20 **Abstract**

21 Volatile organic compounds (VOCs) play crucial roles in regulating the formation
22 of tropospheric ozone. However, limited knowledge on the interactions between
23 vertical VOC variations and photochemical ozone formation in the planetary boundary
24 layer (PBL) has hindered effective ozone control strategies, especially in large cities.
25 In this study, we investigated the vertical changes in concentrations, compositions, and
26 key driving factors of a large suite of VOCs using online gradient measurements taken
27 from a 325 m tall tower in urban Beijing. The impact of these vertical VOC variations
28 on photochemical ozone formation were also analyzed using box model simulations.
29 Our results indicate that VOCs exhibited distinct vertical variation patterns due to their
30 differences in sources and chemical reactivities, along with the diurnal evolution of the
31 PBL. During daytime, reactive VOCs (e.g., hydrocarbons) are rapidly oxidized as they
32 mix upwards, accompanied by the formation and accumulation of oxygenated VOCs
33 (OVOCs) in the middle and upper layers. In addition, the photochemical formation of
34 ozone responds positively to changes in both NO_x and VOCs. As a result, the
35 production rate of ozone declines with height due to the simultaneous decreases in
36 concentrations of reactive VOCs and NO_x, but remains high in the middle and upper
37 layers. The strong production of ozone aloft is primarily driven by the presence of high
38 OVOCs concentrations. Therefore, careful consideration should be given to the vertical
39 variations in both photochemical ozone production rates and formation regimes in the
40 whole PBL when developing regional ozone control strategies.

41 **1 Introduction**

42 Volatile organic compounds (VOCs) are crucial constituents of atmospheric
43 chemicals (*Li et al., 2022c*) and play important roles in regulating the atmospheric
44 oxidation capacity and contributing to the photochemical formation of tropospheric
45 ozone (*Zhao et al., 2022; Yang et al., 2024b*). Ozone is a major air pollutant in urban
46 environments, with increasing trends reported globally over recent decades (*Fleming et*
47 *al., 2018; Cooper et al., 2020*), despite stringent measures to control its precursor
48 emissions (*Wang et al., 2020b; Yeo and Kim, 2021; Li et al., 2022b; Perdigones et al.,*
49 *2022*). As highlighted in previous studies, reducing emissions of reactive VOCs is key
50 to controlling ozone pollution at present and in the foreseeable future (*Zhao et al., 2022;*
51 *Wang et al., 2024*).

52 The primary prerequisite for effective regional ozone pollution control is the
53 determination of the photochemical ozone formation regime (*Souri et al., 2020; Zhao*
54 *et al., 2022*), which facilitates the development of reduction schemes for key precursor
55 emissions (*Ou et al., 2016; Wang et al., 2019*). The main challenges in controlling
56 ozone pollution stem from the complex compositions of its precursors (e.g., VOCs and
57 NO_x) in ambient air (*Guo et al., 2017; Wu et al., 2020; Li et al., 2022c*), as well as the
58 complicated responses of photochemical ozone formation to changes in these
59 precursors (*Shao et al., 2021; Perdigones et al., 2022*). Furthermore, the interactions
60 between vertical variations of ozone precursors and ozone formation remain unclear
61 (*Tang et al., 2017; Sun et al., 2018; Li et al., 2024*), adding to the complexity of ozone
62 pollution control.

63 In most cases, the identification of key ozone precursors has been conducted using
64 ground-level observations (*Qi et al., 2021; Lu et al., 2022*) or compiled source emission
65 inventories (*Ou et al., 2015; An et al., 2021; Wang et al., 2022b*). While these methods
66 are undoubtedly helpful in determining key ozone precursors and corresponding
67 reduction strategies, they often encounter unexpected uncertainties in urban regions.
68 (*Mo et al., 2018; Mo et al., 2020*). Consequently, ground-level measurements of ozone

69 precursors have been favored to constrain model calculations (*Lu et al., 2012; Wang et*
70 *al., 2022a; Yang et al., 2022*) or provide empirical evidence for hypothesized theories
71 (*Hofzumahaus et al., 2009; Wang et al., 2022c*). However, these ground-level
72 measurements cannot fully characterize atmospheric chemical processes in the entire
73 planetary boundary layer (PBL) due to strong vertical variations in precursor
74 concentrations (*Velasco et al., 2008; Li et al., 2018; Sun et al., 2018*).

75 Ambient VOCs, as crucial ozone precursors, are composed of myriad species (*Wu*
76 *et al., 2020; Gkatzelis et al., 2021; Ye et al., 2021; He et al., 2022*) and serve diverse
77 functions in photochemical ozone formation (*Vo et al., 2018; Li et al., 2022a; Zhang et*
78 *al., 2022*). Owing to the impact of variations in emission sources, chemical removal,
79 advection and convection transport, and secondary formation, the concentration and
80 composition of VOCs typically display notable vertical variability within the PBL,
81 especially in urban areas (*Li et al., 2022c*). The ozone formation regime likely
82 undergoes significant transitions from the ground to the upper boundary layer (*Li et al.,*
83 *2024; Liu et al., 2024a*). Ozone generated throughout the PBL can influence surface
84 ozone levels due to enhanced atmospheric vertical mixing during the day. Consequently,
85 it is imperative to comprehend the vertical variations and principal determinants of
86 VOCs, as well as their effects on photochemical ozone formation within the PBL.

87 With the rapid development of cities in the recent two decades in China, a large
88 number of pollution-emitting industries and factories have been relocated from city
89 centers to alleviate air pollution. Concurrently, there's been a swift increase in the
90 ownership of electric vehicles (*Guo et al., 2021*). These shifts in energy consumption
91 have driven the change in concentrations and compositions of VOCs in major cities like
92 Beijing (*Liu et al., 2024b*), subsequently affecting photochemical ozone formation
93 (*Wang et al., 2024*). However, the vertical variations and key drivers of VOCs and their
94 impacts on photochemical ozone formation in the urban PBL remain elusive. A primary
95 hurdle in studying these vertical changes in photochemical ozone formation is the
96 scarcity of reliable vertical VOC data (*Dieu Hien et al., 2019; Li et al., 2022c*).
97 Engaging in vertical profiling of VOCs, ensuring all necessary species represented and

98 obtaining sufficient sample size, is especially challenging in the lower PBL where
99 atmospheric chemical reactions are most intense (*Benish et al., 2020; Kim et al., 2021*).

100 Previous studies on vertical distributions of photochemical ozone formation in the
101 PBL have been conducted using measurements of a limited number of VOC species
102 and samples (*Zhang et al., 2018; Benish et al., 2020; Geng et al., 2020*). In this study,
103 online gradient measurements of ozone, NO_x, and a large suit of VOCs were made on
104 a 325 m tall tower in urban Beijing during the summer of 2021. Additionally, box model
105 simulations constrained by the gradient measurements were performed to analyze the
106 vertical variations and key drivers of VOCs as well as their impacts on photochemical
107 ozone formation.

