10 **Abstract:** This study investigates the biological communities and bioweathering of the marble
11 surfaces of the Hall of Prayer for Good Harvests at the Temple of Heaven in Beijing. The dominant
12 organisms are aerophytic cyanobacteria, which thrive in calcareous environments, are drought-
13 resistant, slow-growing, and highly resilient. These cyanobacteria exhibit different community
14 compositions depending on the orientation of the marble surface. On east-facing, warm and humid
15 surfaces, the communities are mainly composed of small filamentous cyanobacteria such as
16 *Scytonema* sp.2 and coccoid cyanobacteria like *Gomphosphaeria* sp. On west-facing, hot and humid
17 surfaces, the dominant organisms are *Scytonema* sp.1 (a small filamentous cyanobacterium) and
18 mosses. On north-facing, cold and humid surfaces, the biological communities mainly consist of
19 coccoid cyanobacteria such as *Myxosarcina* sp. and *Gomphosphaeria* sp. On south-facing, hot and
20 dry surfaces, the communities are primarily made up of small or large filamentous cyanobacteria,
21 including *Scytonema* sp.1 and *Nostoc* sp. The intensity of weathering observed varies by orientation:
22 South > West > East > North. This pattern aligns with the observed "Cloud Chi Heads" weathering
23 features on surfaces facing different directions. The biological communities on the marble surface
24 display a range of colors, with gray-black being the most common, followed by gray-white, black,
25 brown, and dark brown. The gray-black communities are mainly composed of *Myxosarcina* sp. and
26 *Gomphosphaeria* sp. These communities also exhibit various morphologies, including membranous,

E-mail address: typ@cugb.edu.cn (Y. Tian)

27 pilose, carpet-like, leathery, shell-like, and powdery layers. The species composition varies across
28 these morphological types. The growth of aerophytic organisms on rock surfaces is controlled by
29 macroscopic hydrodynamics and micro-topographical features. At the macro scale, in areas with
30 low rainfall intensity, biofilms are sparse and biological weathering is weak. In areas with high
31 rainfall, cyanobacteria-rich "ink bands" can form, leading to intense biological weathering. At the
32 micro scale, micro-topographical features regulate local hydrological conditions and determine
33 colonization patterns: rough, uneven surfaces and discrete water films promote spot-like bio-
34 colonies that lead to solution pores and pits; linear decorations or joints with directional water
35 retention drive linear biological growth, forming solution marks and grooves; smooth, dense
36 surfaces with uniform water film coverage support planar microbial growth, ultimately resulting in
37 overall layer separation from weathering. The mechanism of biological weathering involves the
38 secretion of organic acids by aerophytic organisms. These acids dissolve inorganic salts in the rock,
39 providing nutrients while gradually "eroding" the rock, damaging its surface structure, and leading
40 to progressive weathering. Preventing or reducing the growth of aerophytic organisms is key to
41 slowing the biological weathering of the stone relics on the Hall of Prayer for Good Harvests.

46

47 1. introduction

48

49 The Hall of Prayer for Good Harvest, located in the Temple of Heaven in Beijing, China,
50 was completed in 1420. It served as the site for the emperors of the Ming and Qing dynasties to
51 perform the "Heaven Worship" and "Prayer for Good Harvest" rituals. It is also the largest
52 existing ancient architectural complex for heaven worship in the world. In 1961, the State
53 Council of China designated the Temple of Heaven as a "National Key Cultural Relic Protection
54 Unit." In 1998, it was recognized by UNESCO as a "World Cultural Heritage Site." The base
55 of the Hall of Prayer for Good Harvests is a three-tiered circular platform made of white marble,
56 6 meters high and surrounded by a balustrade (Fig. 1-a). The marble used in the construction is

