 14:00 UTC, 21 March 2022. The range-corrected signals and time-averaged optical profiles between 20:00 and 23:00 UTC are shown in Figs. 19 and 20. Different from Case 1, three stratified layers can be identified: Layer 1 below 2 km, Layer 2 centred at 4 km, and Layer 3 centred at 5.4 km. Dust could be abundant in the upper two layers (Layer 2 and Layer 3) due to their high PLDRs compared to the bottom layer (Layer 1). Figure 21 shows the HYSPLIT back trajectories of the three layers ending at 21:00 UTC, 21 Mar 2022 (Rolph et al., 2017). It can be seen that although the upper two layers both originated from the Saharan region, they went through different transporting pathways and times. The “dust RGB” products from the Spinning Enhanced Visible and Infrared Imager (SEVIRI) on board the Meteosat Second Generation (MSG) satellite (Lensky and Rosenfeld, 2008) (Fig. S3) reveal that the pathway of Layer 3 largely overlapped with that of dust lifted from Northwest Algeria between March 14-15. The synoptic conditions (Kanamitsu et al., 2002) (Fig. S4) during these days show low-pressure cyclones over the region with daily averaged 10-m wind speed exceeding 7 m/s, which are favourable for dust emission. Both the trajectory and satellite images indicate that after the emission, the dust layer was elevated up to ~6 km, crossed the Mediterranean, and dispersed over Western Europe. Meanwhile, thick ice clouds continuously existed with the dust, implying the dust might undergo cloud processing. The dust enriched in Layer 2 was emitted probably during the daytime of March 17 near the border between Tunisia and Libya and elevated by the easterly trade winds (Khan et al., 2015). Although ice clouds kept forming above, the dust was not likely to go through cloud processing due to its lower altitudes. However, given the main lifting procedure happening over

the sea and the longer time remaining over the Mediterranean compare to Layer 3, Layer 2 could contain more sea salts (Denjean et al., 2016). The different transport and aging processes of these two dust layers can lead to contrasts of their microphysical properties and, consequently, the optical properties. As can be seen in Fig. 20, compared to the upper layer, the lower layer has a larger  $\delta_{355}$ , a larger  $LR_{355}$  and a smaller  $BAE_{355-532}$ . However, here we only perform retrievals for Layer 3 because the measurement quality of Layer 2 is not guaranteed due to the relatively low aerosol loading.

Figure 22 displays the microphysical property profiles retrieved with different configurations for Layer 3. Moving from  $(3\beta + 2\alpha + 3\delta)$  to  $(3\beta + 2\alpha)$  inversion, changes of the retrievals are still in accordance with the simulation results. When the  $(3\beta + 2\alpha + 3\delta)$  data are inverted, the retrieved effective radii slowly decrease from 0.7 to 0.5  $\mu\text{m}$  as altitude increases, in accordance with the slowly increase of EAE. Compared to Case 1, the IH and spheroidal models obtain less divergent results and both retrieve smaller  $r_{\text{eff}}$  and larger  $m_i$  in Case 2 when the  $(3\beta + 2\alpha + 3\delta)$  data are inverted. Such contrasts could result from the distinct spectral PLDRs of the two cases. Moreover, the IH-obtained  $m_R$  (1.5-1.55) in Case 2 is smaller than that (1.58-1.6) in Case 1, consistent with the higher LR in Case 2 than in Case 1. The differences in optical and microphysical properties between the two cases might be explained by the longer aging process of dust particles in Case 2 than Case 1, particularly the persistent dust-cloud interactions in Case 2 which could considerably modify dust size (Mahowald et al., 2014; Ryder et al., 2015; Weinzierl et al., 2017; Wurzler et al., 2000).

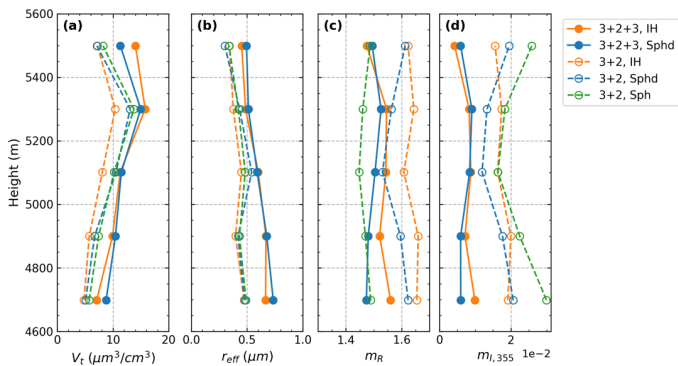

Figure 22. Same as Fig. 17 but retrieved from the averaged optical data in Fig. 20, for the layer 4.6-5.6 km.