108 **2 Methods and materials**

109 **2.1 Description of the site, instrument, and field campaign**

110 The data utilized in this study was derived from an intensive field campaign
111 conducted at the Beijing Meteorological Tower (BMT: 39°58' N, 116°23' E) between
112 July 6 and August 4, 2021. The BMT has a height of 325 m and is located in the northern
113 part of downtown Beijing, positioned between the third and fourth ring roads (Fig. S1).
114 A vertical observation system, established using long perfluoroalkoxy alkane (PFA)
115 Teflon tubes (OD: 1/2 in.), was used to make online gradient measurements of ozone,
116 NO_x, and a set of VOCs on the BMT. Five specific heights, namely 15, 47, 102, 200,
117 and 320 m above ground level, were selected to mount the tube inlets, as depicted in
118 Fig. S3. An additional inlet, situated approximately 5 m above ground level, was
119 mounted on the rooftop of the observation room that was adjacent to the tower.
120 Consequently, the vertical observation system totally included a total of six sampling
121 inlets. The sampling inlet at the 15 m height was not utilized during this field campaign.

122 Filters were installed downstream of the tubing inlets on the tower to remove fine
123 particles. A rotary vane vacuum pump was used to simultaneously and continuously
124 draw sample air from the five tubes, ensuring that all tubes were flushed by ambient air

125 to reduce tubing delays of sticky organic compounds (*Pagonis et al., 2017; Liu et al.,*
126 *2019*). Five critical orifices were employed to control the flow rate of the air stream in
127 each tubing, resulting in flow rates ranging between 15 and 20 standard liter per minute
128 (SLPM). Instruments drew sample air from the five tubes sequentially through a Teflon
129 solenoid valve group at designated time intervals. The switching time intervals of the
130 Teflon solenoid valve group were set as 4 minutes during this field campaign. The
131 measurements of trace gases in the first and last 1 minute of a four-minute period were
132 discarded to eliminate cross interferences between different inlet heights. Detailed
133 information on the vertical observation system and the assessment of trace gas
134 measurements through hundreds of meters long PFA tubes has been provided in our
135 previous works (*Li et al., 2023; Song et al., 2024; Yang et al., 2024a*).

136 Ozone was measured using the ultraviolet photometry method (49i, Thermo Fisher
137 Scientific Inc., USA). NO, NO₂, and NO_x were measured using the chemiluminescence
138 method (42i, Thermo Fisher Scientific Inc., USA). Gradient measurements of ozone
139 and NO_x were conducted at a time resolution of 10 seconds. The photolysis frequencies
140 of NO₂, represented by $j(\text{NO}_2)$, were measured by a spectrometer (PFS-100, Focused
141 Photonics Inc., China) situated on the rooftop of the observation room and have a time
142 resolution of 8 seconds. In situ measurements of meteorological parameters including
143 wind speed, air temperature, and relative humidity were made at 15 heights between 8
144 m and 320 m on the BMT with a time resolution of 20 seconds. Planetary boundary
145 layer height (PBLH) was obtained from the Air Resources Laboratory
146 (<https://ready.arl.noaa.gov/READYamet.php>, last access: 10 June 2024) and was
147 linearly interpolated to hourly values based on the initial time resolutions of three hours
148 (*Li and Fan, 2022*).

149 A high-resolution proton-transfer-reaction quadrupole interface time-of-flight
150 mass spectrometer (PTR-ToF-MS, Ionicon Analytik, Austria) was employed to measure
151 VOCs at a time resolution of 10 seconds. The PTR-ToF-MS used both hydronium ion
152 (H₃O⁺) (*Yuan et al., 2017; Wu et al., 2020; Li et al., 2022c*) and nitric oxide ion (NO⁺)
153 (*Wang et al., 2020a*) as reagent ions. These two reagent ions were automatically

154 switched every 60 min for H_3O^+ and every 22 min for NO^+ throughout the campaign.
155 The PTR-ToF-MS operated at an E/N value of approximately 120 Td in H_3O^+ mode
156 and an E/N value of around 60 Td in NO^+ mode. Instrument backgrounds were
157 automatically measured during the last two minutes of each operation mode by passing
158 ambient air through a platinum catalyst heated to 365 °C. A gas standard containing 39
159 VOC species was used to calibrate the PTR-ToF-MS daily. Sensitivities for the
160 remaining species were determined based on reaction kinetics of the PTR-ToF-MS (*Wu*
161 *et al.*, 2020). Impacts of ambient humidity on the PTR-ToF-MS measurements were
162 corrected by using humidity-dependence curves of VOCs obtained in our laboratory
163 (*Wang et al.*, 2020a; *Wu et al.*, 2020). Carbon dioxide (CO_2 in dry air) and humidity
164 were measured using a CO_2 and H_2O gas analyzer (Li-840A, Licor Inc., USA) at a time
165 resolution of 10 seconds.

166 Gradient measurements of the total OH reactivity (OHR) of atmospheric trace
167 gases were made using the improved comparative reactivity method (ICRM) developed
168 by our team (*Wang et al.*, 2021a) from July 28 to 31. In addition, gradient measurements
169 of carbon monoxide (CO), methane (CH_4), CO_2 , and H_2O were simultaneously
170 measured using the cavity ring-down spectroscopy (CRDS) method (G-2401, Picarro
171 Inc., USA) at a time resolution of 10 seconds from May 15 to June 25. Sulfur dioxide
172 (SO_2) was measured using the ultraviolet fluorescence method (43i, Thermo Fisher
173 Scientific Inc., USA) at a time resolution of 10 seconds from June 25 to August 3. The
174 total OHR of VOCs, denoted by OHR_{VOCs} , can be estimated by excluding those of the
175 inorganic species (namely ozone, NO_x , CO, SO_2 , and CH_4). It should be noted that
176 gradient measurements of CH_4 and CO were not made during July 28-31, and their
177 average concentrations in daytime (11:00-16:00 LT) between May 15 and June 25 at 5
178 m were used for all altitudes to calculate OHR_{VOCs} . This method will bring minor
179 uncertainties due to the minor vertical differences in concentrations of CH_4 and CO in
180 daytime (Fig. S4). The OHR of VOCs can also be calculated by summing the products
181 of their measured concentrations and their reaction rate coefficients with OH radicals,
182 as formulated in Eq. (1):

$$\text{OHR} = \sum k^i_{\text{OH-R}}[\text{VOC}_i] \quad \text{Eq. (1)}$$

183 where $k^i_{\text{OH-R}}$ is the reaction rate coefficient of the i^{th} VOC species with OH radical
 184 and $[\text{VOC}_i]$ is the concentration of the i^{th} VOC species.