57 divided into two types: White marble and Bluish-white marble. White marble, due to its fine
58 texture and ease of detailed carving, is often used in decorative parts such as balustrades and
59 carvings. Bluish-white marble, with its higher compressive strength (Ye and Zhang, 2019) and
60 better corrosion resistance compared to White marble (Qu, 2018), is typically used in load-
61 bearing and wear-resistant areas such as the base and paving. Most of the White marble and
62 Bluish-white marble used in the construction come from the marble quarries in Dashiwo Town,
63 Fangshan District, Beijing. (Wu and Liu, 1996; Lü and Wei, 2020). Compared to other types of
64 rock used in the Temple of Heaven complex (such as limestone, granite, and sandstone), the
65 marble used in the Hall of Prayer for Good Harvests is the most susceptible to weathering due
66 to its lower hardness. White marble, a special variety of marble, is particularly sensitive to
67 weathering (Ye and Zhang, 2019). Additionally, because marble is rich in calcium, it serves as
68 a preferred substrate for biological growth (Miller, et al., 2006). However, the organisms are
69 not uniformly distributed across the entire marble surface; their distribution is selective. In
70 addition to requiring a calcium-rich substrate, they also need water. In areas with low rainfall
71 intensity (such as high and protruding locations on the marble surface), where water is scarce,
72 there is little to no biological growth, and the surface appears white or yellowish-white with
73 minimal biofilm and weak bioweathering. In contrast, in areas with high rainfall intensity (such
74 as water convergence points, channels, and Chi Heads), where water is abundant, there is
75 extensive biological growth, and the surface appears black (with patches of brown and gray-
76 black) with a prominent biofilm and strong bioweathering. (Fig.1-b). The gradient distribution
77 of the biofilm on the rock surface is significantly spatially coupled with the variations in
78 instantaneous runoff, reflecting an optimal water allocation mechanism in arid environments
79 (Tian, 2004; Macedo, et al., 2009). In addition to the rock substrate and precipitation,
80 environmental factors such as wind and air pollution also influence microbial colonization, a
81 phenomenon known as "bioreceptivity" of vulnerable structural materials (Guillitte and
82 Dreesen, 1995; Miller, et al., 2012). Among these organisms, cyanobacteria are particularly
83 significant because they can grow with just light and water, and they can survive within the
84 rock, playing a crucial role in the degradation of stone cultural relics (C., Gaylarde, 2020).

85

86

b

87 **Fig. 1.** The hall of Prayer for Good Harvests in the Temple of Heaven, Beijing, China, and
 88 the distribution of black biofilm on its marble surface.

89 a. The Hall of Prayer for Good Harvests has a base consisting of three tiers of marble platforms is
 90 covered with black biofilm, which is distributed according to the intensity of rainfall. In areas with low rainfall intensity, the biofilm is not
 91 noticeable. In areas with high rainfall intensity (such as channels, water convergence points, and Chi Heads), there is a significant
 92 distribution of black biofilm.

93

94 Black microbial distributions, forming black crusts, have been observed on marble surfaces in
 95 many regions (Checcucci, et al., 2022; Monte and Sabbioni, 1986; Praderio, et al., 1993; Gorbushina,
 96 et al., 2002). This phenomenon is also referred to as marble blackening (Moropoulou, et al., 1998),
 97 bioweathering, or biodeterioration. The microbial communities on marble surfaces exhibit high
 98 diversity (Timoncini et al., 2022). The black crust microbial communities are primarily composed
 99 of coccoid and filamentous cyanobacteria from the genera *Chroococcus*, *Gloeocapsa*, and
 100 *Tolyphothrix* (Lombardozzi, et al., 2012), as well as green algae, fungi (Isola, et al., 2016; Leo, et al.,
 101 2019; Marvasti, et al., 2012), and lichens (Pinna, et al., 2018). *Chroococcus* can bore into the marble
 102 surface, demonstrating remarkable environmental adaptability: not only do they form blue-green
 103 biofilms on the rock surface (epilithic growth), but they also penetrate through cracks
 104 (chamomendolithic growth), colonize mineral interstices (cryptoendolithic growth), and even
 105 actively excavate (euendolithic growth) deeper into the marble. The tubular tunnels drilled by
 106 *Chroococcus* in calcite crystals involve both chemical dissolution and mechanical erosion, making
 107 them a dominant species in the community (Golubić, et al., 2015; Scheerer, et al., 2009). Biofilms