Figure 23 shows for different configurations the retrievals of VSD and SSA, as well as the comparisons between the real and reproduced measurements in the layer 5-5.5 km. Consistent with the change in  $m_I$ , the retrieved SSAs are in general lower than those in Case 1. All the inverted measurements can be reproduced from the retrievals with biases smaller than their maximum errors. However, the IH model performs better in reproducing the intensive optical properties (LR and PLDR) than the spheroidal model. A more detailed discussion is given in Section 6.

Deleted: 5.4-5.6

Deleted: All retrieval configurations derive monomodal VSDs with  $r_{eff}$  in 0.46-0.56  $\mu m$ , accompanied by  $m_R$  in 1.45-1.64,  $m_{I,355}$  in 0.0085-0.0175, and  $\sigma_{355}$  in 0.84-0.9.

Deleted: Compared to Case 1, the smaller  $r_{eff}$  in Case 2 is in line with the size evolution of dust particles during the transport processes (Arimoto et al., 1997; Hu, 2018; Uematsu et al., 1983). Furthermore, the overall higher  $m_I$  in Case 2 is consistent with laboratory measurements by Di Biagio et al. (2019) which manifests that Saharan dust is more absorbing than Taklamakan dust. Retrievals with all the scattering models effectively fit the measured optical properties within the measurement uncertainty. However, the IH model failed to accurately represent the spectral dependence of extinction coefficients measured by lidar. The AERONET level 1.5 retrieval at 21 March 2022, 15:58 UTC, Lille, is also shown for comparison. Note that it is the low aerosol loading ( $AOD_{440} < 0.4$ ) that precludes the retrieval from being level 2.0. In other words, other metrics like solar zenith angle and sky error satisfy the level 2.0 criteria so that the retrieved CRI and absorption properties are still reliable (Holben et al., 2006). Unlike in Case 1, AERONET derives a bimodal VSD with the coarse-mode  $r_{eff}$  obviously larger than the BOREAL results. Moreover, compared to the BOREAL retrievals, the CRI from the AERONET retrieval is smaller and spectrally dependent for both real and imaginary parts. Compared to Case 1, the lidar profiles (Fig. 21) in Case 2 indicate more heterogeneity of aerosol vertical distribution and less contribution of the dust layer to the columnar optical properties which make the two types of retrieval less comparable.

## 6 Discussion

### 6.1 Capabilities of the IH and Spheroid models to mimic measured optical properties

Both simulations and real dust retrievals in this study demonstrate the significance of considering dust non-sphericity in the retrieval from lidar measurements. The spherical model severely underestimates  $m_R$  or overestimates  $m_I$  as it considerably overestimates  $\beta$  of non-spherical particles. Therefore, it should be replaced with a proper non-spherical model. Comparing the spheroidal and IH models, we may argue that the latter is preferable because spheroids are too “smooth” and “spherical” to be like real dust particles. However, note that it is unrealistic to take the exact shape of every single dust particle for optical and radiative transfer calculations. In this regard, all applicable non-spherical models are kinds of optically equivalent approximation. We may also argue that compared to the IH model, the spheroidal model ignores the CBE effect, which results in underestimates of  $\beta$  (Huang et al., 2023; Zhou, 2018). However, this in turn cancels the enhancement of  $\beta$  due to the more spherical shape of spheroids than IH particles (Gasteiger et al., 2011; Kalashnikova and Sokolik, 2002; Mishchenko et al., 2002). In remote sensing applications, we should focus on which model is able to mimic dust optical properties that are more consistent with real measurements. As mentioned in Sect. 2.3.1, the deficiency of the spheroidal model in mimicking particle backscattering properties has been found in many previous studies (Haarig et al., 2022; Müller et al., 2010; Noh et al., 2017; Shin et al., 2018; Tesche et al., 2019). In addition, Kampainen et al. (2015) found that the assumption of ellipsoids (a general case of spheroids) cannot fit the measured scattering matrix of irregular dust-like particles unless the CRI was largely biased from the true value. Huang et al. (2023) found that neither the spheroidal nor the ellipsoidal dust optics could reproduce the scattering matrix of the Amsterdam-Granada Light Scattering Database samples (AGLSD, Muñoz et al., 2012) well. Although there have been increasing calls for using the IH model in dust scattering calculation (e.g., Castellanos et al., 2024), we only found a very latest study where a simple conclusion (without details) that the IH model is superior to the ellipsoid model in mimicking the scattering pattern of Martian dust analogues was given (Martikainen et al., 2025). In this regard, our study provides a direct comparison of lidar-related optical properties simulated by the IH and spheroidal models.