185 2.2 Estimation of NMHC concentrations at the BMT site

186 The PTR-ToF-MS is limited in its ability to measure VOC species with proton
 187 affinities higher than H_2O (691 kJ mol^{-1}) when operating in the H_3O^+ mode (*Yuan et*
 188 *al., 2017*). This limitation results in the absence of certain nonmethane hydrocarbons
 189 (NMHCs), such as alkanes and many alkene species, which play important roles in
 190 photochemical ozone formation. To obtain a comprehensive understanding of vertical
 191 variations in concentrations, compositions, and environmental impacts of VOCs, this
 192 study estimated the vertical profiles of those unmeasured NMHC species based on the
 193 concentrations of measured VOCs using the PTR-ToF-MS. Detailed information on
 194 estimation of NMHC concentrations is provided in SI.

195 2.3 Box model setup

196 A zero-dimension box model (F0AM) coupled with the Master Chemical
 197 Mechanism (v3.3.1) (*Wolfe et al., 2016; Yang et al., 2022*) was used to compute the
 198 production rate of ozone, denoted by $P(\text{O}_3)$ as formulated in Eq. (2):

$$P(\text{O}_3) = k_{\text{HO}_2+\text{NO}}[\text{HO}_2][\text{NO}] + \sum k^i_{\text{RO}_2+\text{NO}}[\text{R}^i\text{O}_2][\text{NO}] \quad \text{Eq. (2)}$$

$$199 \quad k_{\text{RO}_2+\text{NO}}[\text{RO}_2][\text{NO}]$$

200 where $[\text{HO}_2]$ and $[\text{NO}]$ is the concentrations of HO_2 and NO , $[\text{R}^i\text{O}_2]$ is the concentration
 201 of the i^{th} organic peroxy radical. The relative incremental reactivity (RIR) of
 202 photochemical ozone production to changes in different precursors was determined
 203 using Eq. (3):

$$\text{RIR}(X) = \frac{[P_{\text{O}_x}^S(X) - P_{\text{O}_x}^S(X - \Delta X)]/P_{\text{O}_x}^S(X)}{\Delta S(X)/S(X)} \quad \text{Eq. (3)}$$

204 where X represents ozone precursors, $P_{O_x}^S(X)$ is the contribution of X to the production
205 rate of O_x , ΔX is the amount of change in ozone precursors, $S(X)$ is the initial
206 concentration of X. RIR values were used to discern sensitivities of photochemical
207 ozone formation to changes in precursor gases. A positive RIR(X) value suggests that
208 an increase in X enhances ozone formation, while a negative RIR value indicates that
209 an increase in X inhibits ozone formation.

210 Model calculations were constrained by measurements of ozone, NO_x , CO, a suit
211 of VOCs, air temperature, and relative humidity. In addition to the measured or
212 estimated concentrations of NMHCs, nine oxygenated VOC (OVOC) species (Table
213 S1) measured by PTR-ToF-MS were used to constrain the model calculation. The
214 model was run in a time-dependent mode with a time resolution of 5 minutes and a
215 spin-up period of 2 days (Lu et al., 2012; Wang et al., 2022c). The dry deposition
216 velocity of ozone was set as 0.27 cm s^{-1} when calculating $P(O_3)$ 5 m and was zeroed
217 out when calculating $P(O_3)$ at other heights.

218 **3 Results and discussions**

219 **3.1 Temporal and vertical variations in concentrations of trace gases**

220 As shown in Fig. 1, the meteorology in Beijing was characterized by high air
221 temperature ($27.3 \pm 2.9 \text{ }^\circ\text{C}$), high humidity ($83.9\% \pm 16.2\%$), and gentle winds (1.1 ± 0.4
222 m s^{-1}) throughout the campaign. The intense solar radiation, elevated air temperature,
223 and mild winds favored the photochemical formation and accumulation of ozone,
224 leading to frequent occurrences of ozone pollution episodes. Fig. 1 also presents time
225 series of mixing ratios of ozone and its selected precursors (namely isoprene, toluene,
226 monoterpenes, and NO_x) along with $j(NO_2)$ measured at 5 m. The campaign mean
227 ozone mixing ratio was $45.6 \pm 25.3 \text{ ppb}$, but the maximum hourly mean ozone mixing
228 ratio reached 129.3 ppb , indicating strong photochemical reactions in urban Beijing
229 during the campaign. Surface ozone concentrations exhibited a typical diurnal variation

230 pattern with the maximum occurring at 16:00 LT (Fig. S6), implying its predominant
231 source from local photochemical production.

232 Isoprene is a typical tracer of biogenic emissions and is also a highly reactive VOC
233 species (*Atkinson and Arey, 2003*). Isoprene had a campaign mean mixing ratio of
234 0.7 ± 0.6 ppb. The average diurnal profile of isoprene at 5 m has a unimodal pattern with
235 the maximum occurring at 14:00 LT (Fig. S6), exhibiting strong dependence on solar
236 radiation. Monoterpenes were also generally recognized as typical tracers of biogenic
237 emissions (*Gómez et al., 2020*) and have a campaign mean mixing ratio of 0.3 ± 0.3 ppb.
238 The average diurnal profile of monoterpenes was characterized by low mixing ratios in
239 daytime with two peaks occurring at 05:00 and 20:00 LT, respectively.

240 Toluene and NO_x are recognized as typical tracers of anthropogenic emissions in
241 urban regions (*Niu et al., 2017; Li et al., 2022c*), with campaign mean mixing ratios of
242 0.7 ± 0.7 and 8.1 ± 4.8 ppb, respectively. The average diurnal profiles of toluene and NO_x
243 at 5 m exhibited similar variations with larger values at night than during the day. Based
244 on the measured concentrations and diurnal variations of ozone and its key precursors
245 at ground level, it can be inferred that urban Beijing is experiencing severe ozone
246 pollution, which is predominantly contributed by local photochemical production. As
247 key ozone precursors, ambient concentrations of VOCs are contributed by the mixture
248 of anthropogenic and biogenic sources.

249 Fig. 2 shows the average diurnal and vertical variations in mixing ratios of ozone,
250 NO_x, Ox (O₃+NO₂), and six selected VOC species (three hydrocarbons and three
251 OVOCs) within the measurement height range of 5-320 m. High mixing ratios of ozone
252 were observed in the afternoon following the enhancement of solar radiation, which
253 was consistent with the diurnal change pattern of ozone concentrations at the ground
254 level. The vertical gradients of ozone mixing ratios were positive throughout the day
255 but substantially enhanced at night (Fig. 3). The lower ozone mixing ratios near the
256 surface than aloft were mainly caused by the enhancement of dry deposition and NO
257 titration (*Brown et al., 2007; Ma et al., 2013; Li et al., 2022b*).

258 NO_x is a primary pollutant and mainly contributed by vehicular exhausts in urban
259 regions. In contrast to ozone, NO_x mixing ratios were low in daytime and exhibited
260 negative vertical gradients throughout the day, as shown in Figs. 2B and 3A-B. In
261 nighttime, large amounts of local NO_x emissions were trapped and accumulated in a
262 shallow boundary layer (<100 m). NO_x concentrations rapidly decreased with height
263 even in the overlying residual layer due to the suppression of turbulence vertical mixing.
264 With the onset of sunlight, the PBL rapidly expanded due to the surface heating effect.
265 The accumulated high concentrations of NO_x in the shallow nocturnal boundary layer
266 were thereupon diluted and removed by photochemical reactions.