108 alter the thermal and moisture properties of the material, exert colloidal mechanical stress, and
109 secrete acidic and redox metabolites, which intensify mineral lattice destruction and promote the
110 formation of harmful crusts (Guiamet, et al., 2013; Warscheid and Braams, 2000). They can also
111 accelerate rock weathering, leading to the formation of pits (Danin and Caneva, 1990) and control
112 the micro- and macro-morphology of the rock surface (Tian, 2004). Black biofilms on marble
113 surfaces show differential erosion based on orientation, such as differences between windward and
114 leeward faces (Danin and Caneva, 1990). Height differences also play a role, with height having a
115 greater impact on microbial weathering than orientation. The microenvironmental gradients on the
116 rock surface are the core driving factors for the biological erosion of stone cultural heritage (Trovão
117 and Portugal, 2024). In extremely arid environments, "gravel shell" microbial communities
118 composed of lichens, cyanobacteria, and fungi drive the decomposition of rock particles and the
119 formation of primitive soil (terrestrial protopedon) through bioweathering mechanisms such as pH
120 changes, swelling and shrinking, enzymatic activity, and mineral migration (Jung, et al., 2020). Even
121 in areas with fewer black biofilms, the frequency of microbial presence increases as the physical
122 and chemical acid erosion of marble forms a powdery layer, accelerating the transformation of
123 marble into soil and posing a serious threat to marble cultural heritage. Understanding the
124 bioweathering patterns on marble surfaces is crucial for the conservation of marble cultural heritage.
125 For example, targeted use of microbial methods to remove black crusts can be more effective than
126 purely chemical or laser methods (Gioventù, et al., 2011).

127 Current research on the weathering of marble cultural heritage in Beijing has primarily focused
128 on the roles of physical and inorganic chemical processes, such as acid erosion. Studies have found
129 that the surface peeling and pollution of the marble steles at the Confucian Temple in Beijing are
130 caused by acid rain erosion (He, 2021). Freeze-thaw cycles can lead to internal structural damage
131 in rocks, while salt fog crystallization causes pore expansion and degradation (Li, 2023).
132 Temperature changes affect the physical and mechanical properties of dolomitic marble in Beijing,
133 leading to surface peeling, dissolution of dolomite crystals, and the formation of crusts due to SO₂
134 and dust pollution (Liu, 2020; Zhang, et al., 2016; Wang, et al., 2022). The mechanism of granular
135 peeling on marble surfaces is attributed to the low amount of cementing material between particles,
136 resulting in weak cementation. Surface particles are disrupted by mining unloading, processing
137 damage, stress concentration, and temperature variations, leading to peeling (Wang, 2010).

138 Temperature fluctuations, acid rain dissolution, water erosion, and salt micro-crack filling are the
139 main causes of weathering in Fangshan marble in Beijing (Zhang, et al., 2015). Research on the
140 weathering of white marble components in the Hall of Supreme Harmony in the Forbidden City
141 indicates that thermal stress from solar radiation and rain erosion are the primary factors (Wu, et al.,
142 2023). It has been found that under the combined action of acid and salt, dolomite crystals degrade
143 through dissolution, interstitial erosion, and spalling. Salt crystallization accelerates the latter two
144 types of damage, while acid erosion promotes salt penetration, significantly increasing the rate of
145 degradation (Zheng, et al., 2025). Regarding bioweathering of marble in Beijing, only a few studies
146 have mentioned it (Beijing Institute of Ancient Architecture, 2018). The main types of damage to
147 marble in Beijing include fissures, peeling, disintegration, crust formation, solution pits, erosion,
148 component loss, discoloration, biological parasitism, and improper human restoration (Yang, 2016).
149 Two types of peeling in white marble in the Beijing area have been identified: one driven by the
150 synergistic effects of thermal weathering, lichen, and rainfall, and the other by acid rain and capillary
151 water absorption (Zhang, 2022). To understand the patterns of bioweathering in marble, it is
152 essential to know the composition, structure, and metabolic potential of the resident microbial
153 communities and their interactions with the stone (Pinna, 2017; Marvasti, et al., 2019). This study
154 focuses on analyzing the community composition, structure, and relative biomass of biofilms on the
155 marble surface of the Hall of Prayer for Good Harvests in Beijing. By identifying the development
156 process and patterns of the biofilm communities, we aim to reveal the mechanisms of biocorrosion
157 and provide a scientific basis for developing more targeted conservation strategies for marble
158 cultural heritage.

