Abstract. Studies on CO₂ effects on coccolithophores, unicellular calcifying phytoplankton, show species-specific responses, although only less than 5% of the ~280 living species have been tested so far. *Helicosphaera carteri* significantly contributes to carbon fluxes and CaCO₃ storage due to its size and high calcite production. Despite its importance, few studies have examined *H. carteri* under experimental conditions, and only one has addressed the effects of rising CO₂/decreasing pH. Being *H. carteri* a large-sized, obligated calcifier species, an important aspect to understand is how changes in seawater carbonate chemistry may affect its morphology. It has already been suggested for other coccolithophores species, that the presence of malformed coccoliths may represent a disadvantage for these organisms. Moreover, an alteration in coccolith morphology may affect their contribution to CaCO₃ sedimentation and ballasting. As for *H. carteri*, it has also been suggested that due to its high PIC:POC ratio, the species could show a high sensitivity to CO₂ rise. In this study, we investigate for the first time whether high pCO₂/low pH does affect the morphology of *H. carteri* coccoliths, by culturing this species under pre-industrial CO₂ levels (~295 µatm) and ~600 µatm, i.e., the SSP 2-4.5 scenario for 2100 (IPCC, 2021). We also analyzed cellular PIC and POC quotas using morphometric data, roundness, and protoplast and coccosphere size to observe the pCO₂ influence on the calcification and photosynthesis ratio.

Our results indicate that *H. carteri* morphology is not significantly affected by increasing CO₂, in contrast to other heavily calcified species. The protoplast volume and coccosphere shape of *Helicosphaera carteri* did not vary with changes in CO₂, and neither did its particulate inorganic carbon (PIC) and particulate organic carbon (POC) quotas, nor the PIC:POC ratio, indicating unaltered physiological state.

The low PIC:POC ratio found in this work for *H. carteri* compared to ratios previously measured in the same strain under different experimental conditions, and compared to other highly-calcified species, could explain the observed low sensitivity of *H. carteri* to CO₂. Moreover, the observation of a stable ratio between calcification and photosynthesis in *H. carteri* under

increasing CO₂ might suggest a constant contribution to the rain ratio under climate change. However, further studies comparing experimental and field data from past ocean acidification events will be required to confirm the conclusions drawn here.

1 Introduction

Since the industrial revolution, human activities have led to a rapid increase in atmospheric CO₂ concentration. A large amount of this emitted CO₂ (~30%) is absorbed by the oceans (Canadell et al., 2007; Sabine et al., 2004), causing a significant imbalance in the ocean chemistry, which is moving more and more towards lower pH values (IPCC, 2021).

To date, several studies have focused on the effects of seawater carbonate chemistry on calcifying organisms, including coccolithophores (e.g., D’Amario et al., 2020; Dong et al., 2023; Gattuso et al., 1998; Gazeau et al., 2024; Jokiel et al., 2008; Keul et al., 2013; Langdon et al., 2000; Riebesell et al., 2000; Ries et al., 2011), and different and sometimes contrasting evidence have been collected for this group (e.g., Iglesias-Rodriguez et al., 2008; Kroeker et al., 2013; Langer et al., 2006; Meyer & Riebesell, 2015; Raven & Crawford, 2012; Riebesell et al., 2000). Up to now, these studies have also demonstrated that to predict the responses of this group of calcifying microalgae, the consideration of different species, and even strains (Langer et al., 2009) is required. Indeed, while at the beginning, most of the efforts have been focused on common and easy-to-grow species, such as *Emiliania huxleyi* and *Gephyrocapsa oceanica*, in the last two decades, many studies have also focused on other species, like *Calcidiscus leptoporus*, *Calcidiscus quadriperforatus*, *Coccolithus pelagicus* subsp. *braarudii* and *Scyphosphaera apsteinii* (e.g., Diner et al., 2015; Fiorini et al., 2011; Gafar et al., 2019a, b; Krug et al., 2011; Langer et al., 2006; Langer and Bode, 2011). The latter species are characterized by lower abundances compared to *E. huxleyi*, but nevertheless play an important role in coccolithophore CaCO₃ production in modern oceans (Baumann et al., 2004; Daniels et al., 2014, 2016; Gafar et al., 2019b; Menschel et al., 2016; Ziveri et al., 2007).

Another low-abundant but highly contributing to CaCO₃ production is *Helicosphaera carteri* that is considered one of the main contributors to carbon (C) export and storage into deep-sea sediments (Ziveri et al., 2007), thanks to its large size and higher rates of organic C fixation and calcite production, compared to smaller species (García-Romero et al., 2017; Menschel et al., 2016; Rigual Hernández et al., 2020; Young & Ziveri, 2000). Indeed, while *E. huxleyi* produces between ~6 and ~20 pg cell⁻¹ day⁻¹ of calcite, *H. carteri* produces between ~80 and ~120 pg cell⁻¹ day⁻¹ of calcite (De Bodt et al., 2010; Langer et al., 2009; Šupraha et al., 2015).

Helicosphaera carteri is generally considered to be a species typical of warm waters (e.g., Baumann et al., 2005; Brand, 1994), with moderately high-nutrient levels (e.g., Andruleit and Rogalla, 2002; Findlay and Giraudeau, 2000, 2002; Ziveri et al., 1995, 2004). However, it has a general wide distribution (as reported in the CASCADE database; de Vries et al., 2024) and it seems to be an opportunistic species, easily adaptable to different environmental conditions (Dimiza et al., 2014 and references therein). This adaptability of *H. carteri* is confirmed by its long fossil record, spanning back more than 20 Million years (Aubry, 1988; Young, 1998).