267 Ox is frequently used as a conserved metric to investigate temporal and spatial
268 variability of ozone by eliminating the NO titration effect. As shown in Fig. 2C, the
269 mixing ratios of Ox had similar diurnal and vertical variation patterns to those of ozone,
270 but the vertical gradients of Ox were weaker than those of ozone. This result suggests
271 that the vertical distribution of NO concentrations played an important role in regulating
272 the vertical change of ozone concentrations. The enhanced positive gradients of ozone
273 mixing ratios at night were predominantly due to the strict suppression of turbulence
274 vertical mixing (*Geyer and Stutz, 2004*). The higher concentrations of ozone aloft are
275 considered as the residual of the ozone produced in the daytime PBL and have been
276 recognized as an important reservoir for the enhancement of surface ozone in morning
277 periods (*Kaser et al., 2017; Li and Fan, 2022; He et al., 2023*).

278 Benzene and toluene demonstrated similar diurnal and vertical variations to NO_x,
279 with low concentrations in daytime and high concentrations at night, as shown in Figs.
280 2D-F and 3A-B. The concentrations of both benzene and toluene decreased with height
281 throughout the day, confirming their primary emissions from ground-level sources.
282 However, unlike benzene, the diurnal and vertical variations of toluene were more
283 pronounced. Isoprene emissions are highly dependent on solar radiation, resulting in its
284 higher concentrations in the early afternoon compared to other times of the day.
285 Isoprene mixing ratios also exhibited strong negative vertical gradients below 320 m
286 throughout the day. In contrast to toluene, isoprene concentrations decreased more

287 rapidly with height in the daytime. For instance, the mixing ratios of isoprene decreased
288 by approximately 70% from 5 to 320 m in the daytime, while it was only 30% for
289 toluene.

290 Fig. 3A-B show the average vertical profiles of the NMHCs, normalized to their
291 respective ground-level concentrations measured by the PTR-ToF-MS in daytime and
292 nighttime. The normalized mixing ratios of the NMHCs exhibited significantly
293 differentiated gradients in daytime. In contrast, apart from monoterpenes, the
294 differences in vertical gradients of the normalized vertical profiles for other NMHCs
295 were relatively small at night. The differentiated vertical gradients of the NMHCs in
296 daytime were primarily caused by their intrinsic chemical reactivities, such as reactions
297 with OH radicals. As shown in Fig. 4, concentration ratios of the NMHC species
298 between 320 m and 5 m with k_{OH} values lower than $2.5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$
299 exhibited slight variability and rapidly declined with the further increases in k_{OH} . The
300 lower NMHC concentrations at higher altitudes were predominantly caused by the
301 combined effects of atmospheric diffusion and chemical removal (*Sangiorgi et al.*,
302 2011).

303 Considering the effects of atmospheric diffusion and chemical removal by
304 reactions with OH radicals, concentration ratios of NMHC species between 320 m and
305 5 m in daytime can be estimated using Eq. (4):

$$y = A \times \exp(-k_{OH}[\text{OH}]\Delta t) \quad \text{Eq. (4)}$$

306 where y represents concentration ratios of the NMHC species between two altitudes, A
307 represents the effect of atmospheric dilution, k_{OH} is the reaction rate coefficient of
308 NMHCs with OH radicals, $[\text{OH}]$ is the concentration of OH radical, Δt is the
309 turbulence mixing time scale between the two altitudes. The term $[\text{OH}]\Delta t$ thus refers
310 to the exposure of NMHCs to OH radicals between the two altitudes. As shown in Fig.
311 4, the average concentration ratios of NMHCs between 320 m and 5 m in daytime
312 during the campaign can be well reproduced using Eq. (4) with the coefficients A of
313 0.88 and $[\text{OH}]\Delta t$ of $1.0 \times 10^{10} \text{ molecules cm}^{-3} \text{ s}$. Atmospheric diffusion processes have
314 same impact on the vertical distributions of all trace gases. The differences in vertical

315 gradients of NMHCs were mainly determined by the differences in their chemical
316 removal rates without considering influences from advection transport.

317 Methanol, as one of the most abundant OVOC species in the atmosphere, had its
318 lowest concentrations during daytime and displayed negative vertical gradients
319 throughout the day, as shown in Fig. 2G. The vertical and diurnal variations of methanol
320 suggest that its ambient concentrations in urban Beijing were mainly contributed by
321 local primary emissions. Conversely, formaldehyde and MVK+MACR (the first-
322 generation oxidation products of isoprene), as the photochemical oxidation products of
323 NMHCs, had higher concentrations during daytime than at night and exhibited
324 relatively weak vertical concentration gradients (Fig. 2H-I). This is mainly because
325 these OVOCs are produced from the oxidation of NMHCs during turbulence vertical
326 mixing and will accumulate in high altitudes. These phenomena were also observed for
327 other OVOC species, as shown in Fig. 3.

328 The vertical and diurnal variations in concentrations of ozone, NO_x, and VOCs
329 are intricately governed by their sources, chemical reactivities, and the evolution of the
330 PBL (namely the vertical dilution conditions). A significant accumulation of VOCs in
331 the shallow nocturnal PBL is subsequently vertically diluted and chemically removed
332 during daytime, thereby impacting the photochemical formation of ozone within the
333 daytime PBL. In addition, the observed vertical changes in concentrations of VOCs
334 imply that they will play distinct roles in contributing to photochemical ozone
335 formation.

336 **3.2 Vertical variations in contributions of VOCs to OHR**

337 During the daytime, VOCs are primarily oxidized by OH radicals and contribute
338 to the photochemical formation of ozone. To provide an overview on the vertical
339 variations in contributions of different VOCs to OHR, another 1204 ions measured by
340 the PTR-ToF-MS and can be quantified were used for analysis. All the VOCs were
341 classified into three large categories, namely C_xH_y (including alkanes, alkenes,
342 aromatics, and other hydrocarbons; 121 species), OVOCs (C_xH_yO₁, 121 species;

343 $C_xH_yO_2$, 120 species; $C_xH_yO_{\geq 3}$, 256 species), and N/S-containing (653 species), as
344 shown in Fig.5. Acetylene is included in alkenes.

