Abstract. Stratosphere-to-troposphere transport results in the stratospheric intrusion (SI) of O₃ into the free troposphere through the tropopause folding. However, the mechanism of SI influencing the atmospheric environment with the cross-layer transport of O₃ from the stratosphere, free troposphere to the atmospheric boundary layer has not been elucidated thoroughly. In this study, a SI event over the North China Plain (NCP, 33–40°N, 114–121°E) during May 19–20, 2019 was taken to investigate the mechanism of the cross-layer transport of stratospheric O₃ with the impact on the near-surface O₃ based on the multi-source reanalysis, observation data and air quality modeling. The results revealed a mechanism of stratospheric O₃ intrusion to the atmospheric environment induced by an extratropical cyclone system. The SI with downward transport of stratospheric O₃ to near-surface layer was driven by the extratropical cyclone system with vertical coupling of "upper westerly trough-middle the Northeast Cold Vortex (NECV)-lower extratropical cyclone" in the troposphere. The deep trough in the westerly jet aroused the tropopause folding, and the lower stratospheric O₃ penetrated the folded tropopause into the upper and middle troposphere; the westerly trough was cut off to form a typical cold vortex in the upper and middle troposphere. The compensating downdrafts of the NECV pushed the further downward transport of stratospheric O₃ in the free troposphere; The NECV activated an extratropical cyclone in the lower troposphere, and the vertical cyclonic circulation governed the stratospheric O₃ from the free troposphere across the boundary layer top invading the near-surface atmosphere. In this SI event, the averaged contribution of stratospheric O₃ to near-surface O₃ was accounted for 26.77%. The proposed meteorological mechanism of vertical transport of stratospheric O₃ into the near-surface atmosphere driven by an

35 extratropical cyclone system could improve the understanding of the influence of stratospheric O₃ on atmospheric environment with implications for the coordinated control of atmospheric pollution.

Keywords: Stratospheric intrusion; Tropopause folding; Near-surface ozone; Extratropical cyclone system

1 Introduction

The prominence of tropospheric O₃ pollution is growing increasingly conspicuous in China (Chen et al., 2021; Li et al., 2020; 40 Luo et al., 2022). The widely concerned photochemical reactions and regional transport are the principal sources of tropospheric O₃ in air pollution. Many studies have ascertained the mechanism of these factors on tropospheric O₃ and proposed targeted control strategies for O₃ pollution (Ding et al., 2019; Li et al., 2019; Li et al., 2020; Liu et al., 2021; Verstraeten et al., 2015). In addition, approximately 90% of the atmospheric column O₃ abundance concentrates in the stratosphere. The stratosphere intrusion (SI) with the downward cross-layer transport of stratospheric O₃ is also considered 45 an essential natural source of tropospheric O₃ (Bourqui and Trepanier, 2010; Chen, et al., 2023a; Holton et al., 1995; Wild, 2007), which has been non-comprehensively understand with the effect mechanism and degree on atmospheric environment change.

Under specific configuration of atmospheric circulations, stratospheric O₃ could invade downwards through the tropopause along with the dry and cold stratosphere air with high potential vorticity (PV), increasing the tropospheric O₃ concentrations 50 with a contribution of about 300–700 Tg O₃·yr⁻¹ (Stevenson et al., 2006; Wild, 2007). As the primary pathway of stratosphere-troposphere transport (STT), SI is achieved by multiple synoptic-scale and mesoscale processes (Stohl et al., 2003). Ordinarily, SI is closely associated with the subtropical westerly jet, cut-off low pressure, tropopause folding, trough-ridge system, tropical cyclones, and convection systems, etc (Chen et al., 2022; Chen et al., 2023b; Ding and Wang, 2006; Holton et al., 1995; Jiang et al., 2015; Zhao et al., 2021). The deeply folded tropopause in the subtropical westerly jet 55 with a cold front passing the western United States induced near-surface O₃ increases (Langford et al., 2012). The widespread subsidence movement in the south of the subtropical jet in March 2010 brought about a significant increase of O₃ in the low troposphere in Hong Kong (Zhao et al., 2021). In June 2014, the peripheral downdrafts in deep convection of the large-scale tropical cyclone Hagibis directly drove the STT of O₃, prompting the stratospheric O₃ transport downwards and causing rapid abnormal enhancements in surface O₃ (Jiang et al., 2015).

60 SI exhibits greater prominence in the mid-latitudes with the prevailing subtropical westerly jet. In the mid-latitudes of the northern hemisphere, approximately 20–30% of the O₃ reserve in the troposphere is sourced from the stratosphere. (Lelieveld and Dentener, 2000). SI events were observed frequently in the western United States, the eastern Mediterranean, the Middle East, and East Asia (Akritidis et al., 2016; Langford et al., 2009; Lefohn et al., 2011; Wang, X. et al., 2020). In parts of the US, the contribution of SI to surface O₃ is almost comparable to that of local O₃ precursor emissions (Lin et al.,

65 2012; Pfister et al., 2008). In China, the tropospheric O₃ exhibited an annual increase of 0.78% yr⁻¹ on account of the SI
processes (Verstraeten et al., 2015). The SI caused by a landing typhoon sharply increased the surface O₃ by 32% in the
North China Plain (NCP) (Meng et al., 2022a). Evidently, the artificial uncontrollability of SI impact on surface O₃
complicates the prevention and control of ambient O₃ pollution. Therefore, clarifying the influence mechanism of SI on
surface O₃ could improve the knowledge system on the formation causes of ambient O₃ pollution, which is of great concern
70 for formulating effective prevention of O₃ pollution.

It is generally recognized that the SI processes are closely associated with subtropical westerly jet activities (Archer and
Caldeira, 2008; Langford et al., 2012). The abnormal disturbances of the jet streams, which are the principal reason for the
tropopause folding, could further develop to form a cold vortex over the mid-upper troposphere in mid-high latitudes (Martin,
2021; Satyamurty and Seluchi, 2007). The cold vortex regulates the weather and climate in the mid-high latitudes (Xue et al.,
75 2022; Yang et al., 2017), and triggers vigorous convection, resulting in a variety of disastrous weather and anomalous
climate (Tao et al., 2023; Xue et al., 2021). The Northeast Cold Vortex (NECV) is a typical cold low vortex system in East
Asia (Lian et al., 2016; Xie and Bueh, 2017). The pronounced 500-hPa trough-ridge system of the subtropical westerly jet
from the Caspian Sea to eastern China is considered the precursor of the NECV (Huang et al., 1997). And on account of the
existence of the upper-level jet with the NECV, a significant horizontal wind vertical shear is aroused between the mid-lower
80 stratosphere and the NECV, potentially inducing the stratosphere-troposphere exchange of air mass. The overall impact of
the NECV-resulting mass exchange at the tropopause is the net import of O₃ from the stratosphere to the troposphere (Chen
et al., 2014a; Chen et al., 2014b). However, numerous existing studies on the cold vortex system focus on its causal factors
of formation and structure as well as its effects on precipitation and extreme weather (Fu et al., 2014; Gao and Gao, 2018;
Lian et al., 2016; Tao et al., 2023; Xue et al., 2021), the mechanism of the cold vortex in mid-high latitudes driving the
85 vertical cross-layer transport of stratospheric O₃ and the atmospheric environmental impact still lacks an unambiguous
insight in need of thorough investigation.