159

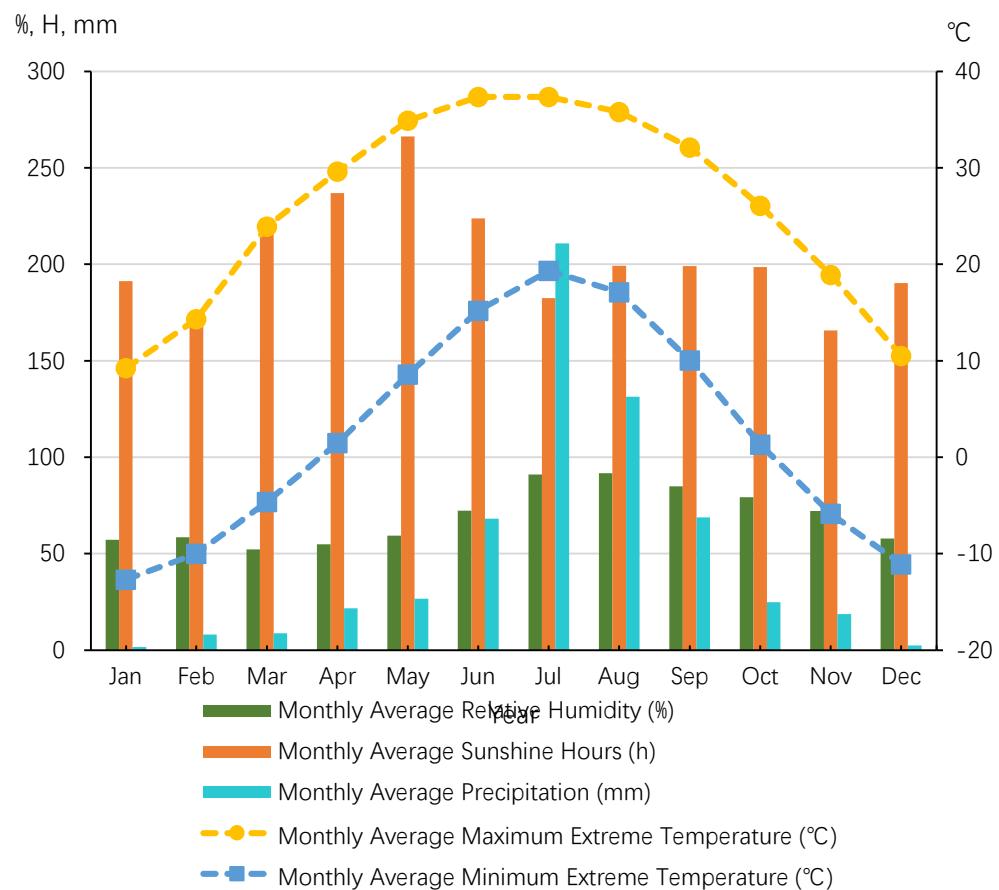

160 1. Overview of the Study Area

161

162 Beijing is located in a warm temperate monsoon semi-humid climate zone, characterized by a
163 cool mountain climate. The region has an average annual temperature of 10.8°C, with a frost-free
164 period of approximately 150 days. In winter, Beijing is influenced by cold air masses from the
165 northwest, resulting in a cold and dry climate. The prevailing wind direction during this season is
166 from the northwest, with an average annual wind speed of 1.9 meters per second. In summer, the
167 influence of the subtropical high-pressure system makes the climate hot, and rainfall is relatively

168 concentrated, especially from July to September, when about 85% of the annual precipitation occurs,
169 often in the form of heavy rain. Autumn in Beijing is generally pleasant, while spring is relatively
170 short. The frost-free period ranges from 190 to 200 days. Under extreme weather conditions, the
171 maximum summer temperature can reach 42°C, and the minimum winter temperature can drop to -
172 25°C. According to data from the National Meteorological Information Center of Beijing from 2009
173 to 2024, the annual precipitation in Beijing shows significant fluctuations (Fig. 2). There is no clear
174 trend in the annual average relative humidity and annual average precipitation, but there is an
175 increasing trend in the annual average sunshine hours and annual average extreme maximum
176 temperature, and a decreasing trend in the annual average extreme minimum temperature (Fig. 3).
177 During the period from 2009 to 2024, the multi-year average annual total rainfall was 610 mm.

190

191

192

193 The base of the Hall of Prayer for Good Harvests at the Temple of Heaven is divided into three
194 tiers (Fig. 1-a). Each tier of its white marble base is adorned with 100 intricately carved Chi Heads
195 (Fig. 1-b, Fig. 4). The Chi Head (Chi Shou) is a unique functional and decorative architectural
196 element in traditional Chinese architecture, inspired by the mythical hornless dragon-like creature
197 "chi" Resembling a dragon's head without horns, it is commonly found on the roofs, beams, columns,
198 and stone railings of palaces and temples. Its design integrates both aesthetics and practicality:
199 rainwater is channeled through hidden drainage holes in the Chi Heads, preventing water erosion of

