31 **Abstract**

32       Supersaturation is crucial in cloud physics, determining aerosol activation and influencing cloud  
33 droplet size distributions, yet its measurement remains challenging and poorly constrained. This study  
34 proposes a theoretical framework to simultaneously observe critical activation diameter and  
35 hygroscopicity of activated aerosols through direct measurements of scattering and water induced  
36 scattering enhancement of interstitial and activated aerosols, enabling effective supersaturation  
37 measurements. Advanced optical systems based on this framework allows minute- to second-level  
38 effective supersaturation measurements, capturing fluctuations vital to cloud microphysics. Although  
39 currently limited to clouds with supersaturations below  $\sim 0.2\%$  due to small scattering signals from  
40 sub-100 nm aerosols, advancements in optical sensors could extend its applicability. Its suitability for  
41 long-term measurements allows for climatological studies of fogs and mountain clouds. When  
42 equipped with aerial vehicles, the system could also measure aloft clouds. Therefore, the proposed  
43 theory serving a valuable way for both short-term and long-term cloud microphysics and aerosol-cloud  
44 interaction studies.

## 59 1. Introduction

60 Clouds and fogs play critical roles in weather patterns and climate change, influencing both  
61 precipitation and the radiative balance of the Earth's atmosphere. As such, they are central to accurate  
62 weather and climate predictions. ~~Despite their importance, representing clouds accurately in~~  
63 ~~atmospheric models remains a significant challenge (Seinfeld et al., 2016).~~ Despite their importance,  
64 representing clouds accurately in atmospheric models remains a significant challenge (Seinfeld and  
65 Pandis, 2016) . Supersaturation, defined as the difference between the actual water vapor pressure ( $e$ )  
66 and the saturation vapor pressure ( $e_s$ ) which is typically expressed as a dimensionless quantity  
67  $(e - e_s)/e_s$ , is a key parameter that links aerosols to clouds through the process of aerosol activation,  
68 making it fundamental to cloud physics (Seinfeld and Pandis, 2016). Despite its importance,  
69 supersaturation is difficult to measure and remains poorly understood and constrained (Yang et al.,  
70 2019). Previous studies have highlighted that other than the mean supersaturation, supersaturation  
71 fluctuations also play critical roles in aerosol activation and cloud droplet growth, ultimately  
72 influencing the evolution of cloud droplet size distributions (Kaufman and Tanré, 1994;Sardina et al.,  
73 2015;Chandrakar et al., 2018;Chandrakar et al., 2020;Shaw et al., 2020). For instance, cloud chamber  
74 experiments have shown that supersaturation fluctuations promote aerosol activation and enhance  
75 aerosol activity (Shawon et al., 2021;Anderson et al., 2023), particularly when the magnitude of these  
76 fluctuations is comparable to the mean supersaturation (Prabhakaran et al., 2020). Both experimental  
77 and theoretical analyses suggest that supersaturation fluctuations can broaden cloud droplet size  
78 distributions (Chandrakar et al., 2016;Abade et al., 2018;Saito et al., 2019).

79 Supersaturation fluctuations arise not only from turbulent variations in the temperature and vapor  
80 pressure fields but also from the growth and evaporation of droplets, which drive mass and heat  
81 exchange between droplets and the surrounding air. ~~Field measurements have demonstrated that the~~  
82 ~~supersaturation is indeed a fluctuating quantity (Ditas et al., 2012;Siebert and Shaw, 2017).~~ ~~However,~~  
83 ~~as~~ As noted by Shaw et al. (2020), measuring supersaturation remains a formidable challenge due to  
84 its extreme sensitivity to variations in ~~e and temperature.~~ water vapor pressure and temperature.  
85 Although current techniques of water vapor and temperature measurements could not achieve  
86 accurately measurements of supersaturation, however, direct measurements of water vapor pressure  
87 and temperature were previously used to estimate supersaturation fluctuations, and obtained results  
88 have demonstrated that the supersaturation is indeed a fluctuating quantity (Ditas et al., 2012;Siebert  
89 and Shaw, 2017).. Currently, cloud and fog supersaturation are typically retrieved from aerosol  
90 activation measurements (Ditas et al., 2012) or estimated from vertical velocity measurements (~~Siebert~~

---

91 ~~and Shaw, 2017). Direct measurements of water vapor pressure and temperature are generally used to~~  
92 ~~estimate supersaturation fluctuations but do not provide precise direct supersaturation measurements~~  
93 ~~(Ditas et al., 2012; Siebert and Shaw, 2017).~~ and droplet size distribution measurements (Siebert and  
94 Shaw, 2017; Cooper, 1989). Supersaturation parameterizations based on vertical velocity are common  
95 in models (Abdul-Razzak et al., 1998), while field measurements often rely on aerosol activation data  
96 to investigate supersaturation fluctuations and evolutions in clouds and fogs (Ditas et al.,  
97 2012; Hammer et al., 2014; Shen et al., 2018; Mazoyer et al., 2019; Zíková et al., 2020; Wainwright et  
98 al., 2021; Kuang et al., 2024). In addition, supersaturations were also estimated using the closure  
99 between cloud droplet number and cloud condensation nuclei (CCN) measurements at various  
100 supersaturations (Yum et al., 1998; Sanchez et al., 2016; Sanchez et al., 2021; Saliba et al., 2023).

101 In summary, direct measurements of water vapor pressure and temperature are essential for  
102 quantifying supersaturations; however, they are nearly impossible with current technologies.  
103 Supersaturation measurements from aerosol and cloud microphysics monitoring often reflect an  
104 effective supersaturation that drives aerosol activation, which is indeed critical in cloud physics. The  
105 complexity of cloud formation and evolution and the central role of supersaturation in these processes  
106 underscore the need for precise measurement and representation of supersaturation. Advancements in  
107 measuring and understanding supersaturation are essential for improving the accuracy of models and  
108 reducing uncertainties in weather and climate predictions. In this study, we propose a theoretical  
109 framework for using optical methods to observe effective supersaturations based on aerosol activation  
110 in clouds and preliminarily validated utilizing data obtained from field campaigns. The feasibility of  
111 employing an advanced optical system to measure supersaturation fluctuations were also explored and  
112 discussed.