Therefore, this study targeted the SI event driven by a typical NECV observed over the NCP during May 19–20, 2019 to
investigate the mechanism of stratospheric O₃ intrusion affecting the atmospheric environment. Multi-source reanalysis data
and the Weather Research and Forecasting/Chemistry (WRF-Chem) with integrated process analysis (IPR) are jointly
90 applied to delve into the mechanism of the cold vortex system triggering SI and the SI effect degree on surface O₃. This
study aims to elucidate the mechanism of the vertical structure configuration of cold vortex systems in mid-high latitudes
driving O₃ cross-layer transport and quantify the influence on surface O₃, refining the systematic understanding of the
stratosphere-free troposphere-atmospheric boundary layer (ABL) transport of air pollutants with the application implication
for improving the response capabilities to in atmospheric environment change.

95 **2 Data and Methods**

2.1 Observational and reanalysis data

3-D meteorological data in this study were obtained from the 0.25° ERA5 reanalysis product (<https://apps.ecmwf.int/datasets/>) released by the European Centre for Medium-Range Weather Forecasts (ECWMF). According to previous studies, meteorological variables such as air temperature, wind, and humidity of ERA5 reanalysis data show good performance in both stratosphere and troposphere (Hersbach et al., 2020). The ground meteorological data were collected from 639 meteorological stations in the NCP and surrounding region from the China Meteorological Observation Network. The data of 3-D O₃ concentrations were provided by the Modern-Era Retrospective Analysis for Research and Applications version 2 (MERRA2, https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/data_access/) with a horizontal resolution of 0.5° × 0.625° and a temporal resolution of 3 hours, to characterize the vertical transport of the stratospheric O₃. The MERRA-2 data set assimilates TCO satellite retrievals from ozone monitoring instruments and stratospheric O₃ vertical profiles from microwave limb sounders after 2004 (Gelaro et al., 2017; Levelt et al., 2006; Waters et al., 2006). The MERRA2 O₃ enables the study of SI events because it is consistent well with ozonesondes and could realistically represent the temporal and spatial variations of O₃, especially in the lower stratosphere and near the tropopause (Wargan et al., 2015; Wargan et al., 2017). Hourly observed surface O₃ and CO concentrations retrieved from 440 observation sites of the National Air Quality Monitoring Network (<http://www.mee.gov.cn/>), with quality control based on China's National Standard of Air Quality Observation. To evaluate the reproducibility of the WRF-Chem simulations for the stratospheric O₃ intrusion, the portion (O₃S) of tropospheric O₃ concentrations originating from the stratosphere was applied to compare with our simulation results. The stratospheric tracer tagging method in global chemistry models was used to track the transport of stratospheric O₃ to the troposphere by releasing stratospheric tracers (Barth et al., 2012; Chang et al., 2023). The tracer was set to 1 above the tropopause, and only physically transported and chemically decayed in the troposphere without chemical productions (Chang et al., 2023; Ni et al., 2019). The O₃S in the troposphere was calculated by multiplying the concentrations of O₃ at the tropopause and the stratospheric tracers. The O₃S used in this study was obtained from the ECMWF Atmospheric Composition Reanalysis 4 (EAC4, <https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset>) reanalysis dataset with a spatial resolution of 0.75°, temporal resolution of 3 h, and vertical divided into 60 model layers from 1000 hPa to 1 hPa. The EAC4 dataset produces optimized atmospheric chemical reanalysis results by assimilating multiple observations of atmospheric components, and is widely used in the field of atmospheric environment (Inness, et al., 2019).

2.2 Modeling setup and configuration

The meteorology-chemical online coupled model WRF-Chem with IPR was applied in this study. WRF-Chem has been demonstrated to perform well in the simulation and analysis of SI cases (Chang et al., 2023; Ni et al., 2019; Zhao et al., 2021). The 5-day simulations covering three nested domains started on May 16, 2019, with horizontal resolutions of 81 km, 27 km, and 9 km, respectively. The initial and lateral boundary meteorological conditions at 6-hour intervals are derived

from ERA5 reanalysis data, and the Multi-resolution Emission Inventory of China (MEIC, <http://meicmodel.org/>) provided the anthropogenic emission data. The domain settings are presented in Fig. S1, and the physical and chemical parameterization schemes used in the simulations are listed in Table S1 in the Supplementary Material.

130 Since the stratospheric chemistry is not included in the WRF-Chem, an upper boundary condition (UBC) scheme derived from the Whole Atmosphere Community Climate Model was used to provide the initial and boundary chemical conditions for the stratosphere in the model (Barth et al., 2012). The UBC scheme could generate all key chemical species in the stratosphere, enabling the WRF-Chem to simulate the stratospheric intrusion processes more accurately (Barth et al., 2012; Lamarque et al., 2012; Zhao et al., 2021). To diagnose the impact of stratospheric O₃ on surface O₃ during the SI caused by
135 the cold vortex system, two simulation experiments were devised. The control experiment (CASE_{STRO3}), with the upper boundary conditions of stratospheric O₃ in WRF-Chem (Barth et al., 2012), was used to simulate the real meteorological and atmospheric chemical fields during the SI. The sensitivity experiment (CASE_{noSTRO3}) used identical physical and chemical configurations as in CASE_{STRO3}. The stratospheric O₃ of the UBC scheme in CASE_{noSTRO3} was turned off by setting O₃ concentrations to zero above the tropopause. The differences in O₃ simulation between the experiments CASE_{STRO3} and
140 CASE_{noSTRO3} are used to assess the quantitative effect of the stratospheric O₃ sources on surface O₃ in the SI event.

2.3 Modeling validation

The observed meteorological and chemical parameters, including air temperature at 2 m (T₂), wind speed at 10 m (WS₁₀), relative humidity at 2 m (RH₂), and O₃ concentrations, were used to assess the model performance in CASE_{STRO3} (Fig. S2). We calculated the averages of meteorological elements and O₃ concentrations observed at all stations in the innermost
145 domain and the averages of simulated meteorological elements and O₃ concentrations in the model grids corresponding to the station locations to conduct the modeling validation. It can be found that the simulated T₂, RH₂, and WS₁₀ generally agree well with the observations, the index of agreements (IOA) are 0.92, 0.99, and 0.90, respectively, and the correlation coefficients (R) are higher than 0.92, which all meet the usability criteria (Wei et al., 2019; Zhang et al., 2018). Hourly observed and simulated O₃ concentrations are shown in Fig. S2 (d). The R, MB (mean bias), RMSE (root mean square
150 errors), and IOA of O₃ are 0.88, -8.25 %, 14.37, and 0.90, respectively, indicating that our simulation reasonably reproduced the variations of O₃ in CASE_{STRO3}. In Fig. S3, the differences of simulated surface O₃ between CASE_{STRO3} and CASE_{noSTRO3}, which indicate the contribution of stratospheric O₃ to the near-surface atmosphere, were compared with the O₃S of EAC4 reanalysis data and concluded that the simulations roughly captured the temporal and spatial variations of stratospheric O₃ reaching the near-surface layer during the SI. All these evaluations indicate that our simulations performed well in
155 reproducing the variations of O₃ and meteorological parameters during the SI process.