Despite its relevant role, only a few studies have been conducted on living *H. carteri* under experimental conditions (e.g., Sheward et al., 2017; Šupraha et al., 2015; Šupraha and Henderiks, 2020) and only one of them considered the effects of CO₂ increase on this species (Le Guevel et al., 2024). To assess the potential effects of CO₂ increasing/pH lowering on coccolithophores, it is fundamental to study not only changes in calcite production, but also in coccolith morphology, as previously suggested by Langer et al. (2011). Both calcite production and coccospheres are beneficial for coccolithophores in terms of eco-physiology and evolution (e.g., Henriksen et al., 2003; Langer et al., 2021; Monteiro et al., 2016; Walker et al., 2018). Coccoliths morphology represents a key factor in their ecology (Bown et al., 2004; Young, 1994) and the inhibition or alteration of coccolithophores' ability to calcify can be detrimental for most of the species belonging to this group, as demonstrated by Walker et al. (2018) for *C. braarudii*. Previous studies have also shown that increasing CO₂/decreasing pH can strongly affect coccolithogenesis and coccolith morphology, especially when considering species bearing big-sized and heavily-calcified coccoliths, with a possible detrimental influence on the ability of these organisms to face future climate changes (Diner et al., 2015; Kottmeier et al., 2022; Langer et al., 2006; Langer and Bode, 2011).

Given the importance of *H. carteri*'s role in the C cycle, we investigate here for the first time whether rising pCO₂ does affect coccolith morphology in this species by analyzing the presence of malformations in *H. carteri* cultures grown under pre-industrial CO₂ levels (~290 µatm) and ~600 µatm i.e., scenario SSP 2-4.5 for 2100 (IPCC, 2021). Additionally, we analyze variations in cellular particulate organic (POC), and inorganic (PIC) carbon using morphometric data (e.g., protoplast size, number of coccoliths per coccosphere, coccolith length) and investigate the variations in protoplast and coccosphere size and roundness (RD).

2 Materials and methods

2.1 Experimental setting and chemical analyses

Monospecific cultures of *Helicosphaera carteri* (strain RCC1323, from Southern Benguela upwelling area of South Atlantic from Roscoff Culture Collection) were grown in natural sterile-filtered seawater collected in the Gulf of Trieste (northern Adriatic Sea, Italy), filtered through 0.22 µm pore size Durapore membrane filters (Millipore) and autoclaved, and enriched with vitamins, nutrients, and trace elements following the B medium recipe (<https://cosmi.ogs.it/node/7>). Culture experiments were performed at the National Institute of Oceanography and Applied Geophysics (OGS) in Trieste using the dilute batch culture method (Langer et al., 2013) and keeping constant salinity (35 PSU), temperature (19°C), light irradiance (100 µmol m⁻² s⁻¹), light/dark cycle (12:12 hours) under two different levels of CO₂ (295 and 600 µatm) in 2.5L photobioreactors (Kbiotech) controlled by the BioFlex software. A pitched-blade impeller at 100 rpm rotational speed ensured the culture agitation. Before starting the experiments at different CO₂ levels, the strain was acclimated for ca. 11 generations to the selected CO₂ concentration. Both experiments were run in triplicate. All the experiments were terminated in the exponential phase at low cell density (ca. 10,000 cell mL⁻¹), i.e., in dilute batch mode, corresponding to 6 or 7 days from the inoculation.

To calculate the pH values corresponding to the two selected carbon dioxide concentrations, Total Alkalinity (TA) was measured before starting the experiments. Then, inserting TA, temperature, salinity, phosphate, and silicate data in the CO2SYS program (Lewis and Wallace, 1998), using the constants of Mehrbach et al. (1973) refitted by Dickson and Millero (1987), we identified a pH of 8.18 for 295 μatm , and 7.81 for 600 μatm . The pH was maintained constant for the entire duration of the experiments by CO₂ injection into the headspace or by adding NaOH (1M) in the culture through an automated peristaltic pump controlled by the BioFlex software. The pH was measured with a sensor (Hamilton PHI 225; sensitivity 57-59 mV; frequency of measurements 10 seconds) inserted within the photobioreactor.

To better characterize the carbonate system and the equilibrium among the parameters involved, Dissolved Inorganic Carbon (DIC) and Total Alkalinity (TA) were measured in two replicas on the final day of the experiment as follows.

For DIC analysis, the culture was filtered through pre-combusted 0.7 μm nominal pore size glass fiber filters (Whatman GF/F), and two samples of 50 mL were collected minimizing gas exchange with the atmosphere, and then poisoned with mercuric chloride (HgCl₂) solution in order to prevent biological activity. Samples were stored refrigerated until analyzed.