## 113 2. Methods and Materials

### 114 2.1 Observing effective supersaturations on the basis of $\kappa$ -Köhler theory

115 ~~Fluctuations~~ The concept of effective supersaturation was introduced based on aerosol activation  
116 measurements (Hudson and Yum, 1997; Hudson et al., 2010), which could be defined as the  
117 supersaturation in CCN chamber (CCN activation under constant supersaturation ~~mean~~ conditions) that  
118 resulted in the same aerosol activation fraction with the observed aerosol activation fraction in clouds.  
119 Quick fluctuations in supersaturation would result in the effective supersaturation, which directly  
120 ~~affects~~ determined by aerosol activation, differs from the mean supersaturation. ~~The~~ which is  
121 determined by average water vapor content and temperature. However, the concept of  $\kappa$ -Köhler theory

is established according to a constant supersaturation scenario, therefore provides a framework for deriving effective supersaturation from aerosol activation measurements in clouds (Petters and Kreidenweis, 2007):

$$S = \frac{D^3 - D_a^3}{D^3 - D_a^3(1 - \kappa)} \cdot \exp\left(\frac{4\sigma_{s/a} \cdot M_{water}}{R \cdot T \cdot D_p \cdot g \cdot \rho_w}\right) \quad (1)$$

where  $S$  is the saturation ratio,  $S - 1$  represents supersaturation,  $D$  is the over an aqueous solution droplet with a diameter of  $D$ ,  $D_a$  is the dry diameter,  $\sigma_{s/a}$  is the surface tension of solution/air interface,  $T$  is the temperature,  $M_{water}$  is the molecular weight of water,  $R$  is the universal gas constant,  $\rho_w$  is the density of water, and  $\kappa$  is the hygroscopicity parameter. The  $\kappa$ -Köhler theory tells that if the critical diameter of aerosol activation ( $D_a$ ) and corresponding aerosol hygroscopicity parameter  $\kappa$  are known, the surrounding supersaturation can be retrieved based on air temperature measurements and by assuming  $\sigma_{s/a}$  the surface tension of water (as shown in Fig.S1a). Note that  $D_a$  and  $\kappa$  are not independent with each other, average  $\kappa$  of aerosols with diameter  $D_a$  is needed. Previous studies have shown that the reduction in surface tension (Nozière et al., 2010; Gérard et al., 2016; Ovadnevaite et al., 2017) associated with surfactants in atmospheric aerosols can affect aerosol activation and, consequently, the derivation of effective supersaturation. However, if the derivation of  $\kappa$  (as done in this study) assumes a constant water surface tension, the impact of surface tension changes is minimized, as these effects are already incorporated in the  $\kappa$  calculation. Nonetheless, differences in surface tension between supersaturated and subsaturated conditions (Davies et al., 2019; Petters and Kreidenweis, 2013; Liu et al., 2018), and their impact on effective supersaturation, still exist. Additionally, prior research has suggested that slightly soluble components in aerosols can influence  $\kappa$  values under both supersaturated and subsaturated conditions (Ho et al., 2010; Petters and Kreidenweis, 2008; Lee et al., 2022; Han et al., 2022; Riipinen et al., 2015; Wang et al., 2019; Whitehead et al., 2014). Therefore,  $\kappa$  observed under subsaturated conditions would affect the derivation of effective supersaturation.

However, the simultaneous measurements of  $D_a$  and  $\kappa$  of activated aerosols with diameters around  $D_a$  are indeed challenging. The direct measurements of size-resolved activation ratio (AR) in clouds are essential for  $D_a$  retrievals through the following equation:

$$AR(D_p) = \frac{MAF}{2} \left( 1 + \operatorname{erf} \left( \frac{D_p - D_a}{\sqrt{2\pi}\sigma} \right) \right) \quad (2)$$

---

178 Where  $D_p$  is the particle diameter, MAF is the maximum activation fraction and  $D_a$  is critical  
179 activation diameter,  $\sigma$  is associated with the slope of the ~~curve near  $D_a$~~  size-resolved AR curve near  
180  $D_a$  and mostly influenced by the heterogeneous distribution of aerosols near  $D_a$  as well as  
181 supersaturation fluctuations (note that not effective supersaturation fluctuations). This formula was  
182 previously proposed by Rose et al. (2008) to fit the AR measurements and widely used in AR  
183 parameterizations (Tao et al., 2018b). Therefore, it typically requires a unique inlet system and a suite  
184 of instruments that measure the aerosol size distribution of both interstitial and total aerosol  
185 populations (Hammer et al., 2014; Zíková et al., 2020). Consequently, this is rarely done, even in  
186 ground fog measurements. Instead,  $D_a$  was usually estimated from aerosol measurements and fog  
187 droplet size distributions measurements which indirectly provides the number concentrations of  
188 activated aerosols therefore could be used in retrieving  $D_a$  through assuming that all aerosols larger  
189 than  $D_a$  are activated (Mazoyer et al., 2019; Wainwright et al., 2021; Shen et al., 2018) which brings  
190 uncertainty in  $D_a$  derivations due to that ~~the maximum activation fraction of not all~~ aerosols larger than  
191  $D_a$  are activated, because the MAF in Eq.2 does not equal to unit although usually very close to (Tao  
192 et al., 2018b). For the effective supersaturation measured in aloft clouds, the aerosol number size  
193 distributions inside and outside the cloud as well as cloud droplet number concentrations were used by  
194 Ditas et al. (2012) to derive  $D_a$ , and other approaches were also used (Gong et al., 2023). The  $\kappa$  values  
195 were usually retrieved from size-resolved cloud condensation nuclei measurements under certain  
196 supersaturations (Hammer et al., 2014; Mazoyer et al., 2019) or from growth factor measurements  
197 (Wainwright et al., 2021) or sometime assumed due to the lack of measurements. The  $\kappa$  of activated  
198 aerosols were not directly measured in these studies due to the difficulty of the direct sampling of  
199 activated aerosols as well as subsequent hygroscopicity measurements.