3 Results and discussion

3.1 Vertical configuration triggers O₃ cross-layer transport

The tropopause identifies the top of the troposphere and marks a separation with the stratosphere in terms of both thermal structure and chemical composition. SI events are characterized by the downward transport of stratospheric O₃-rich air, coinciding with high PV and low humidity cross the tropopause into the troposphere (Ganguly, 2012). The height with PV equal to 2 is widely used to indicate the position of the dynamical tropopause at mid-latitudes (Holton et al., 1995). The tropopause over the NCP presented the obvious variation over May 18–20, 2019 (Fig. S4), especially the tropopause folding with the contour at PV = 2 curving extremely downwards to below 400 hPa over the NCP region on May 19, 2019 (Fig. S4b). Figure 1 shows the latitudinal- and meridional-vertical structures of the dynamical tropopause on May 19, 2019 over the NCP. The tropopause noticeably folded over the area of 110–120E° and 39–42N°, dropping down to 500–600 hPa. In the tropopause folding region, strong downdrafts penetrated from the lower stratosphere to the near-surface layer, and the strong vertical velocity reaching up to 0.2 m·s⁻¹ was inclined to drive the downward transport of the stratospheric O₃ to the troposphere (Fig. 1). Correspondingly, the vertical O₃ distribution presented a tongue pattern with the O₃ concentrations exceeding 200 ppb poured into the troposphere along with the dry and cold air from the stratosphere (Fig. S4b), which indicating the SI influencing O₃ in the ambient atmosphere.

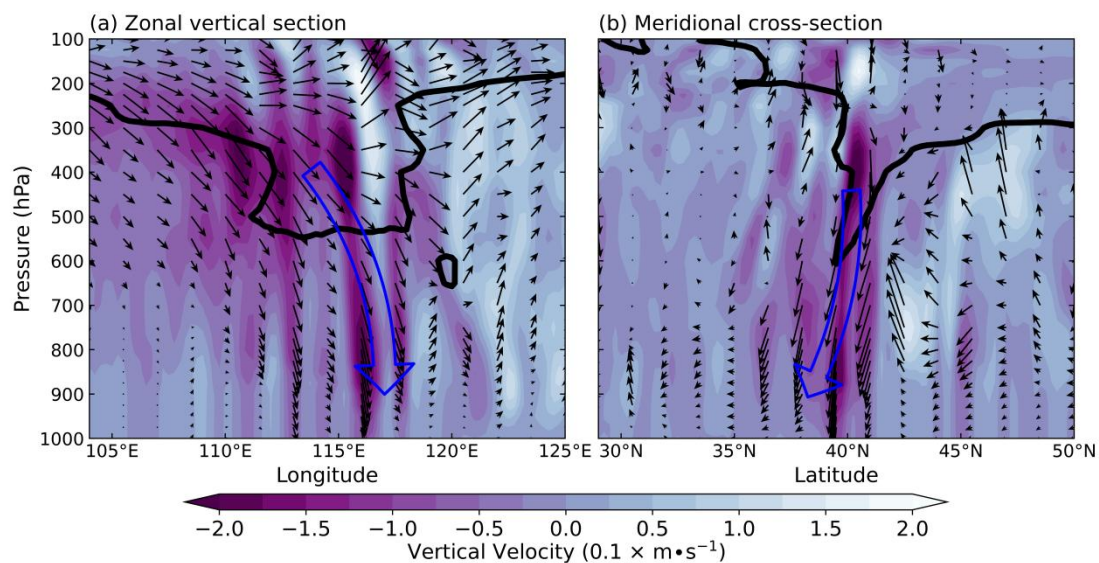

Figure 1: The vertical sections of the vertical velocity (color contours; $0.1 \times \text{m} \cdot \text{s}^{-1}$) and wind vectors of the components of U and V with $W \times 50$ from the ERA5 data averaged (a) over 32°N–40°N and (b) over 114°E–121°E in the NCP region on 19 May 2019. Black solid lines indicate the dynamical tropopause marked with the isolines at PV=2. The blue hollow arrows indicate the downdraft flows of SI in the troposphere.

Figures 2 (a–c) and S5 presented the upper, middle and lower tropospheric atmospheric circulations at 200 hPa, 500 hPa, and 850 hPa with the temporal variations during the NECV period. At 16:00 LST (Local Standard Time in 24-hour system) on May 18, 2019, the shallow troughs were located over 95–100E° in the subtropical westerly jets at 200 hPa and 500 hPa (Fig. S5). The subtropical westerly jet evolved from zonal to meridional patterns with the trough moving eastward and deepening

southward in the westerly wave fluctuations, and the prominently deepening troughs moved to the northern NCP on May 19 (Fig. 2a–b). The deepening troughs at the upper and middle troposphere at 200 hPa and 500 hPa were cut off forming the cyclonic cold vortex system—the NECV during May 19–20, 2019 (Figs. 2 and S5). The NCP was situated at the periphery of the NECV with the compensating downdrafts, which could drive the vertical transport down in the free troposphere (Fig. 2). Moreover, the NECV in the upper and middle troposphere induced the extratropical cyclone in the lower troposphere at 850 hPa on May 19, 2019, and the strong northwest horizontal wind prevailed behind the extratropical cyclone in the NCP (Fig. 2). On May 20, the NECV moved northeastwards and lost control of the NCP (Fig. S5). Figure 2d presents the section of the vertical velocity from the NCP to the center of the extratropical cyclone (red solid line in Fig. 2c) on May 19. The intense rising motions presented near the center of the NECV and the extratropical cyclone, ranging from the near-surface layer (1000 hPa) up to 100 hPa. The sinking branch of the vertical circulation of the cold vortex and the lower-tropospheric cyclone from the upper troposphere (200–400 hPa) to the near-surface layer was situated over the NCP (Fig. 2d), governing the downward transport of the stratospheric O₃ to the near-surface layer. Namely, the atmospheric circulation presented the vertical configuration in troposphere with upper westerly trough, middle NECV and lower extratropical cyclone. The downdraft branch of the system opened up a vertical transport channel from the lower stratosphere to the surface, allowing

stratospheric O₃ to invade the surface.