DIC was determined using the Shimadzu TOC-V CSH analyzer (Shimadzu Corporation, Japan). For DIC, samples were injected into the instrument port and directly acidified with phosphoric acid (25%). Phosphoric acidification for DIC and combustion conducted at 680°C, generated CO₂ that was carried to a non-dispersive infrared detector (NDIR). The variation coefficient of the analyses was <2%; and the reproducibility of the method ranged between 1.5 and 3%. Typical OA scenarios do not feature decreasing DIC concentrations. In our experiment the lowest DIC is ca. 1400 μM (high CO₂, low pH) and the highest ca. 1700 μM (low CO₂, high pH, Table 1). Despite this atypical CO₂-DIC combination for OA scenarios the latter does not undermine the suitability of our experimental setup because DIC is not the parameter of the C-system affecting coccolithophores in typical OA studies (Bach et al., 2011; Hoppe et al., 2011; Langer and Bode, 2011). Only under DIC concentrations below ca. 1000 μM , DIC and/or bicarbonate ion concentration might play a role too (Buitenhuis, 1999). The parameters of the C-system that will have affected *H. carteri* most likely are either pH or CO₂ (Bach et al., 2011; Langer and Bode, 2011); a possible but unlikely candidate is carbonate ion concentration. All three parameters fall within the range of typical OA studies (e.g., Bach et al., 2011; Hoppe et al., 2011; Kottmeier et al., 2022; Johnson et al., 2022; Langer et al., 2009; Langer and Bode, 2011; Milner et al., 2016; Zondervan et al., 2002). Therefore, our experimental setup is suitable for our purpose.

For the TA, 100 mL of culture were filtered through pre-combusted 0.7 μm nominal pore size glass fiber filters (Whatman GF/F), poisoned with 100 μL of saturated mercuric chloride (HgCl₂) to halt the biological activity, and stored in acid-washed borosilicate flasks at 4°C. TA was measured by potentiometric titration in an open cell (SOP 3b, Dickson et al., 2007) utilizing a non-linear least squares approach. The titration was conducted with the Mettler Toledo G20 titration unit interfaced with a computer, using the LabX data-acquisition software. After titration, data were processed and the TA was calculated using a computer program developed at OGS and adapted to work in association with the Mettler Toledo LabX software and similar to that listed in SOP 3 of DOE (Dickson and Goyet, 1994). The HCl titrant solution (0.1 mol kg⁻¹) was prepared in NaCl background, to approximate the ionic strength of the samples, and was calibrated using certified reference

seawater (CRM, Batch #107, provided by A.G. Dickson, Scripps Institution of Oceanography, USA). Accuracy and precision of the TA measurements on CRM were determined to be less than $\pm 2.0 \mu\text{mol kg}^{-1}$.

The final carbonate system was calculated from temperature, salinity, TA, pH (NBS), phosphate and silicate, using the
 135 CO2SYS program (Lewis and Wallace, 1998), with the same constants mentioned above. The data for the carbonate system are reported in Table 1.

Parameter	Exp. 295	Exp. 600
CO ₂ (μatm)	294.6	601.5
SD	17.84	59.74
CO ₂ ($\mu\text{mol/kg}$)	9.78	19.94
SD	0.59	1.98
HCO ₃ ⁻ ($\mu\text{mol/kg}$)	1413.49	1213.70
SD	106.02	144.50
CO ₃ ²⁻ ($\mu\text{mol/kg}$)	141.44	51.72
SD	16.62	13.38
DIC ($\mu\text{mol/kg}$)	1677.50	1374.72
SD	140.87	142.03
TA (mmol/kg^{-1})	1853.82	1452.54
SD	166.93	146.41
pH NBS	8.18	7.81
SD	0.025	0.064
Ω calcite	3.38	1.24
SD	0.40	0.32

Table 1. Parameters of the carbonate system. In black are the values obtained from the CO2SYS program; in blue are the average

140 values directly measured in duplicates per each replica of both the experiments. The average pH values are derived from the whole
data collected in continuum along the experiments (pH standard deviation 0.01). SD= Standard Deviation.

2.2 Morphological analyses

145 *Helicosphaera carteri* coccospheres were collected from triplicate cultures and filtered on cellulose acetate filters (\varnothing 25 mm
pore \varnothing 0.45 μ m) for subsequent analyses at the Scanning Electron Microscope (SEM). Filters were dried at 30°C for 24
hours. The filters were mounted using carbon tapes on SEM stubs, and then sputter-coated with gold-palladium using the
Emitech K550X/K250 C cathodic metallizer. Analyses at SEM were conducted with a Zeiss Merlin at the Microscopy and
X-ray Diffraction Service of the Universitat Autònoma de Barcelona.

150 After a preliminary observation of the samples, we subdivided the morphologies of *H. carteri* coccoliths in two main
categories: normal and malformed (Fig. 1). At the SEM we observed that the malformations occurring in *H. carteri*
coccoliths are often characterized by underdevelopment or abnormal development of the flange (Fig. 1c, d). Sometimes, the
malformation is also represented by coccoliths presenting a "wavy" shape (Fig. 1c, d). Per sample at least 100 coccoliths
were counted, for a total of ~300 coccoliths per experiment (Table 2).

Figure 1. Scanning electron micrographs of *Helicosphaera carteri* coccoliths. (a, b) normal (c, d) malformed. Scale bars are 2 μ m.