200 Two types of supersaturation fluctuations have been previously identified. The first type involves  
201 fluctuations in supersaturation directly governed by water vapor pressure and temperature, as  
202 described by Siebert and Shaw (2017). These fluctuations are linked to turbulence and water phase  
203 changes that influence water vapor pressure and temperature. The second type concerns fluctuations  
204 in effective supersaturation, which are associated with the activation and deactivation processes of  
205 aerosols, as noted by Ditas et al. (2012). The first type of fluctuations dictates the instantaneous growth  
206 and evaporation of droplets, thereby controlling the activation and deactivation of cloud droplets. As  
207 such, the second type of fluctuation is inherently driven by the first type. The theoretical framework  
208 proposed in this study enables the measurement of fluctuations in effective supersaturation.

209

---

## 241 2.2 Field measurements

242 Kuang et al. [2024] developed an advanced aerosol-cloud sampling system designed to measure  
243 fog and cloud activation processes. This compact, integrated system can automatically switch between  
244 different inlets, including PM<sub>1</sub> (particles and droplets with an aerodynamic diameter < 1 μm), PM<sub>2.5</sub>  
245 (particles and droplets with an aerodynamic diameter < 2.5 μm) impactor, and Total Suspended  
246 Particles (TSP, encompassing all particles and droplets) (as shown in Fig. S2). When combined with  
247 instruments that measure aerosol physical, optical, and chemical properties, this system is well-suited  
248 for investigating cloud microphysics and chemistry. It was utilized in the AQ-SOFAR campaign,  
249 dedicated to studying AQueous Secondary aerOsol formation in Fogs and Aerosols and their Radiative  
250 effects in the North China Plain (Kuang et al., 2024).

251 During this campaign, several radiation fog events were observed, enabling the measurement of  
252 size-resolved AR curves, aerosol hygroscopicity as well as chemical compositions of interstitial and  
253 activated aerosols within fogs. These measurements provided insights into the evolution of  
254 supersaturations (Kuang et al., 2024). Notably, aerosol hygroscopicity was determined using a  
255 humidified nephelometer system, located downstream of the inlet system. This system measured  
256 multiwavelength scattering coefficients (450 nm, 525 nm, 635 nm) under both nearly dry (RH<20%)  
257 and humid conditions (RH~84%), offering aerosol hygroscopicity data based on the optical theory  
258 proposed by Kuang et al. (2017). The size-resolved AR curves and aerosol chemical compositions  
259 were obtained through the aerosol size distribution and the aerosol mass spectrometry measurements  
260 downstream of the inlet system. A schematic of the inlet system and associated instruments is provided  
261 in Fig. S1. Further details about the entire experimental setup, size-resolved AR calculations as well  
262 as data analysis about mass spectrometer measurements can be found in Kuang et al. (2024).

## 2.3 Method of simulating scattering coefficients of interstitial aerosols and activated aerosols

For each paired PNSD and BC mass concentration, the size distribution of dry-state  $PM_{10}$  was obtained using the following formula (the penetration curve shape from Gussman et al. (2002) was also included for considering the non-ideality cutoff of the impactor, and assuming aerosol density of  $1.6 \text{ g/cm}^3$  for converting aerodynamic diameter to mobility diameter) :

$$PNSD (D_p)_{PM_{10}} = PNSD (D_p) \times R(D_p) \quad (3)$$

Where  $R(D_p)$  is the penetration ratio of aerosols as a function of particle diameter  $D_p$  of the  $PM_{10}$  impactor. Further,  $PNSD (D_p)_{PM_{10}}$  and the BC mass concentration was used to simulate the size-resolved aerosol scattering coefficients ( $d\sigma_{sp}/d\log D_p$ ) at 450 nm, 525 nm and 636 nm that is consistent with the angular truncation and light source nonideality of Auora 3000 nephelometer (Müller et al., 2011), where  $\sigma_{sp}$  represents aerosol scattering coefficient. In this Mie calculation, the shape of black carbon mass size distributions are consistent with the one used in simulations of Kuang et al. (2017) assuming fractions of BC mass that are externally mixed is 0.5. Details about the Mie theory calculations can also be found in Ma et al. (2011) and Kuang et al. (2017).

With given size-resolved AR curve that produced using Eq.2, the size-resolved aerosol scattering coefficients of interstitial aerosols can be calculated using the following formula:

$$d\sigma_{sp,inter}/d\log D_p (D_p) = d\sigma_{sp}/d\log D_p (D_p) \times (1 - AR(D_p)) \quad (4)$$

The size-resolved aerosol scattering coefficients of activated aerosols can be calculated using:

$$d\sigma_{sp,act}/d\log D_p (D_p) = d\sigma_{sp}/d\log D_p (D_p) - d\sigma_{sp,inter}/d\log D_p (D_p) \quad (5)$$

Scattering coefficients of total aerosol populations (interstitial plus activated) and interstitial aerosols can be derived through integration of  $d\sigma_{sp}/d\log D_p (D_p)$  and  $d\sigma_{sp,inter}/d\log D_p (D_p)$ .

## 3. Theoretical Framework and Concept Design of the Advanced Optical System

### 3.1 Theory of Observing Critical Activation Diameter Using Scattering Measurements

The typical shape of size-resolved AR curves observed in atmospheric fogs and clouds is illustrated in Fig. 1a (Ditas et al., 2012; Hammer et al., 2014; Zíková et al., 2020; Wainwright et al., 2021; Kuang et al., 2024). In clouds, aerosols can be classified as either activated aerosols, which form