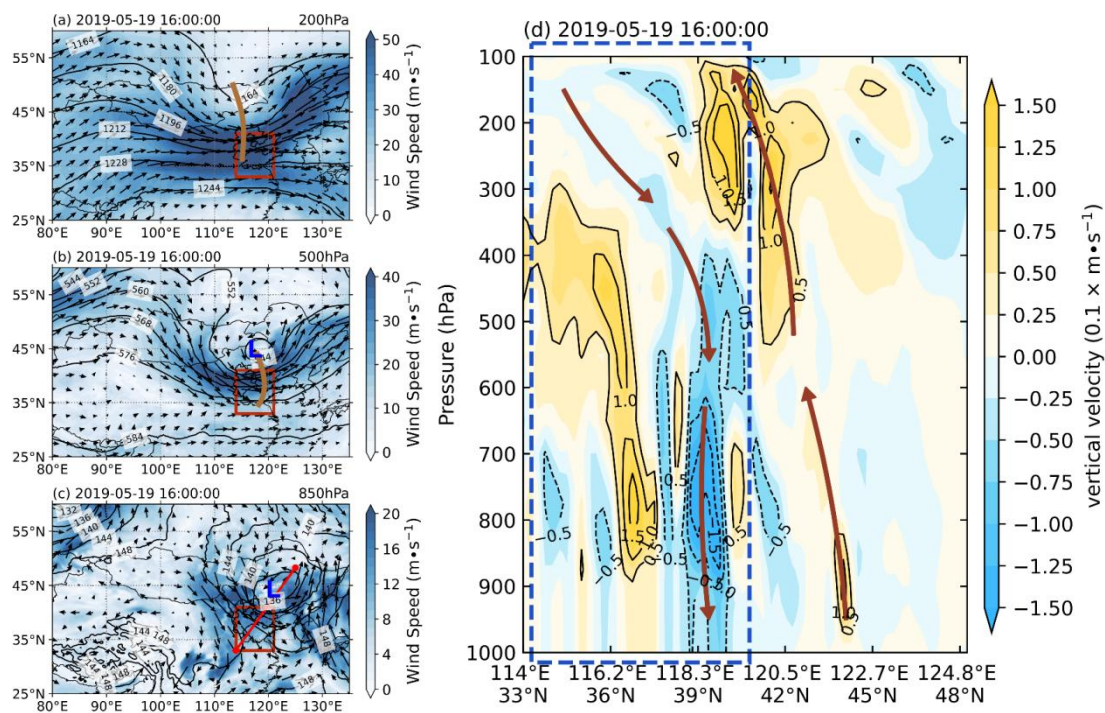

Figure 2: Atmospheric circulation patterns of horizontal wind vectors from the ERA5 data at (a) 200 hPa, (b) 500 hPa, and (c) 850 hPa with brown lines indicating the troughs in the westerlies, and (d) vertical cross sections of vertical velocity (color contours, $0.1 \times \text{m} \cdot \text{s}^{-1}$) along the red straight lines in (c) at 16:00 LST on May 19, 2019. The red solid boxes in (a–c) and the blue dotted box in (d) mark the NCP region. The solid red line in (c) is perpendicular to the northwest wind direction over the NCP region passing through the extratropical cyclone center at 850 hPa, and the brown lines with arrows in (d) indicating vertical transport directions between the lower stratosphere to the lower troposphere.

In the middle and lower troposphere, the downdrafts appeared over the northwest of the NCP and gradually reinforced with
205 the development of the cold vortex and the induced extratropical cyclone (Fig. 3). The mountain airflow on the lee slopes of
the plateau and mountains in western NCP could also contribute to strengthening the subsidence motion in the lower
troposphere (Ning et al., 2018). Strong downdrafts in the lower troposphere, combining with the high turbulent diffusion in
the convective boundary layer during the daytime, could forced the tongue plume with $O_3 > 150$ ppb to cross the boundary
layer top extending to the near-surface layer from 9:30 to 15:30 LST on May 19 (Figs. 3c and d). Horizontally, the strong
210 northwest wind at the rear of the NECV and near-surface cyclone induced the O_3 -rich tongue plume to bend from the
northwest to the southeast of the NCP (Figs. 2c and 3). Therefore, the stratospheric O_3 reached the surface of northwest NCP
in the morning, gradually drifted along the direction of the airflow, and then reached the southeast NCP at night on May 19,
2019 (Figs. 3c–e). In this vertical configuration of atmospheric circulations of "upper westerly trough-middle NECV-lower
extratropical cyclone" from the lower stratosphere to the near-surface layer (Fig. 2), the deep westerly trough with strong
215 vertical wind shear triggered the tropopause folded downward, which was expected to induce the O_3 -rich air mass in the
stratosphere to pour into the middle and upper troposphere (Figs. 2–3). Subsequently, the compensating downdrafts at the
periphery of the cold vortex circulation effectively transport the high concentrated O_3 from the upper troposphere
downwards to the lower troposphere. The descending branch of extratropical cyclone in the lower troposphere further
promoted the transport of stratospheric O_3 from the free troposphere to the ABL in the lower troposphere.