345 Fig. 5A illustrates that the total mixing ratios of VOCs in daytime exhibited a slight
346 downward trend from 5 m to 320 m, primarily due to the rapid decrease in mixing ratios
347 of the C_xH_y category. The total mixing ratios of the C_xH_y category decreased from 16.8
348 to 10.6 ppb from 5 m to 320 m, with alkanes making the largest contribution, followed
349 by alkenes, aromatics, and other C_xH_y . Alkanes constituted 58% of the total mixing
350 ratios of C_xH_y at 5 m, but this proportion increased to 65% at 320 m. The fractional
351 contributions of alkenes and aromatics in the total mixing ratios of C_xH_y slightly
352 declined from 28% to 22% and from 12% to 10%, respectively, between these two
353 altitudes. As for OVOCs, the $C_xH_yO_1$ category was the most abundant among the
354 measurements, contributing to 52%-58% of the total mixing ratios at the five heights,
355 followed by the $C_xH_yO_2$ (8%-10%), and $C_xH_yO_{\geq 3}$ (2%) categories. The mixing ratios of
356 the N/S-containing category slightly varied around 2.8 ppb between 5-320 m,
357 contributed to approximately 6% of the total VOC concentrations.

358 Similar to the vertical variations in concentrations, OHRs of the C_xH_y category,
359 denoted by OHR_{CH} , also rapidly decreased from $6.9 s^{-1}$ to $2.5 s^{-1}$ between 5 and 320 m,
360 accounting for 52%-31% in the total OHRs of VOCs (Fig. 5B). Fractional contributions
361 of alkenes (40-18%), alkanes (5%), and aromatics (5%-4%) to the total OHRs of VOCs
362 all exhibited decreasing tendencies from 5 m to 320 m. The total OHRs of alkenes
363 decreased more quickly from 5 to 320 m than those of alkanes and aromatics. OHRs of
364 the other C_xH_y category stabilized at approximately $0.3 s^{-1}$ below 320 m, exhibiting an
365 increasing contribution (2%-4%) to the total OHRs of VOCs with the increase in height.
366 The OHRs of other VOC categories only slightly varied without exhibiting a clear
367 variation trend from 5 to 320 m during the day. As a result, fractional contributions of
368 the $C_xH_yO_1$ (27%-42%), $C_xH_yO_2$ (12%-18%), and $C_xH_yO_{\geq 3}$ (5%-7%), and N/S-
369 containing (2%-4%) categories in the total OHRs of VOCs all increased with height.
370 The increased contributions of OVOCs and N/S-containing species to the total

371 concentrations and OHRs of VOCs implied that air masses became more aged with the
372 increase in height.

373 As depicted in Fig. 6A-B, high OHR_{CH} values were mainly constrained in the PBL
374 and is mainly contributed by biogenic hydrocarbons, specifically isoprene, during
375 daytime due to their high OH reactivities and enhanced emissions. The fractional
376 contributions of isoprene in OHR_{CH} decreased rapidly with increasing height (Fig. 7A).
377 For instance, isoprene accounted for a campaign median fraction of 58% in OHR_{CH} at
378 5 m in daytime, making it a frequent contributor to photochemical ozone formation in
379 urban regions. However, this fraction decreased to 38% at 320 m. Therefore, it can be
380 speculated that the total contributions of hydrocarbons to the total OHRs of VOCs will
381 also rapidly decline from 320 m to the top of the PBL, which typically ranges between
382 several hundreds of meters to approximately 2~3 km in daytime (Fig. S7).

383 The total concentrations and OHRs of OVOCs only slightly decreased with the
384 increase in height below 320 m in daytime, as shown in Fig. 6C-D. This is consistent
385 with the results of (Wang *et al.*, 2021b), which observed high concentrations of OVOCs
386 in the upper PBL. Consequently, the ratio of OHR_{OVOC} to OHR_{CH} , denoted by
387 $\text{OHR}_{\text{OVOC}}/\text{OHR}_{\text{CH}}$, rapidly increased from 0.87 at 5 m to 2.6 at 320 m (Fig. 7A). This
388 suggests that OVOCs may play more important roles in regulating the photochemical
389 ozone formation in the middle and upper layers. To assess their potential roles in
390 contributing to the photochemical ozone formation throughout the PBL, we calculated
391 the mean OHRs (MOHR) of different VOC categories in daytime using Eq. (5):

$$\text{MOHR}(X) = \left(\sum ([X]_i + [X]_{i-1})(h_i - h_{i-1})/2 \right) / (320 - 5) \quad \text{Eq. (5)}$$

392 where $\text{MOHR}(X)$ is the MOHR of the VOC category X, $[X]_i$ is the concentration of
393 X at the i^{th} altitude (namely 5, 47, 102, 200, and 320 m for h_i) above ground level.

394 As shown in Fig. 7B, the campaign median MOHR for isoprene was 1.7 s^{-1} and
395 accounted for 48% of the campaign median MOHR of the C_xH_y category. This fraction
396 was significantly lower than that of isoprene (57%) in OHR_{CH} at 5 m. In addition, the
397 campaign median MOHR of the C_xH_y category (3.5 s^{-1}) was also significantly lower

398 than the OHR_{CH} (6.0 s^{-1}) at 5 m. By contrast, the campaign median MOHR of OVOCs
399 (4.8 s^{-1}) was comparable to that of OHR_{OVOC} (4.9 s^{-1}) at 5 m. As unsaturated
400 hydrocarbons, most alkene species are more reactive than alkanes and aromatics
401 (*Atkinson and Arey, 2003*). As a result, alkenes had dominant contributions to the
402 MOHR of the C_xH_y category and the OHR_{CH} at 5 m in daytime. As shown in Fig. 7C,
403 the campaign mean OHRs of alkanes, alkenes, and aromatics at 5 m in daytime were
404 0.7 , 5.2 , and 0.7 s^{-1} , respectively, accounting for 10%, 75%, and 10% of the OHR_{CH} .
405 However, the campaign mean MOHRs of alkanes, alkenes, and aromatics were 0.5 , 2.7 ,
406 and 0.5 s^{-1} , respectively, accounting for 12%, 68%, and 12% of the MOHR of NMHC.
407 We can also expect that the total contributions of alkenes to the MOHR of the C_xH_y
408 category in daytime will significantly decrease if their vertical distributions in the whole
409 PBL are considered.

410 This study investigated and compared the vertical profiles of measured OHR_{VOCs}
411 and calculated OHR_{CH} during daytime over the period of July 28-31, as shown in Fig.
412 7D. The campaign median of the measured OHR_{VOCs} exhibited a slow decrease from
413 38.4 s^{-1} at 5 m to 25.4 s^{-1} at 320 m. As anticipated, the $\text{OHR}_{\text{CH}}/\text{OHR}_{\text{VOCs}}$ ratio declined
414 rapidly from 16% to 7% from 5 to 320 m. It is important to note that the small
415 $\text{OHR}_{\text{CH}}/\text{OHR}_{\text{VOCs}}$ ratio and its declining trend with the increasing height do not imply
416 the insignificant roles of hydrocarbons in regulating the secondary pollutant formation
417 in higher altitudes. The measured concentrations of hydrocarbons are merely the
418 remnants of chemical reactions. The oxidation products of NMHCs, such as OVOCs
419 and organic nitrates, formed during vertical mixing in daytime, will continue to
420 participate in atmospheric chemical reactions.