200 the base while creating a distinctive visual effect. The three tiers of the altar collectively have a total
 201 of 300 Chi Heads, with the decorative themes progressively layered—dragon heads (Dragon Chi
 202 Heads) on the upper tier symbolize imperial authority, phoenix heads (Phoenix Chi Heads) on the
 203 middle tier represent auspicious harmony, and cloud patterns (Cloud Chi Heads) on the lower tier
 204 reflect the connection between heaven and earth. During the rainy season, water cascades from the
 205 mouths of the Chi Heads on all three tiers, creating a spectacular sight of "dragons spouting torrents,
 206 phoenixes holding pearls, and clouds rolling like waves." Over time, the weathering of the Chi
 207 Heads has varied significantly depending on their orientation (Fig. 4), vividly illustrating the
 208 dynamic interaction between ancient architectural elements and the natural environment.

210 Fig. 4 Rock surface temperatures and weathering conditions of the Cloud Chi Heads on the third layer of the

211 Hall of Prayer for Good Harvests at the Temple of Heaven in Beijing, China, on a sunny afternoon in April.

212 a: Cloud Chi Heads with complete decorative structures.

213 b: Cloud Chi Heads with partially weathered decorative structures.

214 c: Cloud Chi Heads with completely weathered decorative structures.

215 d: A simplified top view of the Hall of Prayer for Good Harvests shows that its base is divided into three tiers, with 100 Chi Heads

216 arranged along the edge of each tier. The Chi Heads exhibit different degrees of weathering. This article has documented the weathering of

217 the outermost layer of Cloud Chi Heads: Red indicates that the decorative structure of Cloud Chi Heads is completely weathered; Yellow

218 indicates that the decorative structure of Cloud Chi Heads is partially weathered; Green indicates that the decorative structure of Cloud Chi

219 Heads is still intact.

220 e: Statistical count of the number of Cloud Chi Heads with three different weathering degrees in four directions.

221 f: Calculation of the proportion of the three different weathering degrees of Cloud Chi Heads in different directions, revealing that the

222 weathering intensity of the Chi Heads is highest in the south, followed by the west, east, and north.

223

224 The main production area for Beijing marble is Dashiwo Town, located in the southwestern

225 part of Fangshan District, Beijing. In the distribution of marble layers in Fangshan, Bluish-white

226 marble is the first to be quarried due to its shallow burial depth. On the other hand, White marble is

227 found in the deepest layer, with a burial depth that is usually the deepest among the stone layers,

228 ranging from 90 cm to 150 cm in thickness. In the construction industry, both White marble and

229 Bluish-white marble are widely used as marble materials.

230

231 2 Research Methods

232 2.1 Field Work

233 Different forms of biofilm communities on the marble surface were collected (biofilms are

234 loose and easily detachable, so a small amount was gently picked by hand without damaging the

235 cultural relics), placed in specimen boxes, numbered, and photographed. The appearance, color, and

236 morphology of the biofilms were described, and the date and location were recorded. The micro-

237 morphologies formed by the dissolution of the biofilm communities were observed and

238 photographed. A total of 40 biofilm community specimens were collected, and 22 photographs of

239 the field biofilm communities were taken. On clear, sunny days, the surface temperature of the rock

240 in the sampling area was measured using an infrared thermometer (DL333380, Deli, China). At the

241 same time, the degree of weathering of the Chi Heads was marked on the overhead view of the Hall
242 of Prayer for Good Harvests. Chi Heads with complete surface ornamentation were marked in green,
243 those with incomplete ornamentation were marked in yellow, and those with completely weathered
244 and disappeared ornamentation were marked in red. Environmental humidity in different directions
245 was measured using a hygrometer (THM-H1, Delixi, China).

246

247 2.2 Laboratory Work

248 2.2.1 Microscopic Observation

249 The size, morphology, and color of the biofilm communities were observed using a
250 stereomicroscope (Szx7, Olympus, Japan). Then, temporary slides were prepared from different
251 colored biofilm communities and observed under a biological microscope (Bx51, Olympus, Japan).
252 The species of the biofilm communities were identified (Desikachary, 1959; Geitler, 1932; Komarek,
253 1998, 2005, 2013; Zhu, 1991; Fott, 1980; Hu and Wei, 2006), and photographs were taken. For each
254 biofilm community ecological specimen, a microslide was prepared, resulting in a total of 40
255 microslides, and 142 microscopic photographs were taken.