220

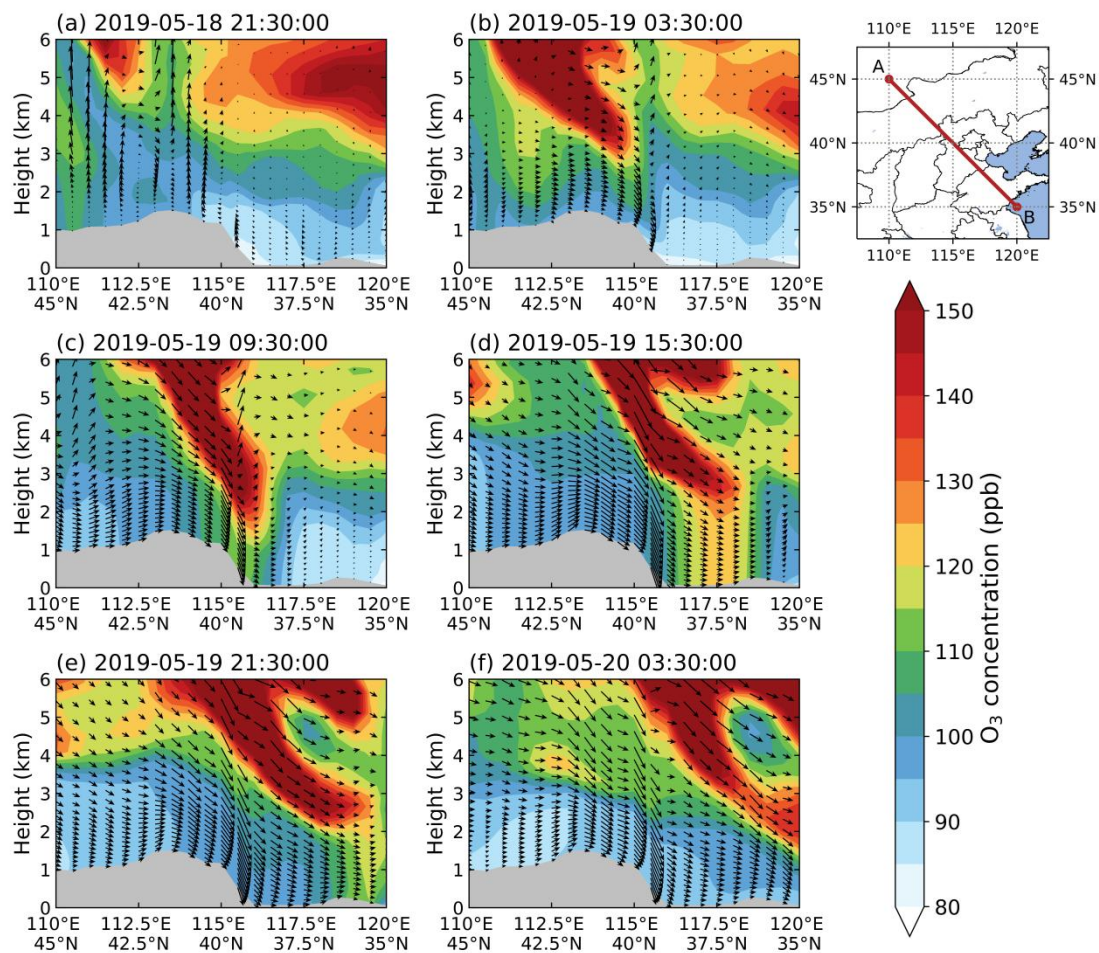

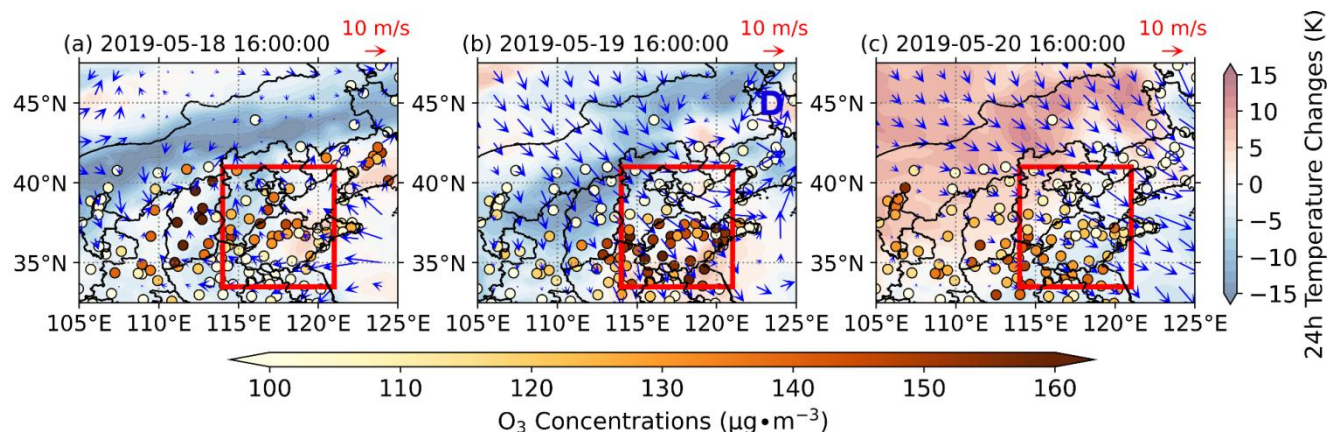

Figure 3: Vertical sections of O₃ concentrations (ppb) and composite wind vectors from the MERRA2 data along the line AB in the middle and lower troposphere over the NCP with the topography marked with gray areas. The line AB crosses the entire NCP along the northwest wind direction.

225 3.2 Impact of the SI on near-surface O₃

To investigate the impact of stratospheric O₃ on near-surface O₃ caused by the SI, the observed near-surface O₃ concentrations, the wind fields, and the 24-hour changes of air temperature at 950 hPa are shown in Fig. 4. Before the NECV formed on May 18, strong cold air was centered in the northeast-southwest zone in north China connecting with a slight cooling in the northwestern NCP, which was reflected by the 24-hour changes of air temperature at 950 hPa (Fig. 4a).

230 Meanwhile, a strong warm easterly airflow prevailed over the eastern and southern NCP with lower O₃ concentrations, and the high O₃ concentrations existed over the convergence zone between weak and strong easterly winds in the northwestern NCP region. With the NECV formation on May 19, the extratropical cyclone in the lower troposphere was activated in the northern NCP and the Northeast China, and the northwest airflows at the rear of cyclone pushed the cold air mass southeastwards and prompted high O₃ in the northwestern NCP to spread downstream (Fig. 4b). On May 20, the NCP region
 235 was beyond of NECV control with decreasing O₃ concentrations (Fig. 4c).

240 **Figure 4: Horizontal wind vectors and 24-hour changes of air temperature (shaded colors) at 950 hPa from the ERA5 data and the observed near-surface O₃ concentrations (color dots) at 16:00 LST on May (a) 18, (b) 19, and (c) 20, 2019. The red rectangles cover roughly the NCP region.**

Figure 5 shows the temporal variations of near-surface O₃ and CO concentrations and meteorological variables over the NCP. Due to the impact of cold air on the NCP, the rising air temperature required for the stronger photochemical reaction was not observed on May 19, 2019 (Fig. 5a). Precipitation in the NCP region could scavenge the O₃ precursors (Fig. 5a), which could modify the photochemical O₃ production (Sato et al., 2006; Yoo et al., 2014). Also, the dense cloud cover could reduce the solar radiation suppressing the O₃ production from photochemical reactions (Fig. 5b). Since the stratosphere is rich in O₃ and poor in CO, the homology between CO and O₃ is commonly regarded as an indicator to identify the source of O₃ (Moody et al., 1995; Parrish et al., 1998; Voulgarakis et al., 2011). The negative correlation between CO and O₃ implies that O₃ derived from the vertical downward STT. As can be found from Fig. 5c, with the formation of tropopause folding and the cold vortex on May 19 (Fig. S2), the regional CO concentrations in the NCP decreased rapidly, reaching nearly half of the initial level. Meanwhile, O₃ concentrations slightly increased. Remarkably, the opposite variations between CO and O₃ combined with the rapidly decreased T₂ and relative humidity (RH₂) could reflect the stratospheric O₃-rich air intrusion into the ground redistributing surface O₃ in the NCP region (Figs. 5a and c). In addition, triggered by the cold vortex in the upper and middle troposphere (Fig. 2), the extratropical cyclone dramatically increased the near-surface wind speed (WS₁₀) over the NCP (Fig. 5b), with the maximum regional averaged wind speed exceeding 7 m·s⁻¹. The strong northwest winds of the cyclone could enhanced the diffusion of O₃, which were beneficial to the decrease of local near-surface O₃ concentrations in the SI event.