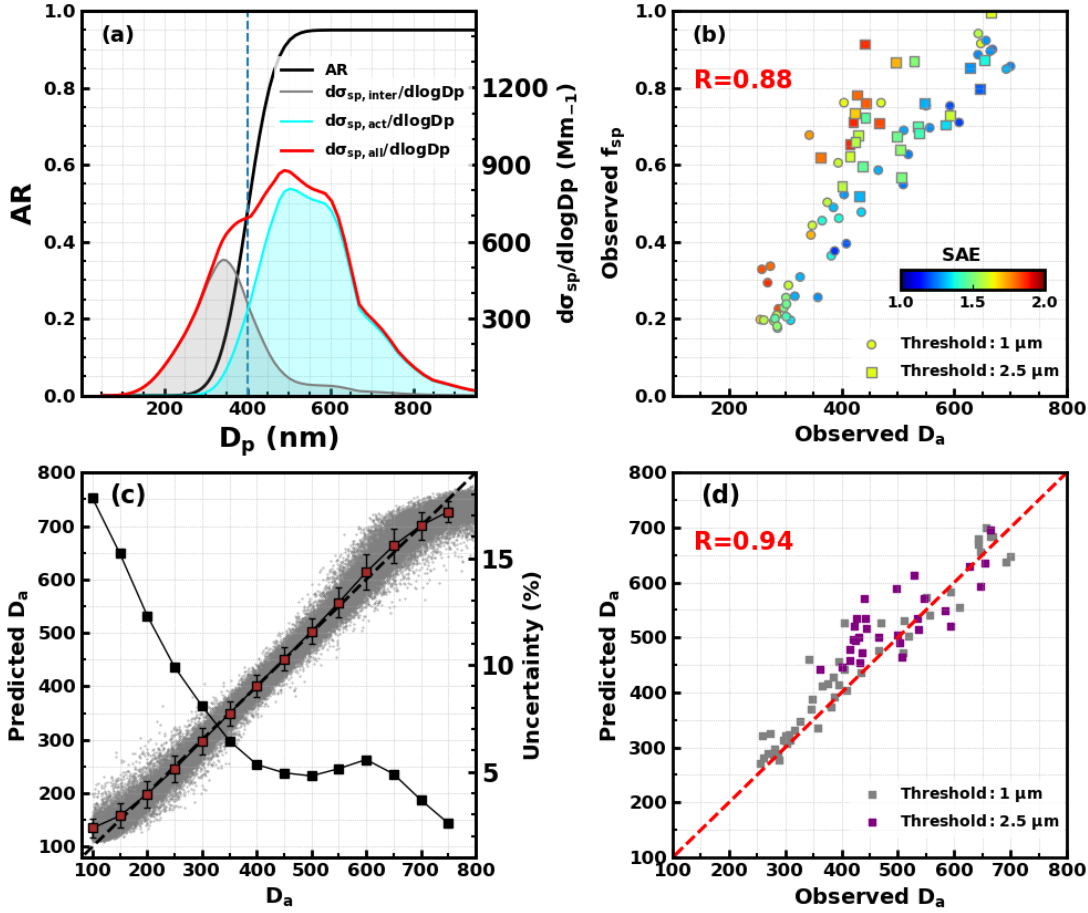

---

299 cloud droplets, or inactivated aerosols, which remain as interstitial aerosols. The critical diameter that  
300 distinguishes interstitial aerosols from cloud or fog droplets varies depending on the supersaturation  
301 (Kuang et al., 2024). A diameter of 2.5  $\mu\text{m}$  is typically suitable for surface fogs with relatively lower  
302 supersaturations ( $<0.1\%$ ), while 1  $\mu\text{m}$  is more appropriate for aloft clouds with higher supersaturations  
303 ( $>0.1\%$ ) (Mazoyer et al., 2019;Kuang et al., 2024;Lu et al., 2020). The typical AR curve shows that  
304 most aerosols larger than  $D_a$  are activated, while most smaller aerosols remain inactivated. As a result,  
305 the scattering properties, such as size-resolved scattering coefficients (Fig. 1a), the scattering Ångström

306  
307

exponent (SAE) and its wavelength dependence, which are directly related to aerosol size distribution, differ significantly between interstitial and activated aerosols.

**Figure 1.** (a) The typical shape of size-resolved aerosol activation ratio (AR) curve produced using the function of Eq. 2, with the  $D_a$  of 400 nm, the MAF of 0.95 and the  $\sigma$  of 30, and the average PNSD observed in the North China Plain from six campaigns (Kuang et al., 2018) and the AR curve was used to simulate an example of the size-resolved aerosol scattering ( $\sigma_{sp}$ ) distributions of interstitial and activated aerosols at 525 nm; (b) Relations between observed  $D_a$  and  $f_{sp}$  during the AQ-SOFAR campaign using 1 and 2.5  $\mu\text{m}$  as the threshold of interstitial aerosols, with the scatter points are colored with corresponding SAE of total dry state  $\text{PM}_{1.0}$  aerosols. (c) Comparisons of all prescribed  $D_a$  and predicted  $D_a$  values represented by scatter points, they are further binned with interval of 50 nm, averages and standard deviations represented by purple squares and their error bars, black squares represent relative uncertainty of the right axis at each bin; (d) The comparisons of  $D_a$  retrieved using activation ratio observations and those predicted using scattering observations as inputs of the trained model, dashed lines represent 1:1 lines.

308  
309  
310  
311  
312

If we focus on  $\text{PM}_{1.0}$  of the total dry aerosol population (the reasoning for this is discussed in Sect. S1 of the supplement), the scattering fraction of interstitial aerosols in the total dry  $\text{PM}_{1.0}$  population, defined as  $f_{sp} = \sigma_{sp, \text{PM}_{1.0}, \text{inter}}(\text{dry}, 525 \text{ nm}) / \sigma_{sp, \text{PM}_{1.0}, \text{all}}(\text{dry}, 525 \text{ nm})$ , where  $\sigma_{sp, \text{PM}_{1.0}, \text{inter}}(\text{dry}, 525 \text{ nm})$  is the scattering coefficient of  $\text{PM}_{1.0}$  interstitial aerosols in a dry state at a wavelength of 525 nm, and  $\sigma_{sp, \text{PM}_{1.0}, \text{all}}(\text{dry}, 525 \text{ nm})$  is that of all  $\text{PM}_{1.0}$  aerosols, is likely to be highly

---

313 correlated with  $D_a$ . Generally, the larger the  $D_a$ , the higher the  $f_{sp}$ . This relationship was directly  
314 confirmed using  $D_a$  and the scattering properties of dry  $PM_1$  interstitial and total aerosols during the  
315 AQ-SOFAR campaign, as shown in Fig. 1b, that observed  $D_a$  correlates highly with observed  $f_{sp}$   
316 ( $R=0.88$ ). However, at a given  $D_a$ ,  $f_{sp}$  can vary significantly, and these variations are closely related  
317 to the SAE of all dry  $PM_1$  aerosols, which are mainly determined by aerosol size distribution. In fact,  
318 aside from the size distribution of the total aerosol population that determines SAE, the shape of the  
319 AR curve also plays a significant role in the variations of  $f_{sp}$ .