421 **3.3 Vertical variations in photochemical ozone formation**

422 The surface ozone budget is intimately linked to the vertical variations of
423 photochemical ozone formation throughout the PBL. Previous studies have consistently
424 reported that the photochemical formation of ozone, encompassing both $\text{P}(\text{O}_3)$ and
425 ozone formation regimes (namely the NO_x -limited, VOCs-limited, and transition

426 regimes), are highly dependent on the change in its precursors (*Shao et al., 2021; Yang*
427 *et al., 2022*). Consequently, any changes in the concentrations and compositions of
428 VOCs and NO_x within the PBL will inevitably lead to alternations in the vertical
429 distribution of P(O₃) and ozone formation regimes (*Tang et al., 2017; Li et al., 2024*).

430 Fig. 8A illustrates the average dependence of P(O₃) on NO_x concentrations along
431 with the normalized probability density (NPD) distribution of NO_x concentrations at 5
432 m, 200 m, and 320 m in daytime during the field campaign. At different heights, P(O₃)
433 all rapidly increased with the rise in NO_x until a critical NO_x mixing ratio was reached,
434 after which P(O₃) decreased slowly. The critical NO_x mixing ratios decreased from
435 approximately 9.5 ppb at 5 m to 5.0 ppb at 320 m, primarily caused by the decreases in
436 both NO_x concentrations and the OHRs of VOCs. As also shown in Fig. 8A, the
437 majority of the measured NO_x mixing ratios fall into the transition zone of the P(O₃)-
438 NO_x curves, suggesting that the photochemical ozone formation in Beijing belonged to
439 the transition regime below 320 m.

440 RIR values were also calculated using the box model results to further elucidate
441 the sensitivities of photochemical ozone formation to changes in multiple precursors at
442 different altitudes. As shown in Fig. 8B, positive RIR values were observed for both
443 NO_x and various VOC groups at the five heights, further confirming that the
444 photochemical ozone formation belonged to the transition regime in the lower layer.
445 RIR values for NO_x rapidly declined from 5 to 320 m, implying that the photochemical
446 ozone formation in higher altitudes was more prone to be controlled by the abundance
447 of VOCs. This is also manifested by the increasing RIR values for both AVOCs and
448 OVOCs from 5 m to 320 m. RIR values for BVOCs significantly decreased with height
449 due to their rapid removal by reactions with OH radicals when being vertically mixed.
450 These results are consistent with the results in section 3.3 that the less reactive AVOCs
451 and OVOCs are the dominant species in regulating the photochemical formation of
452 ozone in urban regions aloft.

453 According to the vertical distribution patterns of the photochemical ozone
454 formation regime, P(O₃) decreases with increasing height alongside simultaneous

455 declines in concentrations of both NO_x and VOCs. Fig. 8C presents the average diurnal
456 and vertical variations in $P(\text{O}_3)$ calculated by the box model during the campaign. The
457 $P(\text{O}_3)$ values were higher in daytime and correlated well with $j(\text{NO}_2)$. $P(\text{O}_3)$ decreased
458 from the ground to 320 m, where it still maintained a relatively high value of
459 approximately 10 ppb h⁻¹ at noon. These results highlight that the photochemical
460 formation of ozone aloft also remained strong compared to those at ground level.
461 Consequently, the downward transport of ozone from high altitudes, driven by
462 turbulence mixing, can become significant sources of surface ozone during the day
463 (*Karl et al., 2023*).

464 Due to the measurement height limitation, the vertical distributions of $P(\text{O}_3)$ in the
465 middle and upper parts of the PBL were not determined in this study. As reported by
466 the work in (*Benish et al., 2020*), $P(\text{O}_3)$ typically exhibited weak and nearly linear
467 decline tendencies from 300 m to the top of the PBL during daytime. $P(\text{O}_3)$ at the PBL
468 top was approximately half of that at 300 m. Consequently, we can assume that $P(\text{O}_3)$
469 decreased linearly from 320 m to the top of the PBL. The integral of $P(\text{O}_3)$ at different
470 heights within the PBL can then be estimated using a similar method as described in
471 Eq. (5).

472 As shown in Fig. 8D, the total amount of ozone photochemically produced below
473 47 m constituted a mere 6% of the entire PBL. This fractional contribution increased to
474 approximately 35% at 320 m, further corroborating that the majority of the boundary-
475 layer ozone was produced in the middle and upper layers. Given the enhancement of
476 turbulence vertical mixing in daytime, ozone produced at high altitudes becomes a
477 significant source of surface ozone. This is substantiated by the widespread reports of
478 strong downward ozone fluxes in the bottom part of the PBL (tens of meters above
479 ground level) (*Fares et al., 2010; Liu et al., 2021; Karl et al., 2023*). Consequently,
480 when devising ozone control strategies, particularly in urban regions with intricate
481 precursor emissions, careful considerations should be given to the vertical variations in
482 the formation regimes of ozone in the PBL.

483 4 Conclusions

484 The inadequate vertical distribution data of volatile organic compounds (VOCs)
485 poses a significant barrier to fully comprehending the mechanisms underlying
486 photochemical ozone formation and devising effective mitigation strategies. To address
487 this concern, ~~In this study, we made vertical gradient measurements investigated the~~
488 ~~vertical variations, key drivers, and environmental impacts~~ of VOCs, NO_x, and ozone
489 ~~in the PBL based on a 325 m tall tower using tower-based online gradient measurements~~
490 in urban Beijing during the summer of 2021. ~~– This study offered more exhaustive and~~
491 ~~nuanced insights into the vertical variability of VOCs compared to previous studies. The~~
492 ~~diurnal and vertical variations of various VOC species~~ Our findings underscored that
493 the vertical variations of VOCs were strictly regulated by the diurnal evolution of the
494 PBL and chemical processes. In daytime, reactive NMHCs ~~species were~~ were rapidly
495 oxidized when they ~~were~~ were mixed upward along with the formation of OVOCs. As
496 a result, concentrations of NMHCs decreased with height and many of OVOC species
497 increased with height. OVOC species played more significant roles in regulating the
498 photochemical ozone formation in urban regions aloft. ~~–~~

499 Model simulations unveiled that ~~The the~~ photochemical formation of ozone
500 belongs to the transition regime in the lower ~~part of the~~ PBL and becomes more
501 sensitive to changes in the concentrations of AVOCs and OVOCs with ~~increasing~~
502 height. ~~With the further increase in height, the photochemical formation of ozone may~~
503 ~~change to the NO_x control regime due to the total OHR of VOCs decreased much~~
504 ~~slower than NO_x concentrations.~~ P(O₃) exhibited decreasing tendencies with height due
505 ~~to coupled declines in concentrations of NO_x and VOCs, but P(O₃) still~~ remained very
506 large in high altitudes, likely driven by ~~the high OVOC concentrations of OVOCs and~~
507 ~~OH radicals.~~ This implies that the bulk of ozone formation occurs within the middle
508 ~~and upper strata of the PBL rather than proximate to the ground surface. ~~–~~~~ Therefore,
509 ~~regional ozone control strategies necessitate meticulous consideration of vertical~~
510 ~~gradients in P(O₃) and the varying regimes of photochemical ozone formation~~
511 ~~throughout the entire PBL. careful consideration should be given to the vertical~~