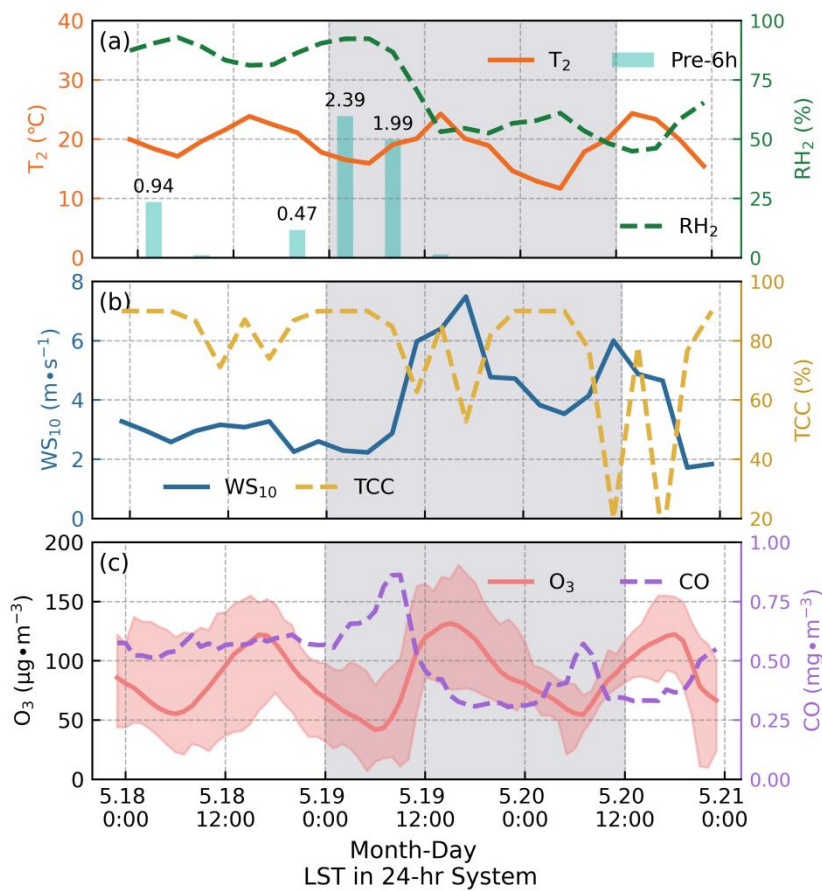

255 Although stratospheric O₃ intensely invaded the near-surface over the NCP region, the near-surface O₃ was strongly diffused downstream by the northwest wind. Meanwhile, the horizontal diffusion also prevented O₃ from the stratosphere from accumulating over the NCP (Figs. 2a–c and Fig. 4). Also, the routine ground observations cannot distinguish whether O₃ comes from the stratosphere or local generation. However, the near-surface O₃ observed on May 19 was slightly higher than
 260 the previous day under such facilitated diffusion conditions (Fig. 5c), which proves that the SI exerted additional contributions on the near-surface O₃ over the NCP region. Additionally, the changes in observed meteorological and environmental elements from the representative sites SJZ and JN in the NCP (The red dots in Fig. S3) were examined in Fig.

S6. The results showed the distinct characteristics compared with the regional averages that the diurnal cycles of O_3 concentrations were disturbed with the O_3 peaks by the SI event. The SJZ in the northwest NCP received stratospheric O_3 earlier and reached the spike at 10:00 LST on May 19. Then the O_3 concentrations gradually decreased under the influence of strong winds but still maintained a high level in the early morning of May 20. The JN in the southeast NCP was affected by the stratospheric intrusion later. While under meteorological conditions conducive to the dissipation of pollutants (wind speed up to $8 \text{ m}\cdot\text{s}^{-1}$), higher O_3 concentrations than the previous day were still observed, reflecting the additional contribution of stratosphere intrusion to near-surface O_3 .

265

270 Overall, the vertical configuration of 1) The abnormal disturbance of the subtropical westerly jet induced a deep westerly trough between lower stratosphere and upper troposphere, and the strong downdrafts on the south side of the trough triggered the tropopause folding, allowing stratospheric O_3 to invade into the upper and middle troposphere (Blackmon et al., 1977). 2) The deepening troughs were cut off forming the cold vortex in the upper and middle troposphere, the sinking branch of the cold vortex vertical circulation driven stratospheric O_3 to continue to be transported downward to the lower

275 troposphere. 3) The cold vortex excited an extratropical cyclone in the lower troposphere, and the compensating downdrafts on the periphery of the cyclone could pushed O_3 from the stratosphere to invade the near-surface, which could be a mechanism of stratospheric O_3 intrusion affect the atmospheric environment in the following study.

280 **Figure 5: Temporal variations of regionally averaged (a) T_2 , accumulated precipitation of 6 hours (Pre-6h, units: mm), RH_2 , (b) WS_{10} , and total cloud cover (TCC), (c) near-surface O_3 and CO concentrations from the observations in the NCP region. The**

shaded areas mark the periods of the SI to the near-surface layer.

Quantification of the influence of NECV-driven SI on near-surface O_3 is crucial to deepen the understanding of SI process in O_3 pollution. To quantify the contribution of stratospheric O_3 to the near-surface layer during the SI event, we adopted the
 285 WRF-Chem model with IPR. The IPR can be used to quantitatively analyze the contributions of physical and chemical processes to O_3 . Five principal processes are considered in WRF-Chem, including subgrid convection (CONV), chemical conversion (CHEM), vertical mixing (VMIX), horizontal advection (ADVH), and vertical advection (ADVZ) (Yang et al., 2022). The ADVH and the ADVZ are caused by the delivery of horizontal and vertical winds, and the ADVZ can be used to characterize the intrusion of the stratospheric O_3 into the ABL.

290

Figure 6: Temporal variations of contributions of atmospheric physical and chemical processes to O_3 from the simulation CASE_{STRO3} in the ABL in representative cities SJZ and JN in the NCP during the SI event.

In this study, we selected two sites of SJZ and JN (the red dots in Fig. S3) respectively in the northern and southern NCP as
 295 representatives to analyze the results of IPR (Fig. 6). It is noteworthy that the ADVH and ADVZ presented the generally reverse contributions in complementary ways, and the positive ADVZ contributions dominated the enhancements of near-surface O_3 , indicating the vertical O_3 transport of the SI associated with the extratropical cyclone induced by the NECV (Figs. 3–6). The compensating subsidence branch of the extratropical cyclone further drove the stratospheric O_3 across the top of the ABL to the near-surface layer, which is reflected with significant positive contributions of ADVZ to O_3 within the
 300 ABL in SJZ and JN. Especially in the early morning of May 20, the contribution of ADVZ to JN peaked at 38.3 $ppb \cdot h^{-1}$ (Fig. 6). However, the negative ADVH contributions reflected the diffusion of O_3 by the intense horizontal winds in the cyclone system. Even at the beginning of SI, the negative effects of ADVH to O_3 were greater than the positive effects of ADVZ. Compared with the vertical transport of O_3 by the ADVZ process, the horizontal O_3 transport driven by ADVH occurred

earlier, which further demonstrated that the extratropical cyclone formed first and then drove the O₃ originating from
305 stratosphere to penetrate the top of ABL downward to the near-surface layer.

The simulation results provided evidence that the surface extratropical cyclone excited by the NECV delivered
stratospheric O₃ downward to the near-surface layer increasing the near-surface O₃ concentrations, while the extratropical
cyclone caused atmospheric horizontal motions that removed the local O₃. Namely, although the intrusion of stratospheric O₃
has the potential to augment surface O₃ levels, rapid dispersion and removal facilitated by the peripheral horizontal winds of
310 the cyclone mitigated this impact. Therefore, the strong intrusion of stratospheric O₃ into the near-surface layer during the SI
process without surface O₃ concentrations exceeding the hourly standard of O₃ pollution of 200 μg·m⁻³ over the NCP (Fig.
5c). Furthermore, SJZ received stratospheric O₃ in the near-surface layer earlier than JN, and the surface stratospheric O₃ in
these two sites peaked in the morning and evening on May 19, respectively (Figs. 6c and i). This phenomenon confirmed the
results in Section 3.1 that stratospheric O₃ injected into the near-surface layer in the northern NCP, and then the northwest
315 wind of the cyclone drove the O₃ to drift southeastern downstream.