256 2.2.2 Biomass Statistics

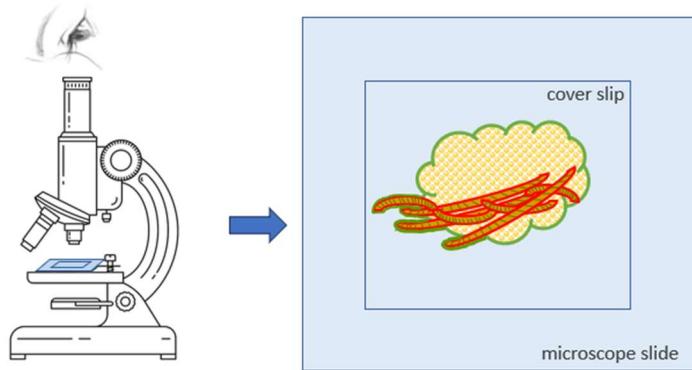

257 The volume percentage of the species in the biofilm communities was recorded. The volume
258 percentages of the species were statistically analyzed to calculate the relative volume (V_x , relative
259 biomass) and the relative volume percentage (Y_x , relative biomass percentage). The statistical and
260 calculation methods are as follows:

261 (1) Relative Volume (V_x , Relative Biomass)

262 To obtain the relative volume, the following steps need to be taken:

263 1) Determine the volume percentage ($v(x)\%$)

264 By estimating the percentage of the volume that each species occupies relative to the total
265 volume of all species in each microslide, the volume percentage ($v(x)\%$) of that species in the
266 microslide is obtained. The estimation can be based on the area occupied by each species in the
267 microslide, as within the same microslide, the thickness between the cover slip and the slide is nearly
268 uniform across different areas. Therefore, under the same thickness, the larger the area occupied by
269 a species, the greater its volume (Fig. 5).

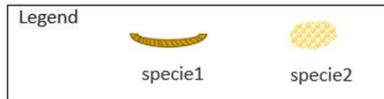

$$V(\text{Specie1})\% = \frac{\text{specie1 area} \times \text{high}}{(\text{specie1 area} + \text{specie2 area}) \times \text{high}} \times 100 \%$$

$V(\text{Specie1})\%$: volume percentage of specie1

area within the red line: specie1 area

area within the green line: specie1 area + specie2 area

270

271 Fig. 5 Visual Method for the volume percentage ($v(x)\%$) of a Specie
272 in a Biofilm Community Microslide

273 If there are two species in the microslide: Species 1 and Species 2, the volume percentage of Species 1 can be estimated by dividing the
274 area occupied by Species 1 by the total area occupied by both Species 1 and Species 2, and then multiplying by 100. This gives the volume
275 percentage ($v(x)\%$) of Species 1 in the microslide.

276

277 2) Sum the Volume Percentages

278 Add up the volume percentages of the same species across all microslides in the study area to
279 obtain the relative volume (Vx) of a species in the study area. The relative volume of a species
280 roughly reflects its relative biomass in the biofilm community of the study area. It does not represent
281 the actual volume but is an estimated relative value that is meaningful for comparison.

282

$$283 Vx = v(x)_{i_1} + v(x)_{i_2} + \dots + v(x)_{i_x}$$

284 i_x is the microslide number; x is a specific species ($x=a, b, c, \dots$); $v(x)_{i_x}\%$ is the volume percentage of
285 species x .

286 (2) Relative Volume Percentage (Yx , Relative Biomass Percentage)

287 This is the percentage of the relative volume (Vx) of a species in the biofilm community of the

288 study area relative to the sum of the relative volumes of all species in the biofilm community. It is
289 also referred to as the relative biomass percentage.

290

291
$$Y_x = \frac{V_x}{n \times 100} \times 100\%$$

292 n is the total number of microslides.