2.3 Morphometric analyses

2.3.1 Coccosphere measurements and PIC calculation

160 On the last day of each experiment, 1mL of culture was collected and combined with 4 μ L of Formalin for coccosphere morphometric analysis. Coccosphere size (\emptyset), aspect ratio ($AR_{\text{coccosphere}}$) and roundness ($RD_{\text{coccosphere}}$) data were obtained by photographing more than 50 coccospheres per each replicate using an inverted microscope Leica CMS-D35578 at 400x magnification and a Leica Camera Ltd CH-9435. The images were processed with ImageJ software (Rueden et al., 2017; Appendix A Fig. A1) using a customized macro (<https://github.com/mbordiga/Coccoliths>). The estimated standard error of
165 the mean are 0.1219 for \emptyset , 0.006119 for $AR_{\text{coccosphere}}$ and 0.004549 for $RD_{\text{coccosphere}}$ at 295 μ atm; while at 600 μ atm are: for 0.1233 \emptyset , 0.006399 for $AR_{\text{coccosphere}}$ and 0.004781 for $RD_{\text{coccosphere}}$. Since AR and RD are based on the ratio between major and minor axes of the coccosphere and/or the protoplast, they are considered dimensionless. Hence, the unit for these parameters is not reported.

$AR_{\text{coccosphere}}$ and $RD_{\text{coccosphere}}$ were strongly correlated (-0.99, p-value <0.0001); therefore, only RD data have been discussed
170 in this work. RD values closer to 1 indicate a more circular shape (for details see Appendix A Table A1).

The cellular particulate inorganic carbon (cellular PIC) of *H. carteri* was estimated from coccosphere geometry data, following Young and Ziveri (2000):

$$\frac{PIC[pg]}{cell} = C_N \times C_L^3 \times K_s \times \rho \times \left(\frac{M_C}{M_{CaCO_3}} \right), \quad (1)$$

175

Where C_N is the number of coccoliths per coccosphere, C_L is the coccolith length (μ m), k_s is the mean species-specific dimensionless shape factor (0.05 for *H. carteri*; Young and Ziveri, 2000), ρ is the calcite density (2.7 pg μ m³) and $\frac{M_C}{M_{CaCO_3}}$ is the molar mass ratio of C and CaCO₃ (0.12).

The number of coccoliths per cell (C_N) was determined from the samples previously used for counting malformed coccoliths
180 (see Sect. 2.2). At least 50 photographs of coccospheres were captured using the SEM and the number of coccoliths per cell was estimated by visually counting the visible ones and assuming they represent 75% of the total (as demonstrated for *E. huxleyi* in Hoffmann et al., 2015).

The averages data used for the calculation and the number of individuals analyzed are reported in the Appendix (Appendix A Table A1).

185 For single coccolith measurements, additional culture samples were obtained by treating 25 mL of culture with 25 mL of a Triton (1%) and 20 microL bleach solution to separate them from the cell (see Šupraha and Henderiks, 2020).

Part of the obtained pellet was then added to a solution of distilled water buffer with ammonia (1L distilled water + 30 mL of 25% ammonia solution). A small amount of this suspension was subsequently pipetted onto a round glass coverslip (\emptyset 13 mm) and dried on a hot plate at 60°C. The coverslip was then mounted on SEM stubs (\emptyset 25 mm) using a carbon disc. To

190 increase the sample's conductivity, four aluminum bridges connecting the coverslip to the edge of the stubs were added in each sample. The samples were then sputter-coated with platinum and analyzed using the Tescan Mira3XMU SEM of the Department of Earth and environmental Sciences at the University of Pavia (CISRIC-Arvedi Laboratory). Unfortunately, due to an alteration in the preservation state of the material, it was not possible to analyze the third replicate of both experiments. For the remaining samples, at least 100 coccoliths were photographed and measured using ImageJ software (Rueden et al., 195 2017) for a total of 409 coccoliths (Appendix A Table A1). Statistical analyses (unpaired t-tests) have been performed for \emptyset and $RD_{\text{coccosphere}}$ using GraphPad Prism (version 9.05 for MacOS; GraphPad Software, Inc., USA).

2.3.2 Protoplast measurements and POC calculation

200 *Helicosphaera carteri* cellular POC was estimated from protoplast size, following Menden-Deuer and Lessard (2000):

$$\frac{POC [pg]}{cell} = a \times V_{cell}^b, \quad (2)$$

Where V_{cell}^b is the protoplast volume, and a and b are constants depending on the considered species (in this case: $a=0.216$ and $b=0.939$; Menden-Deuer and Lessard, 2000). Protoplast volume in μm was calculated as $V_{cell} = (\pi/6)d^2h$, where d and h represent the short and the long-axes cell diameters in μm (Sun and Liu, 2003).

The V_{cell} was obtained by measuring cells from culture samples collected at the T_{final} of each experiment. 4 mL of culture samples were fixed with acidic Lugol solution (40 μL) which dissolves the coccoliths while preserving the protoplast for subsequent measurements. Protoplast size (Θ) data were obtained by analyzing at least 50 photos (collected at the inverted microscope) per sample, with ImageJ software (Rueden et al., 2017) using a custom-made macro (<https://github.com/mbordiga/Coccoliths>; Supplementary materials).

With the same macro, data about protoplast aspect ratio ($AR_{\text{protoplast}}$) and roundness ($RD_{\text{protoplast}}$), were obtained. As for the coccosphere, due to the high correlation between RD and AR , only data about cellular roundness were reported in this work. 215 The averages of the data used for the calculation and the number of individuals analyzed are provided in the Appendix (Appendix A Table A1).