512 ~~variations in both P(O₃) and photochemical ozone formation regimes in the whole PBL~~
513 ~~when making regional ozone control strategies.~~

514 The vertical variations in concentrations and compositions of VOCs significantly
515 influence ~~the ozone formation of secondary pollutants.~~ ~~Furthermore~~In addition, ~~the~~
516 vertical changes in chemical reaction environments (e.g., temperature, humidity, and
517 solar radiation) and concentrations of other chemicals (e.g., particulate matters, NO_x,
518 ozone) can also impact the degradation pathways of VOCs. These factors also affect
519 the formation pathways and production yields of ~~other secondary air pollutants, such as~~
520 ~~formic acid, isocyanic acid, and secondary pollutants~~secondary organic aerosol. This is
521 particularly crucial for the highly reactive NMHCs in urban areas with complex
522 anthropogenic ~~and biogenic~~ emissions ~~and is expected to be thoroughly elucidated in~~
523 ~~future studies.~~

524 Limitations of our study include the confinement of measurements below 320
525 meters due to the tower's height, leaving the mid and upper daytime PBL's VOC
526 distributions and chemistries unexplored. Additionally, the absence of measurements
527 for some key chemical species like HONO, organic aerosol components, and reactive
528 halogen species might have implications for the accuracy of our box model results.
529 Future endeavors could integrate multiple observational techniques to capture a broader
530 vertical scope and a more comprehensive suite of species, thereby enhancing our
531 understanding of how vertical variations in VOC chemistry impact secondary pollution
532 formation.

533 **Data availability**

534 The observational data used in this study are available from corresponding authors
535 upon request.

536 **Author contributions**

537 BY, XBL, and YH designed the research. XBL, BY, YH, XS, JQ, XH, SW, YC,
538 QY, YS, YP, GT, JG, and MS contributed to the data collection and data analysis. XBL,

539 SY, and BY designed and performed the box model simulations. XBL and BY wrote
540 the paper with contributions from all coauthors. All the coauthors discussed the results
541 and reviewed the paper.

542 **Competing interests**

543 The authors declare that they have no conflict of interest.

544 **Acknowledgments**

545 The authors would like to thank the personnel who participated in data collection,
546 instrument maintenance, and logistic support during the field campaign.

547 **Financial support**

548 This work was financially supported by the National Key R&D Plan of China

860

861 **Figure 1.** Time series of hourly mean air temperature (T), relative humidity (RH), wind
 862 speed (WS), and mixing ratios of surface ozone, NO_x, and VOC species along with
 863 $j(\text{NO}_2)$ at the BMT site during the campaign. Meteorological parameters were measured
 864 at 8 m above ground level and mixing ratios of ozone and its selected precursors were
 865 measured at 5 m above ground level.

866

867 **Figure 2.** Average diurnal and vertical variations in mixing ratios of ozone, NO_x , Ox
 868 ($\text{O}_3 + \text{NO}_2$), and six selected VOC species along with the average diurnal profiles of
 869 PBLH and $j(\text{NO}_2)$ during the campaign. The figures were obtained by linearly
 870 interpolating the data at the five inlet heights on both altitude and temporal scales.

871

872 **Figure 3.** Average vertical profiles of (A-B) NMHCs and NO_x, (C-D) OVOCs and O₃
 873 during the daytime (11:00-16:00 LT) and nighttime (23:00-04:00 LT) of the campaign.
 874 The mixing ratios of the chemical species measured above 5 m are normalized to those
 875 at 5 m.

876

877 **Figure 4.** The change in ratios of NMHC concentrations (including acetonitrile)
 878 between 320 m and 5 m as a function of k_{OH} . The vertically-resolved measurements of
 879 VOCs made on the BMT in daytime during the campaign were used for analysis.
 880 Hollow markers represent median values and error bars indicate the range between 25th
 881 and 75th percentiles.