Our simulations show the differences between the two non-spherical models in producing lidar-measured optical properties largely depends on particle size. For  $r_{\text{eff}} < 0.5 \mu\text{m}$ , only EAEs show slight difference within the measurement error; thus, the two models are optically equivalent in this size range. As particle size increases, BAEs, LR and PLDRs simulated with the two models start to be divergent, among which the PLDRs differ most (IH particles produce significantly larger values than spheroids). In addition, it seems that the differences in LR and PLDR also depend on the size parameter, which also leads to distinct spectral variations produced by the two models as  $r_{\text{eff}}$  increases. More significantly, for  $r_{\text{eff}} > 1 \mu\text{m}$ , a size range that is in line with most published in situ and sun photometer retrieval results (Table 1), our simulations found that the IH model can better reproduce the real lidar measurements of BAE, spectral LR and spectral PLDR (Table 2). Therefore, with this regard, we confirm that the IH model performs better than the spheroidal model.

**Deleted:** Table 5 lists the detailed conditions of the two cases. Note the more intensive dust activity reflected in the layer thickness and the layer-averaged extinction coefficient in Case 1. Furthermore, the higher EAE provided by AERONET in Case 2 implies a higher volume fraction of fine-mode particles. Table 6 summarizes the retrieved state parameters and measurement fittings in Figs. 19 and 23, together with the corresponding AERONET retrievals. The  $V_L$  in terms of AERONET is the layer-averaged volume concentration (the columnar volume concentration divided by the aerosol layer height estimated from the lidar profile), and the  $\varepsilon_{\text{fit}}$  in terms of AERONET refers to the sky error (the fitting of sky radiance measurements). Combining Table 6 and Figs. 19 and 23, when inverting  $(3\beta + 2\alpha + 3\delta)$  data, differences between the state parameters retrieved with the Spheroid model and the IH model are more prominent in Case 1 than Case 2. All retrieval configurations lead to a  $\varepsilon_{\text{fit}}$  comparable to the root-mean-square uncertainty of the inverted measurements (4% for the  $(3\beta + 2\alpha)$  data and 4.4% for the  $(3\beta + 2\alpha + 3\delta)$  data). Compared to Case 1, the overall larger fitting error encountered in Case 2 might be attributed to the higher noise level because of the lower aerosol loading. The volume concentrations derived with BOREAL and AERONET are in the same order, while the effective radii derived with BOREAL are smaller than the corresponding AERONET values by 30–50% regardless of the selection of the retrieval configuration. **Table 5. Detailed information about the dust cases.**

**Deleted:** Kemppinen et al.,

However, we have to point out that although we tried to establish representative dust microphysical properties for the simulations based on previous studies, the settings are still limited and cannot cover all the situations. For example, the VSDs are described using the monomodal lognormal distribution with fixed  $S_g = 1.95$ , a value near the middle of the  $S_g$  range in Table 1; situations when  $S_g$  varies or a narrow submicron mode close to the coarse mode simultaneously presents, as many OPC instruments show (Ryder et al., 2013, 2018; Weinzierl et al., 2009, 2011), are not included. In addition, the simulations did not account for other aerosol types like sea salt and anthropogenic pollutants that can either externally or internally (by coating or chemical reactions) mix with pure dust particles, making the aerosol ensemble more spherical and less depolarized (Kandler et al., 2009; Matsuki et al., 2005; Ryder et al., 2015; Weinzierl et al., 2009, 2011; Zhang and Iwasaka, 2004). These omissions might explain the discrepancy between some model-reproduced and real measurements. For instance, although the PLDR spectral variation of Saharan dust can be reproduced by the IH model using the setup for  $S_g = 1.95$ ,  $r_{\text{eff}} > 1 \mu\text{m}$ , the magnitudes from the model are evidently higher, especially at 355 nm. Future study will further compare these two non-spherical models by considering these possibilities.

## 6.2 Retrieval performance and information of $\delta$ measurements

Apart from the capability of mimicking dust backscattering properties, it is also essential to assess the retrieval performance of the IH and spheroidal models. That is, the accuracy and stability of the retrieval as different measurement combinations are inverted and aerosol microphysical states vary. From the results of both synthetic and real optical measurement inversions, we are quite certain that the lack of  $\delta$  measurements causes a trend of underestimating  $V_i$ ,  $r_{\text{eff}}$ , and overestimating  $m_R$ ,  $m_i$ . Retrievals from synthetic optical data (Sect. 4) reveal that spectral PLDR plays a significant role for improving the retrieval accuracy of large particles ( $r_{\text{eff}} > 1 \mu\text{m}$ ) under both of the non-spherical models. Among the three wavelengths,  $\delta_{1064}$  is most essential since it shows the highest sensitivities to  $r_{\text{eff}}$  and  $m_R$ . Although it is independent of  $m_i$ , one can think of that  $\delta_{1064}$  brings effective constraint on particle size to the  $(3\beta + 2\alpha)$  inversion and thus improves the retrieval accuracies of all state parameters. This result is in contrast to that presented by Tesche et al. (2019). They concluded that  $\delta_{355}$  is the most indispensable input measurement in lidar inversion while  $\delta_{1064}$  does not improve the retrieval performance. The main reason could be the fact that they only used the spheroidal model and retrieved real parts of CRI greater than 1.5 (a detailed demonstration has been given in Sect. 4.1). Moreover, the quite different experimental setup and retrieval outputs between the studies could also explain it. First, Tesche et al. (2019) used the spheroidal model and the retrieval methods similar to that of Müller et al. (2013) and Veselovskii et al. (2010). Second, they mainly focused on the retrieval of “spheroid fraction”, a parameter to characterize the mixing state of polluted dust. Finally, they did not consider the spectral variability of dust  $m_i$ . We have discussed the potential limitations of these configurations in details (Sect. 2), which render us confident on our result. In addition, our result is in line with the findings of Gasteiger and Freudenthaler (2014) and Shin et al. (2018), who attributed the greatest informational value to  $\delta_{1064}$  measurements.