320 The nephelometer measures the aerosol scattering coefficient at three wavelengths, enabling  
321 direct measurements of the SAE for both the total dry-state  $PM_1$  aerosols and the interstitial aerosols.  
322 Therefore, the relationship between  $f_{sp}$  and  $D_a$  can be further constrained by the SAE of interstitial  
323 and activated aerosols, as well as their wavelength dependence. This implies that a simple formulaic  
324 relationship between  $f_{sp}$  and  $D_a$  may not exist. However, the six scattering parameters  
325  $\sigma_{sp,PM_1,inter}(dry, \lambda)$ —at 450 nm, 525 nm, 635 nm, and  $\sigma_{sp,PM_1,all}(dry, \lambda)$  at 450 nm, 525 nm, 635  
326 nm—contain both the  $f_{sp}$  information and the SAE characteristics of both aerosol groups, thus  
327 potentially be used to accurately retrieve  $D_a$ . Machine learning techniques, which are well-suited for  
328 handling complex relationships, can be applied to this problem.

329 This assumption was tested using Mie theory, based on aerosol size distributions sampled during  
330 six campaigns conducted in the North China Plain region (Kuang et al., 2018). For each aerosol size  
331 distribution, we randomly assumed different activation curves using Eq.2. ~~The details of this  
332 simulation are provided in Sect. S2 of the supplement. The simulation pairs of these six scattering  
333 parameters and  $D_a$  were used to train a random forest model (Kuang et al., 2018). To preliminarily  
334 validate this approach, we randomly selected 75% of the simulated data points for training the model,  
335 while the remaining 25% were used for validation.~~ That is, for each PNSD from those campaigns, the  
336 scattering coefficients of submicron interstitial and activated+interstitial aerosols at wavelengths of 450  
337 nm, 525 nm and 635 nm corresponding to nephelometer case under 100 size-resolved AR scenarios  
338 were simulated using the procedure. And each size-resolved AR curve was produced by using  
339 randomly produced  $D_a$ ,  $\sigma$  and MAF as inputs of Eq.2. In the random step, the range of  $D_a$  is 100-700  
340 nm, the range of  $\sigma$  is 1-30, the range of MAF is 0.5-1. In each pair, simulated  $\sigma_{sp,PM_1,inter}(dry, \lambda)$ —  
341 at 450 nm, 525 nm, 635 nm, and  $\sigma_{sp,PM_1,all}(dry, \lambda)$  at 450 nm, 525 nm, 635 nm was the x values of  
342 the random forest model, corresponding  $D_a$  is the y value of the random forest model, and the random  
343 forest package from Python Scikit-Learn machine learning library (<http://scikit->

---

344 [learn.org/stable/index.html](https://www.tensorflow.org/stable/index.html)) is used for this purpose. With these configurations, more than million pairs  
345 are simulated. To preliminarily validate this approach, we randomly selected 75% of the simulated  
346 data pairs for training the model, while the remaining 25% were used for validation.

347 The results, shown in Fig. 1c, indicate that this approach could retrieve  $D_a$  with an uncertainty of  
348 less than 10% for  $D_a$  larger than 250 nm, and even as low as ~6% for  $D_a$  larger than 350 nm. However,  
349 the uncertainty increases as  $D_a$  decreases, particularly for  $D_a$  smaller than 250 nm. The larger  
350 uncertainty at smaller  $D_a$  is ~~due to the fact that~~ since aerosols smaller than 250 nm typically contribute  
351 less than 10% to total scattering in the dry state, making  $f_{sp}$  less sensitive to variations in  $D_a$ . This  
352 issue becomes more pronounced when  $D_a$  is less than 100 nm, as aerosols smaller than 150 nm  
353 generally contribute negligibly to total aerosol scattering [Kuang et al., 2018]. This method was further  
354 validated using observations from the AQ-SOFAR campaign. In this validation,  $D_a$  values were first  
355 predicted using aerosol scattering observations with the trained model and then compared with  $D_a$   
356 values retrieved from size-resolved AR measurements, as shown in Fig. 1d. It should be noted that the  
357 impactor operates in a sequence of PM<sub>1</sub>, PM<sub>2.5</sub>, TSP, and then back to PM<sub>1</sub>, with the flow alternating  
358 between a thermodenuder and bypass every 10 minutes for each inlet. To calculate size-resolved AR  
359 curves, we assumed that aerosol populations remained unchanged during the 30-minute period (based  
360 on comparisons between PM<sub>1</sub>/PM<sub>2.5</sub> and TSP inlets), which can sometimes introduce significant  
361 uncertainties in the size-resolved AR calculations. When using PM<sub>2.5</sub> as the threshold, the much lower  
362 number concentrations of aerosols larger than 400 nm can introduce more uncertainty in  $D_a$  retrievals,  
363 partially explaining the lower performance in Fig. 1d when using the PM<sub>2.5</sub> threshold.