882

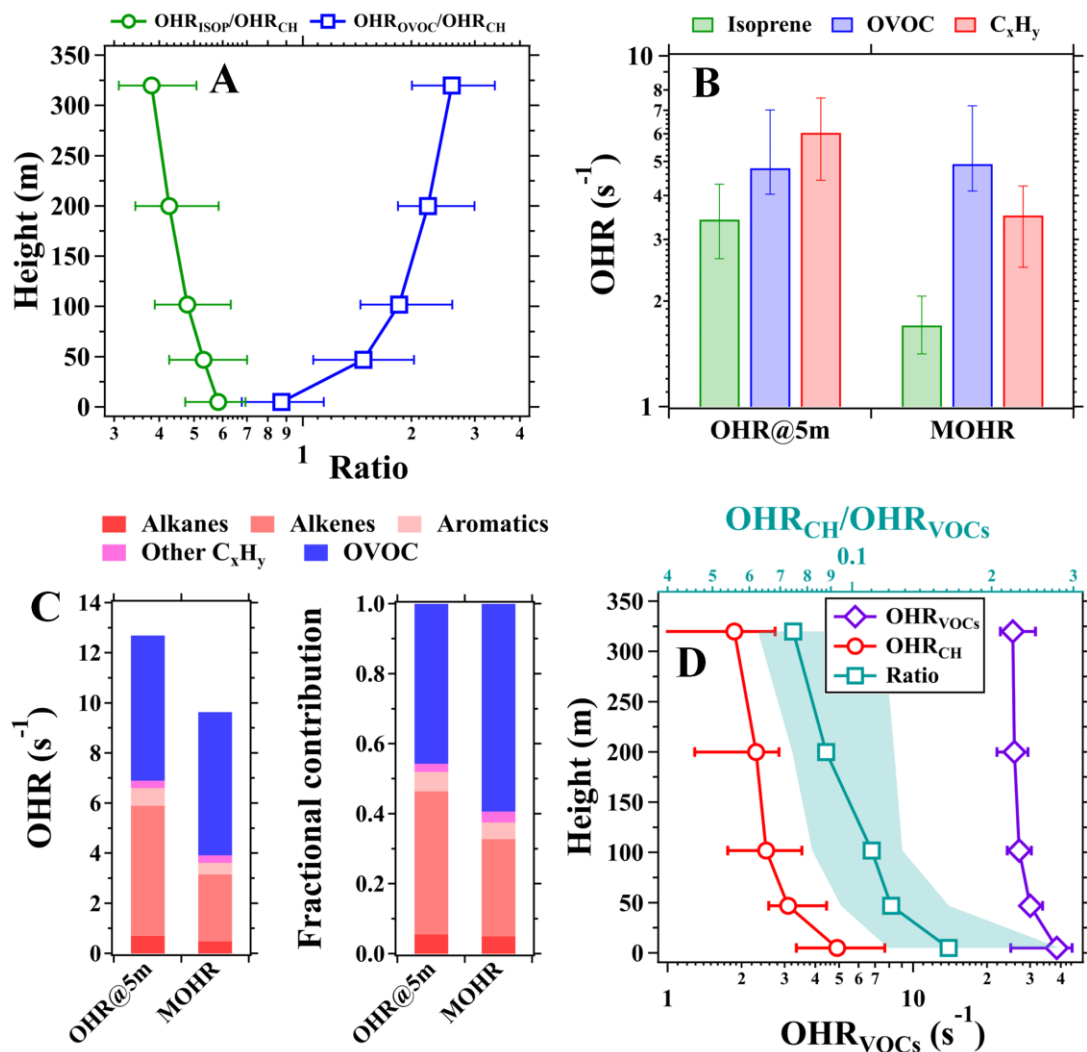

883 **Figure 5.** (A) Mean mixing ratios and (B) OHRs of different VOC categories at the five

884 inlet heights in daytime during the campaign.

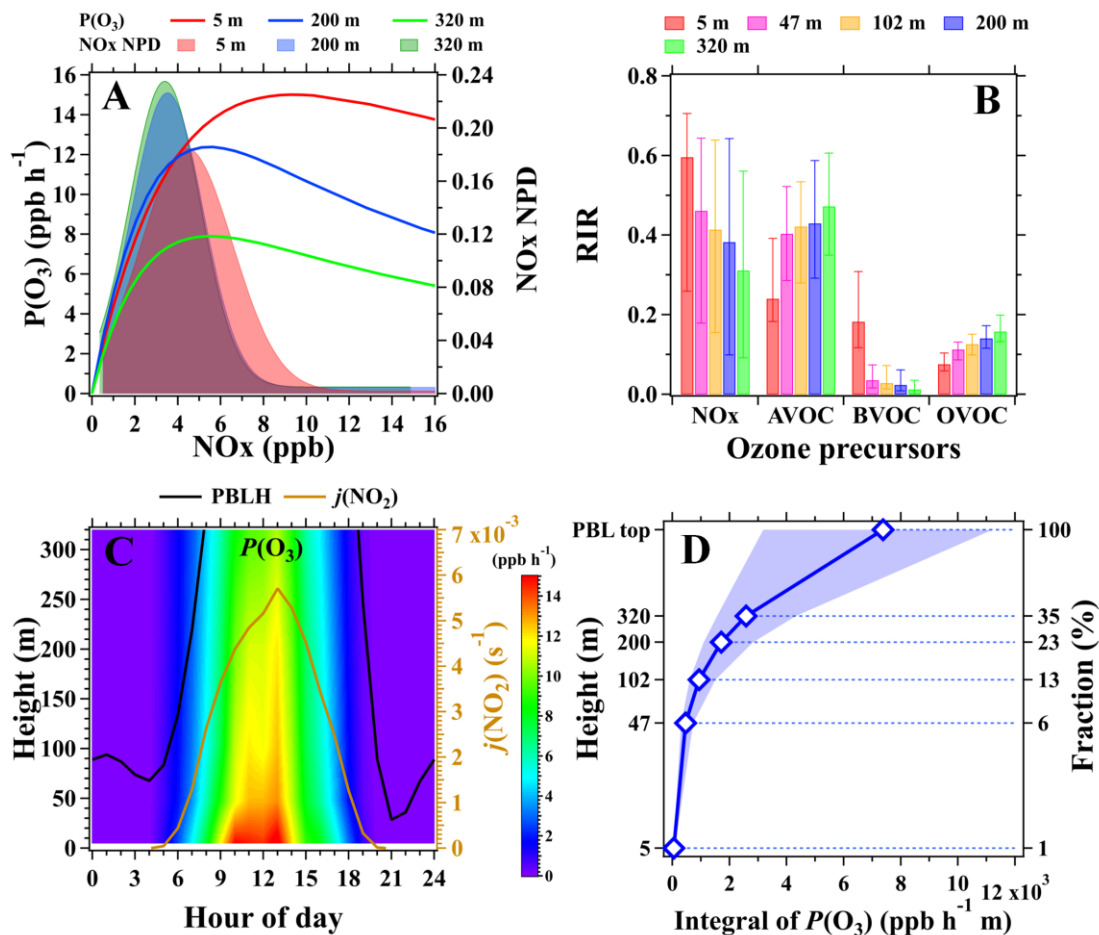

885

886 **Figure 6.** (A-B) Average diurnal and vertical variations in OHRs of C_xH_y and the OHR
 887 ratios of isoprene to C_xH_y ($\text{OHR}_{\text{ISOP}}/\text{OHR}_{\text{CH}}$) during the campaign. (C-D) Average
 888 diurnal and vertical variations in mixing ratios and OHRs of OVOC. ISOP refers to
 889 isoprene. The figures were obtained by linearly interpolating the data at the five
 890 measurement heights on both altitude and temporal scales.

891

892 **Figure 7.** (A) Average vertical profiles of OHR ratios of isoprene to C_xH_y
 893 (OHR_{ISOP}/OHR_{CH}) and OVOC to NMHC (OHR_{OVOC}/OHR_{CH}). (B) Median values of
 894 the OHR at 5 m and the mean OHR (MOHR) between 5 m and 320 m for isoprene,
 895 OVOC, and C_xH_y . (C) Mean contributions of different VOC categories to the MOHR
 896 below 320 m and the OHR at 5 m. (D) Vertical profiles of the measured OHR_{VOCs} and
 897 the calculated OHR_{CH} (bottom axis) and the OHR_{CH}/OHR_{VOCs} ratios (top axis) during
 898 July 28-31, 2021. The data used for analysis in panels A-D was within the time window
 899 from 11:00 to 16:00 LT during the campaign. Markers in panels A and D represent
 900 median values. Shaded areas and error bars in panels A, B, and D indicate the range
 901 between 25th and 75th percentiles.

902

903 **Figure 8.** (A) Left axis: average dependence of $P(O_3)$ on NO_x concentrations in
 904 daytime during the campaign; Right axis: normalized probability density (NPD) of
 905 NO_x mixing ratios in daytime at the three inlet heights. (B) Median RIR values of
 906 photochemical ozone formation to changes in NO_x, AVOC (NMHCs excluding BVOC),
 907 BVOC (isoprene), and OVOC (nine OVOC species in Table S1) at the five inlet heights;
 908 Error bars indicate the range between 25th and 75th percentiles. (C) Average diurnal and
 909 vertical variations in $P(O_3)$ during the campaign; The figure was obtained by linearly
 910 interpolating the data at the five measurement heights on both altitude and temporal
 911 scales. (D) The vertical profile of the integral of $P(O_3)$ in daytime during the campaign;
 912 Markers indicate median values and Shaded areas indicate the range between 25th and
 913 75th percentiles.