3.3 Contribution of stratospheric O₃ from SI to NCP

In this section, the simulations of the control experiment CASE_{STRO3} and the sensitivity experiment CASE_{noSTRO3} with the
model WRF-Chem were applied to examine the atmospheric environmental effects of the stratospheric O₃ with the
quantitative assessment of the contribution of stratospheric O₃ from the SI event. Since stratospheric O₃ was turned off in the
320 simulation of CASE_{noSTRO3}, the impact of the stratospheric O₃ during the SI event to the tropospheric O₃ could be assessed
with the differences in chemical simulations between CASE_{STRO3} and CASE_{noSTRO3}. Figure 7 illustrated the temporal lag
changes of difference peaks in the vertical O₃ transport contributions to O₃ concentrations in the vertical altitude layers of
12–16km, 2–12km, to 0–2km to shed some light on the SI of stratospheric O₃ contributions from the lower stratosphere
through the upper and middle troposphere into the lower troposphere including the ABL. During the SI event, the vertical O₃
325 transport contributions peaked in the lower stratosphere (12–16km) at 00:00 LST on May 19, about 9 hours late in the upper
and middle troposphere (2–12km), and further 12 hour late in the lower troposphere (0–2km) influencing atmospheric
environment (Fig. 7). The appearance times of these three peaks were delayed with the decreasing heights, reflecting that the
SI occurrence could sequentially elevate the contributions of downward O₃ transport in the lower stratosphere, the free
troposphere, and the ABL in the vertical cross-layer transport process of stratospheric O₃ during the SI event.

330

Figure 7: The temporal variations of vertical transport rates of stratospheric O₃ (Δ ADVZ) in the vertical layers of 0–2 km (lower troposphere), 2–12 km (middle and upper troposphere), and 12–16 km (lower stratosphere) with the differences between CASE_{STRO3} and CASE_{noSTRO3} simulations with the WRF-Chem during May 18–20, 2019. The shaded area marks the SI period.

335 The relative contributions of stratospheric O₃ to near-surface O₃ were calculated with dividing the absolute contributions from the simulated near-surface O₃ differences between CASE_{STRO3} and CASE_{noSTRO3} by the surface O₃ concentrations simulated in CASE_{STRO3}. Figure 8 presents the temporal variations of the stratospheric O₃ contributions to the near-surface layer in major urban sites in the NCP. As can be found that the intrusion of stratospheric O₃ sharply raised the relative contributions of O₃ originating from the stratosphere in the northern part of NCP, the contribution of the stratospheric O₃ to

340 near-surface O₃ rapidly peaked at the beginning of the SI and then gradually decreased to about 20% under the diffusion of horizontal wind (Fig. 8). It means that although the horizontal diffusion caused no remarkable increment in observed O₃ over the NCP during this SI event (Fig. 5), stratospheric O₃ contributed a relatively high percentage to the near-surface atmospheric environment. The maximum contributions of stratospheric O₃ to near-surface O₃ in these major cities ranged from 43% to 58%, with the averaged contributions from 28% to 35% in this SI event (Fig. 8). On average, over the NCP

345 region, this SI event made the absolute contributions of 9.61 ppb to the near-surface O₃, accounting for 26.77% in the relative contribution. Compared with the others results, the stratospheric O₃ contribution in our study was lower, but the relative proportion was higher (Chang et al., 2023; Meng et al., 2022a; Meng et al., 2022b; Wang, H. et al., 2020), which could be related to the synoptic and atmospheric environmental conditions during cold vortex activity. Moreover, the peak moments of stratospheric O₃ contributions are delayed from north to south, reflecting the northwest wind of horizontal

350 circulation induced the downward stratospheric O₃ tongue to bend from northeast to southwest.

删除[罗哈哈 haha]: and the peak moments of stratospheric O₃ contributions delayed from north to south.

删除[罗哈哈 haha]: d

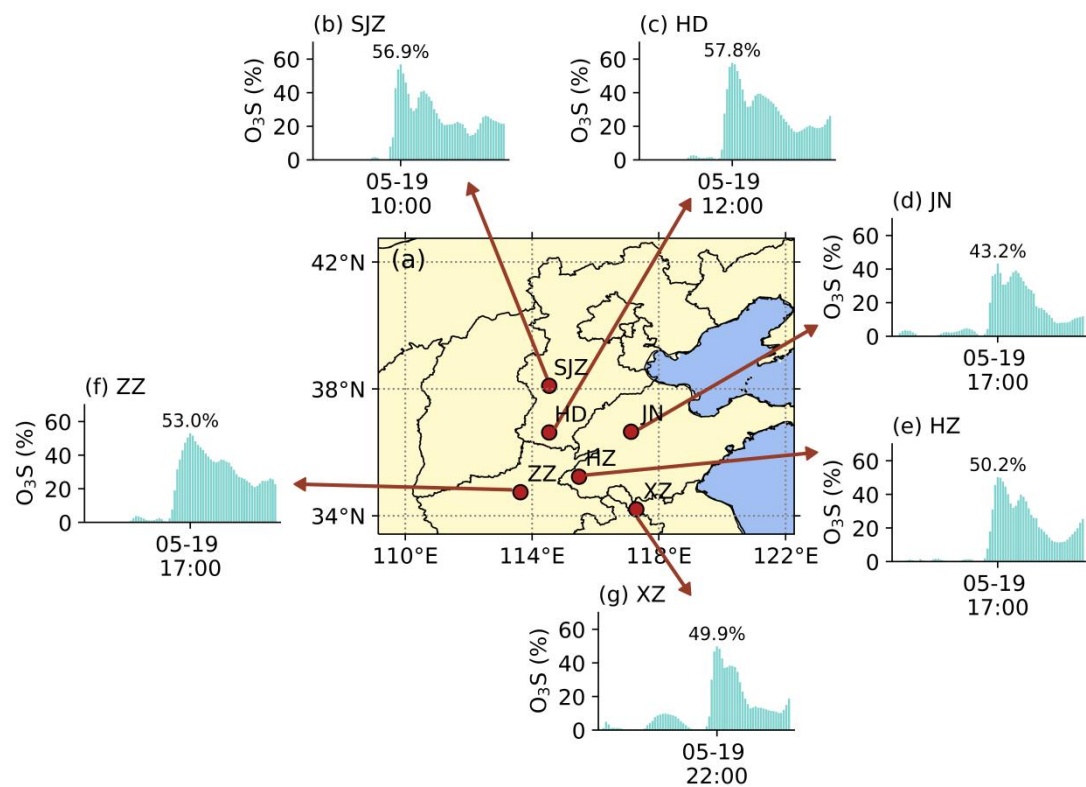

Figure 8: Temporal variations of the simulated contribution of stratospheric O₃ to near-surface O₃ in the urban sites SJZ, HD, JN, HZ, ZZ, and XZ over the NCP. The values annotated on the bars are the maximum contributions of the stratospheric O₃ occurring at the moments (month-day / hour: minute) marked on the x-axis.

4 Conclusions

The SI events could trigger the transport of O₃ from the stratosphere to the free troposphere. The SIs frequently happens around the subtropical westerlies, and the cold vortexes regulating weather and climate in mid-high latitudes are closely related to the westerly development. However, the mechanism of SI effects on the atmospheric environment with the cross-layer transport of O₃ from the stratosphere, the free troposphere to the atmospheric boundary layer has not been elucidated thoroughly. In this study, a SI process triggered by a typical cold vortex over North China was taken as an example to deeply investigate the driving mechanism of the vertical structure configuration of atmospheric circulation in the mid-high latitudes on the cross-layer transport of stratospheric O₃ to the near-surface atmosphere, and to quantify the impact of SI on the near-surface O₃ with jointly adopting the multi-source reanalysis and observation data of meteorology and environment and the numerical modeling of regional air quality.