Changes in Θ and $RD_{\text{protoplast}}$ have been compared using an unpaired t-test on GraphPad Prism (version 9.05 for MacOS; GraphPad Software, Inc., USA).

3 Results

3.1 Coccolith morphology

The analyses at the SEM reveal a non-significant change (t-test p value >0.05) in the proportion of malformed coccoliths moving from ~295 to 600 μatm of CO_2 . However, while at the lower pCO_2 , the species shows almost no malformations (0.66±0.58%) in the second treatment the malformed coccoliths account for an average of 10.65±10.82% (Table 2, Fig. 2).

The percentage of malformed coccoliths at 600 μatm is characterized by a high standard deviation (SD). On the contrary, at 295 μatm , SD is quite low in all the considered categories (Table 2).

None of the observed samples shows extremely malformed coccoliths. A rough estimation of the number of collapsed coccospheres per sample indicates a percentage far below 1%. Therefore, a specific count for this category has not been performed, because it is not meaningful. The saturation state of seawater with respect to calcite (Ω_{calcite}), was lower at 600 μatm than at pre-industrial CO_2 levels. However, the values were always >1, indicating that the system was never

undersaturated, indeed no dissolution was detected (Table 1).

Experiment	CO_2 [μatm]	Normal	Malformed	Total nr. of counted coccoliths
1	295	99.34	0.66	304
SD		2.08	0.58	
2	600	89.35	10.65	316
SD		13.87	10.82	

Table 2. Percentages of counted coccoliths at the two different CO_2 concentrations. Data reported are averages of three replicates. SD = Standard Deviation.

Figure 2. Percentages (%) of normal and malformed coccoliths of *H. carteri*. Values reported represent the averages of the three replicates. Error bars show standard deviation.

3.2 Coccosphere and protoplast geometry

Cellular POC returns an average of 108.14 ± 5.42 pg cell⁻¹ at 295 µatm and 118.51 ± 6.41 pg cell⁻¹ at 600 µatm of CO₂, with an unpaired t-test showing no significant change between CO₂ levels (t-test p value > 0.05; Table 3). A non-significant change is also observed in cellular PIC and in the PIC:POC ratio, showing an average value of 151.86 ± 4.23 pg cell⁻¹ at 295 µatm and 149.47 ± 9.49 cell⁻¹ at 600 µatm of CO₂ (t-test p value > 0.05; Table 3) and of 1.37 ± 0.072 at 295 µatm and 1.27 ± 0.013 at 600 µatm of CO₂, respectively (t-test p value > 0.05; Table 3).

Helicosphaera carteri protoplast (0.90 ± 0.02 and 0.90 ± 0.01 at 295 µatm and 600 µatm, respectively) and coccosphere (0.89 ± 0.02 and 0.88 ± 0.003 at 295 µatm and 600 µatm, respectively) roundness does not show any significant variation with increasing CO₂ (t-test p value > 0.05), indicating the maintenance of a constant shape at different CO₂ levels (Fig. 3a, b; Appendix A Table A1). No changes have been detected for protoplast (11.45 ± 0.19 µm at 295 µatm and 11.81 ± 0.27 µm at 600 µatm; t-test p value > 0.05; Fig. 3c; Appendix A Table A1) and coccosphere size (18.18 ± 0.25 µm and 17.92 ± 0.66 at 295 µatm and 600 µatm, respectively; t-test p value > 0.05; Fig. 3d; Appendix A Table A1).

CO ₂ [µatm]	295	600	p value
---------------------------	-----	-----	---------

CO ₂ [μatm]		295	600	p value
PIC [pg cell ⁻¹]	Mean	151.86	149.47	0.7755
	SD	4.23	9.49	
POC [pg cell ⁻¹]	Mean	108.14	118.51	0.1000
	SD	5.42	6.41	
PIC:POC		1.37	1.27	0.09595
	SD	0.072	0.013	

Table 3. Data of *H. carteri* cellular PIC and POC obtained from geometry data. Values reported are averages of the replicates. SD = Standard Deviation.

4 Discussion

4.1 Morphology in *H. carteri* in response to CO₂ increase

260 In the recent years, several studies have focused on coccolithophores' responses under increasing CO₂ levels, demonstrating that different species, and often different strains of the same species, exhibit a specific at times contrasting response to seawater carbonate chemistry (e.g., Bach et al., 2015; Diner et al., 2015; Langer et al., 2006, 2009, 2011; Langer and Bode, 2011; Müller et al., 2015). These non-uniform results have highlighted the need to analyze the CO₂ influence on both coccolithophore species and strains to better predict the whole group reaction to future climate change.

To evaluate the coccolithophore response under high CO₂, a key but sometimes neglected parameters are the degree of coccolith malformation and data on morphometrics. To date, few studies have evaluated coccolith morphology (i.e., normal, malformed, or incomplete coccoliths) under seawater carbonate chemistry changes not only in a qualitative way, but also in a quantitative way (e.g., Bach et al., 2011, 2012; De Bodt et al., 2010; Diner et al., 2015; Kottmeier et al., 2022; Langer et al., 2006, 2011), but none of them considered the species *H. carteri*. Coccolith morphology is central to ecological and evolutionary success of coccolithophores and is often more telling than calcite production when questions concern the 270 biology, as opposed to the biogeochemistry, of these algae (Henriksen et al., 2003; Langer et al., 2011, 2021; Walker et al., 2018).