### 364 3.2 Method of observing Hygroscopicity of Activated Aerosols

365 Measuring the hygroscopicity  $\kappa$  of activated aerosols at the critical activation diameter  $D_a$  under  
366 varying supersaturations is challenging, not only due to technical limitations but also because of the  
367 inherent variability in  $D_a$ . Kuang et al. (2017) introduced a novel optical method for observing aerosol  
368 hygroscopicity by using the aerosol light scattering enhancement factor  $f(RH)$  that associated with  
369 aerosol hygroscopic growth. This method is particularly suitable for the objectives outlined here. The  
370 method requires SAE and light scattering enhancement factors  $f(RH)$  of activated aerosols as inputs,  
371 and retrieved  $\kappa$  can be termed as  $\kappa_{act,f(RH)}$  which represents the overall hygroscopicity of activated  
372 aerosols and can be understood as the average  $\kappa$  of activated aerosols with the scattering contribution  
373 of each aerosol particle as the weight (Kuang et al., 2020). The scattering coefficients of activated  
374 aerosols at multiwavelength can be calculated as  $\sigma_{sp,PM_1,act}(dry, \lambda) = \sigma_{sp,PM_1,all}(dry, \lambda) -$

375  $\sigma_{sp,PM_{1,inter}}(dry, \lambda)$ , therefore corresponding SAE can be obtained. The  $f(RH)$  of activated aerosols  
 376 at 525 nm can be calculated as the following:

$$377 \quad f(RH)_{act} = \frac{\sigma_{sp,PM_{1,all}}(RH,525\text{ nm}) - \sigma_{sp,PM_{1,inter}}(RH,525\text{ nm})}{\sigma_{sp,PM_{1,all}}(dry,525\text{ nm}) - \sigma_{sp,PM_{1,inter}}(dry,525\text{ nm})} \quad (6)$$

378 During the AQ-SOFAR campaign, a humidified nephelometer system consisting of two  
 379 nephelometers—one measuring aerosol scattering in the dry state and the other at a fixed RH of 84%—  
 380 was placed downstream of the  $PM_1$  impactor. This setup allows for the humidification of dry-state  
 381 interstitial aerosols and total aerosol populations to a high RH (e.g., above 80%), facilitating the  
 382 required measurements, therefore severs one choice. The Retrieved  $\kappa_{act,f(RH)}$  under different  $D_a$   
 383 conditions are shown in Fig.2a, demonstrating significant variations in  $\kappa_{act,f(RH)}$  and its variations  
 384 need to be constrained. Also, the derived  $\kappa_{act,f(RH)}$  are compared to those estimated from aerosol chemical  
 385 composition measurements ( $\kappa_{act,chem}$ , details about calculation methods can refer to Kuang et al.  
 386 (2020)), as shown in Fig.2b and in general agree. Note that the mass spectrometer could not identify

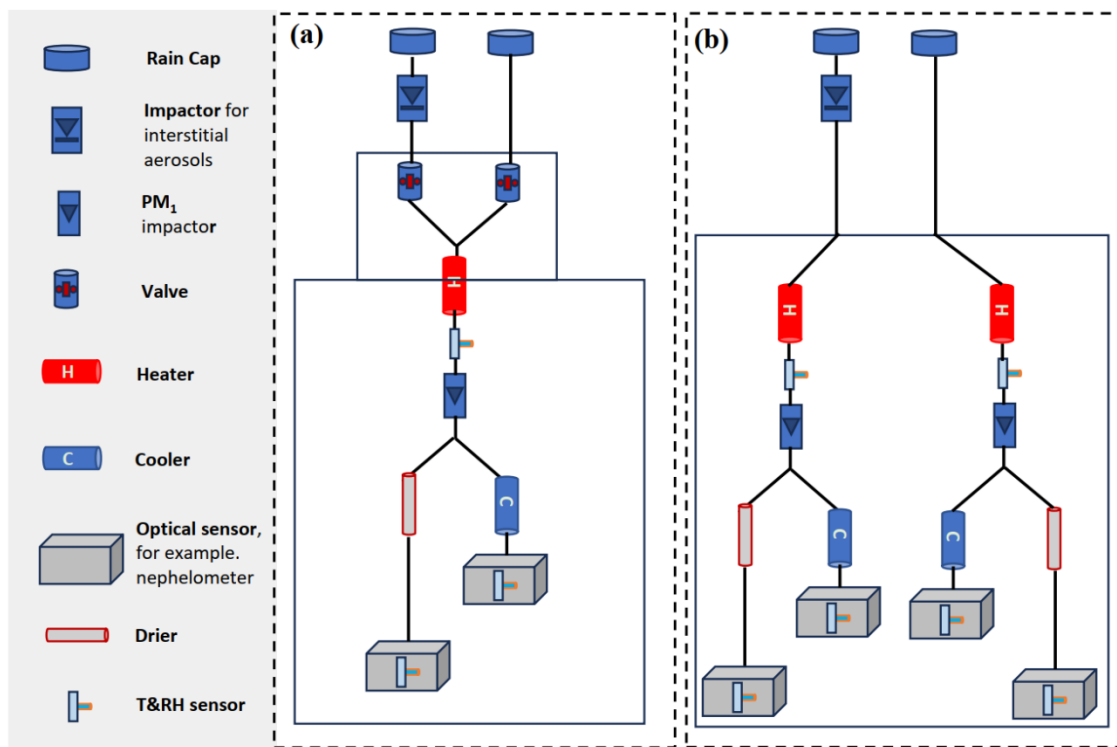

**Figure 2.** (a) Retrieved  $\kappa_{act,f(RH)}$  under different  $D_a$  conditions; (b) Comparison between  $\kappa$  of activated aerosols retrieved from the optical method ( $\kappa_{act,f(RH)}$ ) and estimated from aerosol chemical composition measurements ( $\kappa_{act,chem}$ ); (c) Comparisons between effective supersaturations ( $SS$ s) derived from size-resolved AR measurements as well as  $\kappa_{act,chem}$  ( $SS_{AR}$ ) and from the optical measurements ( $SS_{opt}$ ). Dashed red lines represent 1:1 lines.

387 all aerosol components, and assumptions about the mixing rule as well as densities of components  
 388 would bring uncertainties (Kuang et al., 2021). The comparisons between effective supersaturations  
 389 derived from size-resolved AR measurements as well as  $\kappa_{act,chem}$  and from the optical method are  
 390 shown in Fig.2c. On average, 0.002% of SS bias are observed due to the bias of  $D_a$  which associated  
 391 more with assumptions made in  $D_a$  retrievals as previously discussed. As demonstrated by Kuang et  
 392 al. (2024), for the fog case in the campaign, the threshold of 2.5  $\mu\text{m}$  should be used, however, does not  
 393 affect the comparisons here.