We cannot directly compare the synthetic retrievals across the models as the two non-spherical models are used to invert the synthetic measurements generated by their own. Nevertheless, the retrieval simulations signify that compared to the spheroidal

model, the improvement attributed to  $\delta$  measurements is more manifest if the IH model is used. In particular, significant improvement in  $m_1$  retrieval for large particles ( $r_{\text{eff}} = 2 \mu\text{m}$ ) was observed in the IH model. We also noticed that the combination of  $\delta_{1064}$  with either  $\delta_{355}$  or  $\delta_{532}$ , or both  $\delta_{355}$  and  $\delta_{532}$  allows (1) an improvement of CRI retrievals from a statistical point of view; (2) an effective suppression of retrieval instability caused by measurement noise. Accordingly, we conclude that the IH model is more suitable for lidar-based dust retrieval and suggest using the IH model to invert at least  $(3\beta + 2\alpha + 2\delta)$  measurements with one of the  $\delta$  at 1064 nm to assure retrieval quality.

Inverting the real dust observations allows for direct comparisons of the results retrieved with the two non-spherical models. The two case studies in Sect. 5 verify the finding in the simulation that significant retrieval difference between the IH and spheroidal models is not expected if  $r_{\text{eff}}$  is retrieved to be  $\sim 0.5 \mu\text{m}$ . In addition, when inverting the  $(3\beta + 2\alpha + 3\delta)$  data, the IH model tends to derive higher  $m_R$  and  $m_1$  than the spheroidal model, because of their difference in producing spectral PLDR. It is also interesting to look at the LR at 1064 nm predicted by the  $(3\beta + 2\alpha + 3\delta)$  retrievals. In Case 2, both IH and spheroidal models derive the increasing LR from 532 to 1064 nm, while the magnitude of  $\text{LR}_{1064}$  retrieved with the IH model is more consistent with the measurements of Saharan dust (Gebauer et al., 2024; Haarig et al., 2022). In Case 1, the IH model found a quite distinct  $\text{LR}_{1064}$  compared to the spheroidal model, leading to different spectral variations. Unfortunately, we are currently in short of  $\text{LR}_{1064}$  measurements of Eastern Asian dust for validation.

### 6.3 Comparison of the real case retrievals with AERONET and previous studies

The lack of independent data (ideally collocated in situ measurements) to compare with the results retrieved from the real lidar measurements in Sect. 5 precludes a closure validation of this study. Alternatively, in this section we present the results of comparison with corresponding AERONET retrievals and comparison with previous studies discussed in Sect. 2.2 for a preliminary verification.

Two AERONET retrievals closest to the places and times of the lidar measurements and passing the data quality check (Holben et al., 2006; Sinyuk et al., 2020) are selected for the comparison. However, we are aware that such comparison itself has many limitations. Firstly, in contrast to our lidar which works in the night time to ensure the quality of Raman signals, AERONET makes columnar measurements and works during the daytime. Given the high tempo-spatial variability of aerosol particles, they could target aerosols with different microphysical and optical properties. For example, the layer-averaged  $\alpha_{532}$  from lidar measurements are  $161 \text{ Mm}^{-1}$  in Case 1 and  $64 \text{ Mm}^{-1}$  in Case 2, respectively, while the columnar-averaged  $\alpha_{440}$  from corresponding AERONET measurements are  $186 \text{ Mm}^{-1}$  in Case 1 (0-3.2 km) and  $56 \text{ Mm}^{-1}$  in Case 2 (0-2 km plus 3-6 km). Secondly, retrievals from AERONET are also based on optical inversion and obtained with the spheroidal model. This could render the lidar retrievals using the spheroidal model more consistent with the AERONET retrievals since they utilize the same scattering model. Accordingly, the comparison results must be interpreted with care. Table 6 lists state parameters retrieved with BOREAL under different configurations and those provided by AERONET retrievals for the two case studies. Figure 24 visualizes the VSDs and SSAs from the AERONET retrievals. In Case 1, AERONET derives a monomodal VSD with  $r_{\text{eff}}$  obviously larger than any BOREAL retrievals. As mentioned, it is no wonder that the  $(3\beta + 2\alpha + 3\delta, \text{spheroidal})$  configuration