In this work, for the first time, we show that the percentage of malformed coccoliths in *H. carteri* does not change in a significant way moving from 295 to 600 μatm of CO₂. However, when comparing our findings for *H. carteri* with previous works conducted on other species, it is evident that for most species and strains the percentage of malformed coccoliths at 275 CO₂ levels similar to 295 μatm ($\pm 100 \mu\text{atm}$) is higher (Fig. 4a, b). Specifically, a greater percentage of malformed coccoliths (considering all the categories defined by the authors) was observed in six different strains of *E. huxleyi* (RCC1238, RCC1216, RCC 1256, RCC1212, B92/11, AC481), four strains of *C. leptoporus* (AC365, RCC1135, RCC1141, RCC1168), and one strain (AC400) of *C. pelagicus* (Fig. 4 a, b).

Here we will briefly discuss an issue that distinguishes C-system experiments from other standard culture experiments, 280 namely the fact that the C-system is not one single parameter but multiple (see Table 1), as opposed to experiments studying the effects of temperature for instance. Different methods for changing the C-system are available, i.e., DIC manipulation, TA manipulation, and combined TA-DIC manipulation (Hoppe et al., 2011; Langer and Bode, 2011). Only the latter method allows for an identification of the parameter of the C-system affecting organisms (Langer and Bode, 2011). Very few studies have used this method, and it was found that CO₂ and pH are parameters of the C-system that affect coccolithophores in 285 typical OA studies (Bach et al., 2011; Langer and Bode, 2011). Here we used DIC manipulation resulting in a so-called coupled C-system, as opposed to the decoupled C-system obtainable only in combined TA-DIC manipulation experiments.

A coupled C-system features correlations between pH, CO₂, and CO₃²⁻. It is therefore not possible to distinguish e.g., pH and CO₂ effects. Please note that when we discuss “CO₂ effects” we do not literally mean CO₂ effects but coupled C-system effects. We have decided to use the shorthand “CO₂ effects” because it is common in the literature to do so. Using the strictly correct expression C-system effects has the disadvantage of decreasing readability substantially because a typical phrasing such as “C-system increase/decrease” does not make sense, whereas it does make sense if a single parameter is used as a stand-in for the whole C-system.

When considering responses to CO₂ levels close to 600 µatm, the percentages of malformed coccoliths in *E. huxleyi* (RCC1238 and RCC1256) are lower than *H. carteri* (Fig. 4a, c). In contrast, *E. huxleyi* (B92/11) and the heavily calcified species *C. leptoporus* (RCC1168) and *C. quadriperforatus* (RCC1141) consistently show a higher percentage of malformed coccoliths compared to *H. carteri* (~60-90%, Fig. 4a, c). Today *C. leptoporus* and *C. quadriperforatus* are mostly considered separate species (<https://roscoff-culture-collection.org/rcc-strain-details/1141>), although some authors prefer to consider *quadriperforatus* a sub-species (<https://www.mikrotax.org/>; Young et al., 2022). For a detailed discussion of the taxonomical status of *Calcidiscus* see Geisen et al. (2004).

The comparison of malformations in different strains/species at one single CO₂ level is instructive but not sufficient to assess C-system effects. Malformations in coccolithophores vary both between strains/species and over time in a single strain under constant environmental conditions (Langer et al., 2009; 2013; Langer and Benner, 2009). A better assessment of C-system effects on coccolithophores is achieved when comparing trends of different experiments rather than absolute values of different experiments (Hoppe et al., 2011). Such a comparison clearly suggests species specific responses to CO₂, identifying more/less sensitive species (Fig. 4b, c; Diner et al., 2015; Hoppe et al., 2011; Langer et al., 2006, 2011; Langer and Bode, 2011). We are thus confident in saying that the strains RCC1238 and RCC1256 of *E. huxleyi* and RCC1323 of *H. carteri* are less sensitive to acidification than *E. huxleyi* B92/11 and *Calcidiscus*.

However, it is important to note that different authors have observed varying responses among different strains of both *E. huxleyi* and *C. leptoporus*, indicating the absence of a uniform species-specific behavior, potentially linked to genotypic diversity (see Diner et al., 2015; Langer et al., 2009). These diverse responses could be identified in *H. carteri* too. Therefore, additional studies considering different strains of *H. carteri* will be required to identify if our evidence is strain-specific or it can be extended to species level.