394 Qiao et al. (2024) developed an advanced outdoor nephelometer system that measures aerosol  
 395 dry scattering coefficients and scattering coefficients at nearly ambient RH without the need for  
 396 humidifying the sample air by placing the entire nephelometer system in ambient air, with the  
 397 instruments protected by a specially designed enclosure. This innovative design offers new insights  
 398 into the hygroscopicity measurements of activated aerosols. Under cloud conditions, where the  
 399 ambient RH is close to 100%, aerosol scattering under subsaturated conditions can be measured  
 400 directly by applying heater.

401 **3.3 Concept Design of the Advanced Optical System for Measuring Effective**  
 402 **Supersaturations**

**Figure 3.** Concept design of the advanced optical system with different number of optical sensors, (a) using two nephelometers or other optical sensors; (b) using four nephelometers or other optical sensors.

60%, ensuring the evaporation of most of the water content, to make sure the consistency of needed  $PM_{10}$  cut. The cooler upstream of the 'wet' nephelometer increases the sample RH to approximately 90%, allowing hygroscopicity measurements under conditions close to supersaturation.

403 Based on the proposed optical methods for measuring  $D_a$  and  $\kappa_{act,f(RH)}$ , a conceptual design for  
 404 outdoor instruments capable of measuring effective supersaturation with relatively high time  
 405 resolution can be envisioned, as shown in Fig. 3a. The aerosol-cloud sampling system includes two  
 406 inlets: one equipped with a  $PM_{10}$  or  $PM_{2.5}$  impactor (depending on cloud type) to sample interstitial  
 407 aerosols, and another with a TSP inlet to sample both interstitial aerosols and cloud/fog droplets. A

---

408 PM<sub>1</sub> impactor is placed downstream of the inlet system, where the RH of the sample air is reduced to  
409 70% (as discussed in Sect. S1 of the manuscript) through heater. Downstream of the PM<sub>1</sub> impactor,  
410 the sample flow is split into two streams: one is further dried to an RH below 10% before aerosol  
411 scattering coefficients are measured by the “dry” nephelometer, and the other is passed through an  
412 intelligent cooler to ensure the sample RH in the “wet” nephelometer remains close to 90%. The  
413 sample air is automatically switched between the interstitial inlet and the TSP inlet at set intervals,  
414 such as one minute for each inlet, enabling minute-level measurements of effective supersaturations.  
415 While the nephelometer can output scattering measurements every second, reliable data can only be  
416 achieved at intervals of around 30 seconds (exact values can be determined through future testing) due  
417 to the residence time of aerosols in the nephelometer and potential light source instability. If four  
418 nephelometers are available, a more advanced optical system can be designed (Fig. 3b) that does not  
419 require switching between the interstitial inlet and the TSP inlet. Instead, two nephelometers would be  
420 placed downstream of the interstitial inlet and two downstream of the TSP inlet, enabling higher time  
421 resolution effective supersaturation measurements. Other types of optical instruments exist that can  
422 achieve stable second-level aerosol scattering or extinction measurements with a stable laser light  
423 source [Moise et al., 2015; Zhou et al., 2020]. Therefore, with the development of suitable optical  
424 instruments, it may be possible to achieve second-level effective supersaturation measurements.

#### 425 **4. Discussions on Limitations and Advantages**

426 The proposed theoretical framework enables simultaneous measurements of  $D_a$  and  $\kappa$  for  
427 activated aerosols, leveraging the high time resolution of optical instruments to potentially provide  
428 second-level measurements of supersaturation. However, several limitations should be discussed and  
429 might be improved upon: **(1) Shape of size-resolved AR curve:** Cloud chamber studies have shown  
430 that supersaturation fluctuations can lead to the coexistence of particles with the same critical  
431 supersaturation as both interstitial aerosols and cloud droplets (Shawon et al., 2021). This results in  
432 size-resolved AR curves deviate more from stepwise shape, a phenomenon also observed in some field  
433 measurements (Henning et al., 2004; Mertes et al., 2007). Despite this, a critical diameter  $D_a$  still exists,  
434 and such non-ideal curves can be treated a high standard deviation  $\sigma$  in the activation error function  
435 (Eq. 2), which does not fundamentally undermine the proposed framework, however, should be further  
436 checked for different cloud types. **(2) Measurement of  $\kappa$ :** Although the framework measures the  
437 overall  $\kappa$  of activated aerosols, the  $\kappa$  needed for supersaturation calculations is that of aerosols near  
438  $D_a$  ( $\kappa_{D_a}$ ). For  $D_a > \sim 200$  nm, the derived  $\kappa_{act,f(RH)}$  can provide a first-order estimate of  $\kappa_{D_a}$ , based on

---

439 observed size-dependent characteristics of  $\kappa$  values (Liu et al., 2014; Shen et al., 2021; Wang et al.,  
440 2024), though more comprehensive evaluations are needed. Additionally,  $\kappa$  measured under  
441 subsaturated conditions differs from that under supersaturated conditions (Tao et al., 2023) might also  
442 bring some uncertainties. However, as shown in Fig. S1b, even a bias of 0.1 in  $\kappa$  only ~~results~~result in  
443 a ~0.01% bias when SS is ~0.1% and a ~0.005% bias when SS is ~0.05% in supersaturation retrievals,  
444 making the first-order estimates of  $\kappa_{D_a}$  from optical measurements generally suitable for  
445 supersaturation observations. **(3) Limitations in  $D_a$  Retrievals:** Current techniques using aerosol  
446 scattering measurements at visible wavelengths (e.g., nephelometers) are reliable only for  $D_a > 100$  nm  
447 as shown in Fig. 1a, limiting effective supersaturation measurements to less than 0.21% (assuming a  
448 typical  $\kappa$  of 0.3). This restriction makes the technique most applicable to fog and stratus or  
449 stratocumulus cloud measurements. However, incorporating scattering measurements at ultraviolet  
450 wavelengths could improve sensitivity to smaller  $D_a$  and lower  $\kappa$ , enabling measurements in  
451 conditions with higher effective supersaturation and a broader range of cloud types in the future.