obtains  $V_t$ ,  $r_{\text{eff}}$ ,  $m_R$  and  $m_i$  that are closest to the AERONET retrieval since both retrievals exploit the spheroidal model. However, the SSA retrieved with the IH model shows a better consistency with the AERONET counterpart because the enhancement of SSA due to a smaller  $r_{\text{eff}}$  is compensated for by the weakening due to a larger  $m_i$ . Compared to Case 1, BOREAL and AERONET retrievals are less comparable in Case 2 because the vertical aerosol distribution was more heterogeneous (we have demonstrated that the aerosols in the BL were of different types than the dust layer). The AERONET retrieval in Case 2 shows a bimodal VSD with the fine-mode volume fraction comparable to the coarse-mode volume fraction, and a  $m_R$  value much lower than the BOREAL counterpart. Due to the influence of the BL aerosols, it is hard to evaluate how well the AERONET-derived coarse mode and CRI represent the microphysical properties of the dust layer, let alone the time difference between the lidar and sun photometer observations which further increases the uncertainty of the comparison.

**Table 6. Comparison of the state parameters retrieved with BOREAL under different retrieval configurations and provided by AERONET retrievals for the two case studies in Sect. 5. The CRIs and SSAs from the study of Di Biagio et al. (2019) are also listed in the last column. Lidar observations are averaged between 1.5 and 2 km in Case 1, and between 5 and 5.5 km in Case 2. For AERONET retrievals,  $V_t$  is calculated as the columnar volume concentration divided by the aerosol layer thickness (0–3.2 km for Case 1; 0–2 km plus 3–6 km for Case 2);  $r_{\text{eff}}$  includes the value for the total VSD and that for the coarse mode in the paratheses;  $m_R$  is the spectrally averaged value;  $m_i$  and SSA at lidar wavelengths are derived by linear interpolation or extrapolation.**

**Figure 24. AERONET retrievals selected for comparing with the BOREAL retrievals for the two real case studies. (a) VSD, (b) SSA. The SSA values at three lidar wavelengths are derived by linear interpolation or extrapolation.**

The comparison with the historical results of dust VSD in Table 1 shows that the BOREAL-retrieved effective radii are smaller or comparable with the lower bound of those measurements. Studies have found that compared to in situ measurements, retrievals from both sunphotometer and lidar measurements show systematically smaller  $r_{\text{eff}}$  (McConnell et al., 2008; Müller et al., 2012, 2013). As these studies pointed out, limitations of wavelengths restrain the measurement sensitivity to large particles and moreover, the lack of angular information of the lidar measurements makes it worse (Eck et al., 2008). For the fresh dust in Case 1, it is likely that the BOREAL retrievals undersize the particles because as we have seen in Sect. 4, BOREAL tends to underestimate  $r_{\text{eff}}$  greater than 1  $\mu\text{m}$  even if the  $3\delta$  are incorporated, let alone the giant-mode particles which totally disappear from the retrievals due to the very little sensitivity, whereas are actually ubiquitous for freshly emitted dust (Ryder et al., 2013, 2018). On the other hand, however, the BOREAL outputs are to some extent rational in terms of measurement fitting. Recall that the comparison between the model-simulated and measured LR and PLDR in Sect. 3.1 has shown that compared to real measurements, the IH model tends to overestimate the magnitude of PLDR using monomodal particles with  $r_{\text{eff}} > 1 \mu\text{m}$ , in spite of the consistent spectral variations. Such a phenomenon was also observed by Saito and Yang (2021). Another study of Saito et al. (2021) shows the effective radius which is enabled to fit the Taklamakan dust (another observational case in Hu et al. (2020)) to be 0.75  $\mu\text{m}$ , a value quite close to our result. The situation could be more complicated in Case 2 since dust microphysical and optical properties can be deeply altered by cloud processing and scavenging (Mahowald et al., 2014; Wurzler et al., 2000). As can be seen in Fig. 23f, the spectral variation of PLDR in Case 2 is quite different from that in Case 1 and previous measurements of the Saharan dust (Table 2). The modification of dust size by dust-cloud interactions was also found during Fennec (Ryder et al., 2015) and SALTRACE (Weinzierl et al., 2017) campaigns. It is also worth pointing out that different measuring principles and data processing of various in situ instruments can cause large uncertainty and even bias the results. For example, the uncertainty of aerosol microphysical property assumptions (e.g., shape, CRI) and issues of instrumental response and calibration can lead OPC instruments to oversizing and broadening size spectra (Reid et al., 2003; Walser et al., 2017). The accuracy of aerodynamic measurement systems is affected by the ambiguity of the aerodynamic shape factor, as well as the cut-off and bouncing-off effects (Reid et al., 2003; Ryder et al., 2015). In addition, as pointed out by Saito and Yang (2022), the use of maximum radius ( $r_{\text{max}} = D_{\text{max}}/2$ , see Sect. 2.3.2) or projected