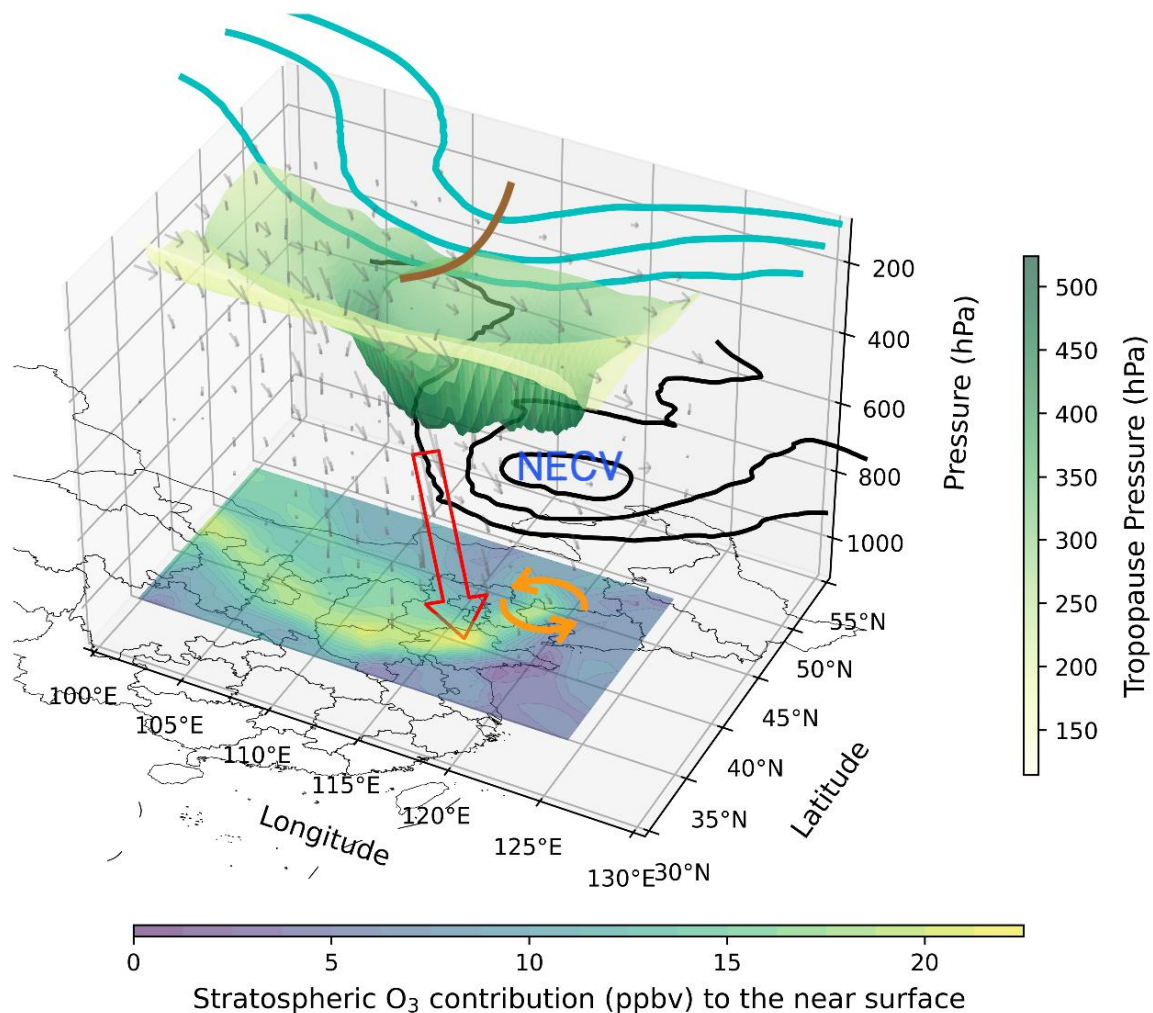

Figure 9: Conceptual diagram of the downward O₃ transport (red arrow) of SI to near-surface layer driven by the vertical configuration of "upper westerly trough-middle NECV-lower extratropical cyclone" in the troposphere. The upper 3D surface indicates the folded tropopause in the vertical air pressures, the green and black solid lines represent the westerly trough and NECV with the geopotential height contours of 200 hPa and 500 hPa in the upper and middle troposphere, respectively. The orange cycle arrows indicate the extratropical cyclone in the lower troposphere. The shaded colors on the surface indicate the stratospheric O₃ contribution to the near-surface (ppb).

This study revealed a mechanism of stratospheric O₃ intrusion into the tropospheric based on a case study of North China.

370 The SI with downward transport of stratospheric O₃ to near-surface layer was driven by an extratropical cyclone system with the vertical coupling of "upper westerly trough-middle NECV-lower extratropical cyclone" in the troposphere (Fig. 9). At first, the disturbances in the westerly jet stream aroused a deep trough in the lower stratosphere and upper troposphere. The vertical shear of the jet stream on the south side of the trough caused broad-scale subsidence, then induced the tropopause folding down to 500–600hPa. The O₃-rich air from the lower stratosphere penetrated the folded tropopause into the upper and middle troposphere. As the upper trough moved eastwards and deepened southward, the westerly trough was cut off in the upper and middle troposphere, forming a typical cold vortex NECV in northern China. The compensating downdrafts of the NECV pushed the stratospheric O₃ in the upper and middle troposphere to further downward transport. Simultaneously, the NECV in the upper and middle troposphere activated an extratropical cyclone in the lower troposphere, and the downdraft on the periphery of the vertical cyclonic circulation governed the stratospheric O₃ from the free troposphere to

385 break through the boundary layer top invading the near-surface atmosphere.

Based on the simulation experiments, we quantified the contribution of stratospheric O₃ to near-surface O₃ during the SI process. The stratospheric O₃ intrusions were strengthened sequentially in the lower stratosphere, middle and upper troposphere, and lower troposphere through vertical transport, reflecting that the stratospheric O₃ was indeed progressively transported downwards from the lower stratosphere to the lower troposphere influencing the atmospheric environment. In
390 this SI event, the average contribution of stratospheric O₃ to near-surface O₃ was 9.61 ppb over the NCP region, accounting for 26.77% in near-surface O₃ levels.

Our study illustrated the meteorological mechanism of vertical transport of stratospheric O₃ into the near-surface atmosphere driven by an extratropical cyclone system, improving the understanding of the influence of stratospheric O₃ on the atmospheric environment. The findings have significant implications for a comprehensive understanding of the cross-layer
395 transport of air pollutants on the coordinated control of atmospheric pollution complex. The study on the mechanism of stratospheric O₃ intrusion into the atmospheric environment will be conducted with climatic analysis of long-term observations of meteorology and environment combined with fine simulations of atmospheric chemical and physical processes, to generalize the meteorological mechanism of stratospheric O₃ intrusion with climatology of stratospheric O₃ contribution to atmospheric environment change.