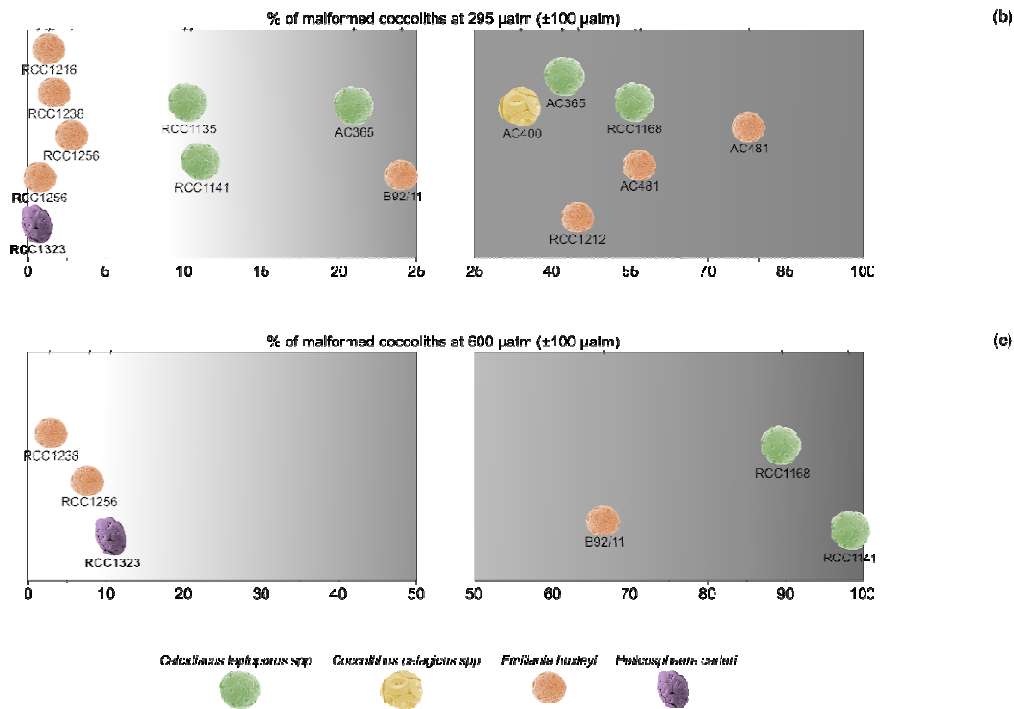

Figure 4. a) Percentages of malformed coccoliths in *H. carteri* (in bold; this work) compared to other species (from literature) at CO₂ levels close to 295 μatm (±100 μatm) and 600 μatm (±100 μatm). “Other” includes other categories used by the authors, such as fragmented coccoliths or incomplete coccoliths without malformations. b-c) Distribution of the considered strains according to a gradient of increasing percentage of malformation at 295 μatm (b) and 600 μatm (c). Different scales have been used. Cocosphere photos are modified from Nannotax.org. Data for comparison include *E. huxleyi* RCC1216, RCC1238, RCC1256 and RCC1212 from Langer et al. (2011); *C. leptoporus* RCC1141 and *C. quadriperforatus* RCC1168 from Diner et al. (2015); *E. huxleyi* AC481

from De Bodt et al. (2010); *C. leptoporus* RCC1135 from Langer and Bode (2011); *C. leptoporus* AC365 and *C. pelagicus* AC400 from Langer et al. (2006); *E. huxleyi* B92/11 from Bach et al. (2011).

4.2 *Helicosphaera carteri* sensitivity towards CO₂ increase

325 Studies on coccosphere and protoplast geometry (e.g., Θ , C_L , C_N) of *H. carteri* strain RCC1323 have been conducted before (Le Guevel et al., 2024; Sheward et al., 2017; Šupraha et al., 2015). However, none of these studies considered the variations in protoplast or coccosphere shapes. In this study, we show for the first time the absence of any significant variation in $RD_{\text{protoplast}}$ and $RD_{\text{coccosphere}}$ with increasing CO₂ (Fig. 3a, b). These results could indicate that the species shape does not depend on CO₂ concentrations. Daily observation of the living culture under a light microscope showed in both CO₂ treatments that *H. carteri* remained in a good condition, with good motility of the cells. These observations combined with the lack of a CO₂ effect on roundness and the small effect on coccolith morphology point to a weak sensitivity of *H. carteri* to seawater acidification/CO₂ increase (Figs. 2, 3a, b).

335 In our study, we also examined the variations in the protoplast and coccosphere geometry (C_N , C_L , coccosphere and protoplast size) in response to an increase in CO₂, observing no significant changes from 295 to 600 μatm (Fig. 3, Appendix A Table A1). Since *H. carteri* Θ , C_L and C_N did not change between our experiments, the cellular POC and PIC content and PIC:POC ratio did not show any substantial variation with increasing CO₂ (Fig. 3c, d; Table 3, Appendix A Table A1).

The maintenance of a stable PIC:POC ratio in the same *H. carteri* strain and at similar CO₂ levels (300 μatm and 600 μatm) has recently been observed also by Le Guevel et al. (2024) (Fig. 5), who also recorded a slight increase in the coccosphere size within this CO₂ range (+0.69 μm from 200 to 600 μatm). These authors grew the species under even higher CO₂ levels, recording a decrease in coccosphere size (-1.05 μm) moving from 600 μatm to 1400 μatm of CO₂. However, this decrease in coccosphere size with increasing CO₂/decreasing pH was not associated with a significant trend in the PIC:POC ratio (Le Guevel et al., 2024).

345 Similar results were documented also in the fossil record by Šupraha and Henderiks (2020), who estimated the PIC:POC ratio for the genus *Helicosphaera* over the last 15 million years (Myr) from the lateral cross-sectional aspect ratio of a coccolith (AR_L), following McClelland et al. (2016). These authors documented a stable PIC:POC ratio of this genus along with a reduction of coccolith (and coccosphere) size in response to the global decreasing trend in CO₂, which ranged from ~350–500 ppm during the Middle Miocene to ~200 ppm in the Pleistocene (Herbert et al., 2016; Sosdian et al., 2018; Super et al., 2018; Zachos et al., 2001; Zhang et al., 2013). Šupraha and Henderiks (2020) attributed the lack of change in the ratio between calcification and photosynthesis to the obligate calcifier nature of the genus *Helicosphaera*.