area-equivalent radius as the size descriptor in aerodynamic methods can also lead to a systematic oversizing of irregular particles compared to the volume-equivalent radius used in this study. Similarly, systematic bias in VSD between using the optical-equivalent-spherical radius (for OPC methods) and the volume-equivalent radius is expected, although currently it is hard to be quantified. To sum up, the discrepancy between the effective radii retrieved from lidar inversion and measured by in situ measurements can result from: (1) the lack of measurement sensitivity due to the limitations of the maximum wavelength and measurement direction; (2) the drawbacks of BOREAL to better constraining the solution; (3) the limitations of the tested scattering models (both the IH and spheroidal models) in reproducing lidar measurements; and (4) the uncertainties in historical in situ measurements.

We also compared our retrieved CRIs and SSAs with the results provided by Di Biagio et al. (2019), as indicated in the last column of Table 6. It can be seen when the  $(3\beta + 2\alpha + 3\delta)$  data are inverted, for Case 1, the spheroidal model leads to more consistent  $m_i$ , while the IH model leads to more consistent  $m_R$  and SSA with the Di Biagio result; for Case 2, the two non-spherical models derive quite similar results, with higher  $m_i$  and SSA, and slightly higher  $m_R$  compared to the Di Biagio result. Note that the SSA was directly measured by the nephelometer and aethalometer while the CRI was retrieved by fitting the scattering and absorption measurements under the spherical assumption in their study. Therefore, their results of SSA are of a higher confidence level than the CRI. In this regard, we may again announce the superiority of the IH model.

Finally, we briefly discuss the influence of using different configurations (scattering models + measurement sets) to retrieve dust microphysical properties on dust radiative effect (DRE) estimation. First of all, numbers of previous studies have demonstrated that ignoring dust non-sphericity, as many global aerosol models do (Gliß et al., 2021), can underestimate dust mass extinction efficiency because compared to a spherical particle, an irregular particle with the same volume-equivalent radius has a greater surface-to-volume ratio (Kalashnikova and Sokolik, 2004), as shown in Fig. 3. This, in turn, leads to overestimates of global dust mass loading (Huang et al., 2023; Kok et al., 2017). Second, diversity in retrieved VSD and CRI can also bias the estimates of DRE. If we adopt the retrievals obtained with the IH model since we have stated that it performs better than the other, the smaller retrieved  $r_{\text{eff}}$  compared to most of the in situ measurements means an increasing loading of finer particles and a decreasing loading of coarser particles. Consequently, the dust short-wave (SW) cooling could increase because the finer dust particles absorb less and scatter more SW radiation than the coarser dust particles (Miller et al., 2006), and this effect could last long given the longer lifetime of the finer dust particles. The lack of  $\delta$  measurements leads to more underestimates of the coarse loading, but the influence on the finer particles becomes ambiguous since apart from  $r_{\text{eff}}$ ,  $V_i$  is also underestimated. At the same time, inversions without  $\delta$  measurements produce higher  $m_i$ , resulting in underestimates of SSA, especially at UV wavelengths, which to some extent compensates for the increase of SW cooling.

## 7 Conclusions

In this study, we investigate the feasibility of retrieving microphysical properties (state parameters) of dust aerosols, including the VSD, volume concentration ( $V_i$ ), effective radius ( $r_{\text{eff}}$ ), complex refractive index ( $\text{CRI} = m_R - im_i$ ), and SSA ( $\omega$ ) from