452 The uncertainty in effective supersaturation observations using this framework primarily arises  
453 from the uncertainties in deriving  $D_a$  and  $\kappa_{D_a}$ . The uncertainty in  $D_a$  observations using the Aurora  
454 3000 nephelometer as the optical sensor under varying conditions is detailed in Fig. 1c. Factors  
455 affecting the accuracy of  $\kappa_{D_a}$  include: (1) the size dependence of  $\kappa$  of activated aerosols; (2)  
456 uncertainties related to surface tension, slightly soluble components, and other factors that lead to  
457 differences in  $\kappa$  differences under subsaturated and supersaturated conditions. Based on previous  
458 studies on the size dependence of  $\kappa$  (Peng et al., 2020) and the differences between subsaturated and  
459 supersaturated conditions (Whitehead et al., 2014; Liu et al., 2018; Tao et al., 2023), a 50% uncertainty  
460 (three times the standard deviation) was assumed in the derivation of  $\kappa_{D_a}$  for the uncertainty analysis.  
461 Using this approach, the uncertainty in effective supersaturation measurements, estimated through the  
462 Monte Carlo method, is shown in Fig. 4. The analysis indicates that applying this framework with the  
463 Aurora 3000 nephelometer as the optical sensor results in an uncertainty of approximately 5%. The  
464 precision of effective supersaturation measurements is directly linked to the accuracy of the optical  
465 sensor's scattering signal. For example, the Aurora 3000 has an accuracy of  $1 \text{ Mm}^{-1}$ , which leads to  
466 different levels of precision in  $D_a$  and hygroscopicity measurements depending on the scattering signal  
467 strength. If the scattering signal from the total aerosol population is  $100 \text{ Mm}^{-1}$ , the precision of the  
468 observed interstitial aerosol scattering fraction  $f_{sp}$  is about 1%. Based on the relationship between  $f_{sp}$   
469 and  $D_a$  shown in Fig. 1b, this leads to a precision of approximately 3 nm for  $D_a$ , which results in an  
470 effective supersaturation precision of ~0.01% when supersaturation is near 0.2%, or ~0.0002% when

471 [supersaturation is near 0.02%. However, if the scattering signal is lower \(e.g., 10 Mm<sup>-1</sup>\), a bias of 1](#)  
472 [Mm<sup>-1</sup> could result in effective supersaturation bias to as much as ~0.07% when supersaturation is near](#)

473 [Figure 4. The standard deviations of effective supersaturations under different effective](#)  
474 [supersaturation \(SS\) levels.](#)

475 [0.2%, making the measurements unreliable. In summary, while the proposed framework demonstrates](#)  
476 [the feasibility of observing effective supersaturation with an advanced optical system, the accuracy](#)  
477 [and precision depend on the resolution of the optical sensors, the scattering parameters being measured,](#)  
478 [and the scattering signal levels of aerosols in clouds. Enhancing the sensor precision to 0.1 Mm<sup>-1</sup> or](#)  
479 [even 0.01 Mm<sup>-1</sup>, and incorporating ultraviolet wavelengths and multiple scattering angles, might](#)  
480 [enable high-accuracy supersaturation measurements across a broad range of supersaturation conditions,](#)  
481 [especially in cleaner environments.](#)

482 [As mentioned in Sect. 2.1, the theoretical framework proposed in this study is designed to observe](#)  
483 [effective supersaturation fluctuations, rather than supersaturation fluctuations themselves. While there](#)  
484 [are non-negligible uncertainties associated with observing effective supersaturation using the proposed](#)  
485 [theory, the size and hygroscopicity distributions of total interstitial and activated aerosol populations](#)  
486 [remain nearly constant when measured with second-scale or shorter time resolution. The parameter](#)  
487 [that changes over time is the dynamic exchange between interstitial and activated aerosols.](#)  
488 [Consequently, fluctuations in the scattering signals of interstitial and activated aerosols can reflect this](#)  
489 [exchange at high temporal resolution. Since effective supersaturation fluctuations result from](#)  
490 [underlying supersaturation variations, they could, in principle, provide insights into the causes of these](#)  
491 [fluctuations, such as turbulence, though this would require further investigation and endeavor. In](#)  
[addition, for size-resolved AR, both  \$\sigma\$  and MAF are crucial parameters. However, using scattering](#)

---

492 [retrieving  \$\sigma\$  and MAF. If  \$\sigma\$  and MAF could be measured more precisely through the extended optical](#)  
493 [framework, it would provide deeper insights into supersaturation fluctuations.](#)

494 Despite these limitations, the proposed theoretical framework represents the first system capable  
495 of directly providing high time resolution measurements of effective supersaturations using a single  
496 instrument. This system is particularly well-suited for surface fog and mountain cloud observations,  
497 and when coupled with aerial vehicles, it could also be employed for measurements in aloft clouds.  
498 The system offers several advantages for cloud and fog measurements: **(1) High-Resolution**  
499 **Supersaturation Measurements:** The system can provide measurements of effective supersaturations  
500 at even a second-level resolution, making it feasible for observing effective supersaturation  
501 fluctuations and supporting investigations into fog and cloud evolution mechanisms. **(2) Long-Term**  
502 **Measurement Capability:** The optical measurements, such as those from the nephelometer system,  
503 are well-suited for long-term observations, making it possible to acquire climatological data on the  
504 variability of fogs and mountain clouds. **(3) Comprehensive Aerosol and Cloud Data:** In addition to  
505 measuring effective supersaturations, the system directly captures the scattering and hygroscopic  
506 properties of both interstitial and activated aerosols. With further algorithm development, it could also  
507 retrieve the number concentrations of available cloud condensation nuclei (CCN) at certain  
508 supersaturations, as well as cloud droplet number concentrations, based on previous studies that have  
509 observed CCN using optical methods (Tao et al., 2018a). **(4) Monitoring Aerosol Hygroscopic**  
510 **Behavior:** The system continuously monitors aerosol hygroscopic behavior under subsaturated  
511 conditions along with the corresponding optical properties. This allows for clear documentation of the  
512 formation and dissipation of fog/cloud events, as well as the variation in aerosol optical and  
513 hygroscopic properties. Overall, the datasets generated by this system are well-suited for in-depth  
514 investigations of cloud physics and aerosol-cloud interactions. This system has the potential to  
515 significantly advance fundamental research on clouds and fogs. However, further theoretical studies  
516 are needed to refine and optimize this type of system.