350 Some coccolithophores such as *Coccolithus braarudii* are obligate calcifiers, i.e., they need to calcify, whereas others such as *Emiliania huxleyi* are facultative calcifiers, i.e., they do not necessarily need to calcify (Walker et al., 2018). As per our own observation, and the extensive observational record available at the RCC Roscoff (<https://roscoff-culture->

collection.org/; I. Probert, personal communication) *H. carteri* is an obligate calcifier which might imply a stable PIC/POC ratio because a complete coccosphere is essential for survival (Šupraha and Henderiks, 2020; Walker et al., 2018).

355 The obligate calcifier-nature of *Helicosphaera* represented by the maintenance of a stable PIC:POC observed both under experimental conditions; (this work, Le Guevel et al., 2024) and in the fossil record (Šupraha and Henderiks, 2020), could represent an advantage in future oceans where the species could stabilize the future C-cycle despite changes in CO₂ concentrations. However, to confirm this hypothesis, studies on fossil material deposited during paleo-analogues of future CO₂ rise above 600 μ atm are required. Reconstructing different coccolithophore species' PIC:POC ratio during past climate events is, indeed, a fundamental tool to better predict their response also to future climate changes. Unfortunately, the chances to find entirely preserved coccospheres in the fossil record is relatively low (Henderiks et al., 2008). Thus, combining culture studies on PIC:POC estimates from coccosphere, protoplast, AR, and coccolith measurements with observations conducted on fossil coccoliths represents a key tool for investigating the species-specific contribution to the organic C fixation and calcite production in the fossil record, improving our knowledge on the inorganic *versus* organic C balance in the oceans.

With regard to the relationships between PIC:POC ratio and CO₂ sensitivity of different species and strains one of the most significant and consistent evidence is that coccolithophore species with a higher PIC:POC ratio such as *C. leptoporus* (2.08) and *G. oceanica* (1.25) should be more sensitive to increasing CO₂ compared to species with lower average PIC:POC ratio such as *E. huxleyi* (0.67), *Syracosphaera pulchra* (0.19), and *Umbilicosphaera sibogae* (0.62; Gafar et al., 2019b). The latter authors hypothesize that a high PIC/POC ratio produces a high cellular proton load that is particularly harmful under Ocean Acidification conditions. More recently a cellular mechanism underpinning the hypothesis of Gafar et al. (2019b) was proposed (Kottmeier et al., 2022). This cellular mechanism involves Hv-type plasma-membrane proton channels which close under Ocean Acidification conditions therewith preventing proton export out of the cell with cytosolic acidification ensuing. The low sensitivity of species with lower PIC:POC ratio, like *E. huxleyi*, is confirmed by the comparison in Figure 4b, c, where *E. huxleyi* appears more resilient in terms of malformations to increasing CO₂ levels, compared to both *H. carteri* and *C. leptoporus*. As for *H. carteri* RCC1323, the range of PIC:POC ratio considered by Gafar et al. (2019b), based on data from Šupraha et al. (2015), spans from 2.29 to 2.30, thus a relatively high ratio leading to a first inference that this strain may be highly sensitive to CO₂ increase. However, recent data about *H. carteri* PIC:POC ratio documented a lower PIC:POC values for this strain (1.27-1.37 ratio this work; ~1.4-1.6 ratio Le Guevel et al., 2024) (Fig. 5). The identification of a lower PIC:POC ratio for *H. carteri* RCC1323 (average ratio 1.8) could explain our data documenting a low sensitivity of this strain to increasing CO₂, compared to *C. leptoporus* (average ratio 2.08) and *C. quadriperforatus* (average ratio 2.01) (see Sect. 4.1; Diner et al., 2015; Gafar et al., 2019b).

However, in the literature there are sometimes contrasting results on coccolithophore sensitivity towards CO₂ in relation to the PIC:POC ratio. Langer et al. (2009), while testing different strains of *E. huxleyi* grown under varying seawater chemistry conditions, documented that the strain with the highest PIC:POC ratio (RCC1216; maximum PIC:POC value 1.2) exhibited the highest percentage of normal coccoliths, corresponding to a low sensitivity towards higher CO₂. The most likely

explanation for these observations is that the PIC:POC ratio is not a sufficient predictor for the strain's sensitivity to increased CO₂. For instance, genetic factors, as suggested by Diner et al. (2015) and Langer et al. (2009), may play a significant role. This once again underscores the importance of analyzing different species and strains and under varying experimental conditions.

Figure 5. Comparison of coccosphere size and PIC:POC ratio of *H. carteri* under increasing CO₂, measured in this work and in Le Guevel et al. (2024).

5. Conclusions

Based on our findings, we can conclude that:

1. *Helicosphaera carteri*, exposed to pre-industrial CO₂ levels and 600µatm of CO₂, shows a low sensitivity to rising CO₂, as inferred from protoplast and coccosphere roundness, and chiefly from coccolith morphology.
2. The low sensitivity of *H. carteri* to high CO₂ is contrasted with the relatively high sensitivity of *Calcidiscus*. An explanation for this surprising species specificity might be the low PIC:POC of *H. carteri* determined here.
3. The PIC:POC ratio of *H. carteri* does not change with changing CO₂ suggesting a constant contribution of this species to the rain ratio under ocean acidification.