**Deleted:** The retrievals from both synthetic optical data (Sect. 4) and real lidar observations (Sect. 5) show results that fit the measurements within the prescribed measurement uncertainty, regardless of the retrieval configurations, i.e., different choices of scattering model and input measurements. This indicates that BOREAL combining with any of the scattering model<sup>†</sup> is able to retrieve state parameters that well reproduce the input measurements. However, with regards to different retrieval configurations, the retrievals differ to various extent.<sup>‡</sup> When the conventional  $(3\beta + 2\alpha)$  data are inverted, all three scattering models behave similarly for particle size retrieval, resulting in similar VSD,  $V_i$  and  $r_{\text{eff}}$ . Moreover, due to the limited sensitivity of  $(3\beta + 2\alpha)$  to large particles, the retrieved  $V_i$  and  $r_{\text{eff}}$  tend to be underestimated, accompanied by  $m_R$  and  $m_i$  that are often overestimated. Such retrieval bias exacerbates with the increase of particle size. However, using the Sphere model to retrieve non-spherical particles results in severe underestimation of  $m_R$  or overestimation of  $m_i$  so as to compensate for the strongly enhanced backscattering coefficient caused by the spherical particle assumption.<sup>§</sup> When the augmented  $(3\beta + 2\alpha + 3\delta)$  data are inverted, apparent improvement of retrieval accuracy for use of non-spherical models is observed due to the extended information contents provided by the additional spectral PLDR measurements. Nevertheless, the extent of the improvement depends on the model's representation of PLDR. The simulations have shown that the model-produced PLDR exhibits various sensitivities to the state parameters when they change, which means the scattering model has different information contents for different domains of the state parameters. Tables 3 and 4 indicate the larger the particle size, the higher the retrieval bias for the  $(3\beta + 2\alpha)$  inversion, and the more improvement after the inclusion of  $3\delta$ .<sup>¶</sup> Retrieval difference between the two non-spherical models stems from their difference in representing lidar-measured optical properties, of which the extent in turn depends on the retrieved state parameters. This can be further illustrated by looking at the two real case retrievals in Sect. 5. In Case 1 (fresh Taklamakan dust), when inverting  $(3\beta + 2\alpha)$ , the  $r_{\text{eff}}$  is retrieved similarly by the two non-spherical models between 0.71–0.78  $\mu\text{m}$ , a range where the  $(3\beta + 2\alpha)$  data yielded by the two non-spherical models show little difference. As a result, other state parameters are also retrieved similarly by the two non-spherical models. When inverting  $(3\beta + 2\alpha + 3\delta)$ , however, obvious retrieval difference in Case 1 is observed –compared to the IH model, the Spheroid model derives higher  $V_i$  and  $r_{\text{eff}}$  while lower  $m_R$  and  $m_i$  (consistent with the results shown in Fig. 13) because of significant contrast between the PLDR produced by the two non-spherical models. To the contrary, in Case 2 (transported Saharan dust), when inverting  $(3\beta + 2\alpha + 3\delta)$ , the  $r_{\text{eff}}$  is retrieved by the two non-spherical models between 0.54–0.55  $\mu\text{m}$ , a region where the  $(3\beta + 2\alpha + 3\delta)$  data yielded by the two non-spherical models do not exhibit clear contrasts and consequently, other state parameters are also retrieved similarly by the two non-spherical models. With an absence of  $3\delta$ , as demonstrated above, the  $r_{\text{eff}}$  decreases to 11–12  $\mu\text{m}$  due to the loss of sensitivity. However, compared to the IH model, the Spheroid model retrieves lower  $m_i$  and significantly lower  $m_R$  as a response of the  $\beta$  difference between the two non-spherical models which approaches to the maximum in the retrieved  $r_{\text{eff}}$  range (Fig. 4).<sup>||</sup> The comparison between BOREAL and AERONET retrievals on the one hand substantiates the significance of considering dust non-sphericity and incorporating the spectral PLDR measurements to improve the retrieval accuracy. On the other hand, it manifests the limitations of both IH and Spheroid models in reproducing the ... [8]

**Deleted:** CRI

combinations of spectral extinction ( $\alpha$ ), backscattering ( $\beta$ ) and ~~particle linear depolarization ratio (PLDR,  $\delta$ )~~ lidar measurements ~~using a lidar-aerosol retrieval algorithm, BOREAL~~. For the first time, ~~we assess the performances of three particle shape models, namely the spherical, spheroidal and IH models, in terms of mimicking dust backscattering properties and retrieving dust microphysical properties. Based on both simulation and real case retrieval results, we conclude that compared to the other shape models, the IH model is preferable because it better reproduces real lidar measurements as well as leads to superior retrieval accuracy. Compared to the IH model, the use of the spherical model severely underestimates  $m_R$  or overestimates  $m_I$  to compensate for the enhancement of  $\beta$  due to the spherical assumption, which is consistent with the study of Veselovskii et al. (2010); the use of the spheroidal model, however, tends to produce lower  $m_R$  and  $m_I$  mainly due to the difference in the model-produced PLDR. The simulations also manifest great improvement of retrieval accuracy after incorporating spectral PLDR measurements into the conventional inversion of the  $3\beta + 2\alpha$  measurements. Specifically,  $\delta_{1064}$  brings the largest improvement when inverting the error-free optical data, especially for larger particles ( $r_{\text{eff}} > 1 \mu\text{m}$ ), whereas the combinations of  $\delta_{1064}$  with  $\delta_{355}$  or  $\delta_{532}$  greatly ameliorates the retrieval stability when measurement noise presents.~~

The retrievals from real lidar measurements ~~substantiate the conclusions derived from the simulations. On the other hand, the comparison with AERONET retrievals and previous in situ measurement results imply a smaller effective radius from the BOREAL/Lidar retrievals. The possible reasons are: (1) the lack of sensitivity of lidar measurements to larger particles; (2) the shortcomings of BOREAL to better constrain the VSD; (3) the biases of the AERONET and in situ results from ours due to the differences in measuring principles; and (4) the potential limitations of the tested shape models in reproducing backward lidar measurements. The smaller retrieved  $r_{\text{eff}}$ , sometimes accompanied by a larger  $m_I$  if the  $\delta$  measurements are absent, likely to increase the dust SW cooling effect.~~

~~This study stands out the prospect of retrieving height-resolved dust microphysical properties from lidar measurements using the IH model. At the same time, we are aware of the main weakness as the lack of coincident independent measurements (ideally in situ measurements), which precludes a closure validation of the results. Another limitation is that this study does not consider external or internal mixing with other species and only focuses on pure dust. Moreover, the influence of varying the shape factor (i.e., the axis ratio distribution in the spheroidal model and the degree of sphericity in the IH model) is not accounted for. Therefore, more future studies with regards to these issues are needed. Finally, more direct lidar measurements of dust extinction and backscattering coefficients at 1064 nm, like the study of Haarig et al. (2022), will be of great interest so as to further examine the model behaviour at longer wavelengths.~~

**Deleted:** optical properties simulated with three scattering models: the Sphere, Spheroid and IH models are compared and their sensitivities to the state parameters are assessed. Using the BOREAL retrieval algorithm, we evaluate the influence of utilizing the aforementioned scattering models to invert different lidar measurement sets on the retrieval results. The simulations reveal that in a typical dust size range, the Sphere model can overestimate the backscattering coefficient of non-spherical dust particles by a factor of 5 at most, which causes severe underestimation of the real part ( $m_R$ ) of the CRI (by  $\sim 0.2$  at most) and overestimation of the imaginary part ( $m_I$ ) of the CRI (by  $\sim 0.025$  at most). Meanwhile, the

**Deleted:** the  $3\delta$

**Deleted:** – with the presence of measurement noise, accuracies of 10–22% for  $V_r$ , 12%–27% for  $r_{\text{eff}}$ , 0.02–0.036 for  $m_R$ , 0.001–0.002 for  $m_I$ , and 0.012–0.015 for  $\sigma$  are achieved for defined aerosol models. However, compared to extinction and backscattering coefficients, obvious distinctions between the two non-spherical models (Spheroid and IH models) lie in the representation of PLDR, which results in an increase of retrieval difference between the two non-spherical models after the inclusion of depolarization measurements. The extent of this retrieval difference depends on the retrieved  $r_{\text{eff}}$ .

**Deleted:** consolidate the results and

**Deleted:** they expose some issues worth noting. When inverting  $(3\beta + 2\alpha + 3\delta)$  measurements, retrieval differences between the IH and Spheroid models for the fresh Taklamakan dust retrieval are 30% for  $V_r$ , 29% for  $r_{\text{eff}}$ , 0.11 for  $m_R$ , 0.002 for spectral-averaged  $m_I$ , and 0.03 for spectral-averaged  $\sigma$ , respectively, larger than those for the transported Saharan dust retrieval. All the retrievals fit the measurements well with a fitting error comparable with the measurement uncertainty. The comparison with corresponding AERONET retrievals indicates that when inverting  $(3\beta + 2\alpha + 3\delta)$  measurements, the lidar-retrieved  $r_{\text{eff}}$  can be smaller by 30–50%. Apart from the reason that the difference in measurement time and vertical inhomogeneity of the aerosols make the two types of retrievals less comparable and the reason that BOREAL has the trend to underestimate particle size due to the reduction of measurement sensitivity to large particles, it is also a result of fitting the depolarization measurements for the used non-spherical model. Among the exploited retrieval configurations, the  $(3\beta + 2\alpha + 3\delta)$ , Spheroid) configuration derives the results most consistent with AERONET because the Spheroid model is also exploited by AERONET for dust retrievals.\*

**Deleted:** demonstrates the robustness of the retrieval method (BOREAL) for

**Deleted:** combined spectral extinction, backscattering and depolarization

**Deleted:** However, on the other hand, it reveals potential limitations of the IH and Spheroid models in producing dust backscattering properties, particularly the PLDR, which result in biases not only between the retrievals from the two non-spherical models, but also between the retrievals from lidars and other types of measurements (sun-sky photometers, in situ, laboratory measurements, etc.). Such biases will undoubtedly increase the uncertainty in aerosol modelling and radiative effect estimation that further studies are needed to evaluate in the future.\*

1960 and provided the IH model. FD helped with the programming. TP and GD took the charge of the maintenance, automatization and operation of the lidar system, and provided raw data processing.