293

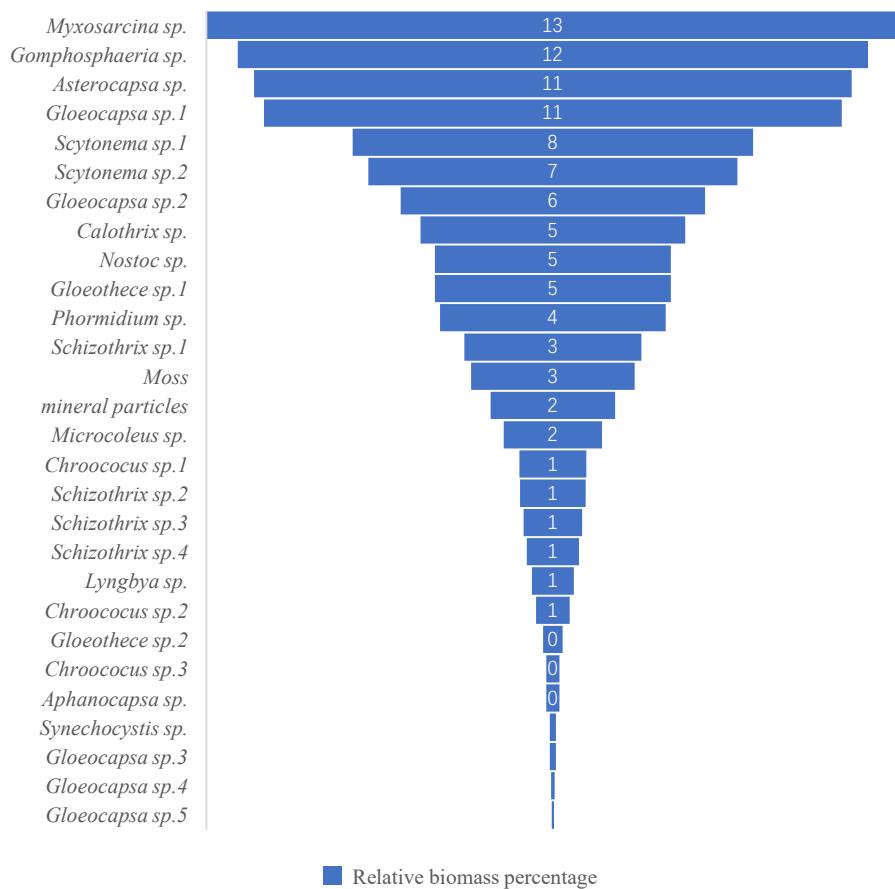

294 The relative volume percentage, also known as the relative biomass percentage, does not
295 represent the actual biomass. This is because it is currently very difficult to accurately measure the
296 biomass of biofilm communities on marble rock surfaces. By estimating through microscopic
297 observation, one can get a rough understanding of the growth status of the biofilm community. It is
298 a relative value and is meaningful only for comparative purposes.

299

300 3 Results

301 3.1 Distribution of communities in the Study Area

302 The composition of the biofilm communities on the marble surface in the study area includes
303 a total of 30 genera and species (Fig. 6). The most abundant species is *Myxosarcina* sp., followed
304 by *Gomphosphaeria* sp., *Asterocapsa* sp., *Gloeocapsa* sp.1 (Fig. 7), and *Scytonema* sp.1, among
305 others.

313 3.2 Characteristics of the distribution of biological communities on marble surfaces with
 314 different orientations in the study area

315 The Hall of Prayer for Good Harvests at the Temple of Heaven is a circular building (Fig. 4).
 316 The marble surfaces facing different directions receive varying amounts of sunlight. The south-
 317 facing surface receives the most sunlight, followed by the east and west-facing surfaces, which
 318 receive sunlight for half a day. The north-facing surface is shaded and receives no direct sunlight.
 319 This variation in sunlight exposure leads to differences in the biological populations on the rock
 320 surfaces. The details are discussed below:

321
 322 3.2.1 Characteristics of Biological communities on East-Facing Rock Surfaces

323 The biological communities on east-facing rock surfaces are primarily characterized by gray-
 324 white, gray-brown, brown, gray-black, black-brown, white, and black-brown leathery appearances.
 325 The main species include *Scytonema* sp.2, *Chlorococcum* sp., *Gloeocapsa* sp.2, *Gloeothece* sp.1,
 326 *Myxosarcina* sp., *Phormidium* sp., *Calothrix* sp., *Gloeothece* sp.2, *Lyngbya* sp., *Gloeocapsa* sp.5,
 327 and *Chroococcus* sp.1 (Fig.8) . Among these, the dominant species are *Scytonema* sp.2,
 328 *Chlorococcum* sp., accounting for 25% and 23% of the relative biomass percentage (Fig. 9) .

335 Prayer for Good Harvest in the Temple of Heaven, Beijing, China.

336

337 3.2.2 Characteristics of Biological communities on West-facing Rock Surfaces

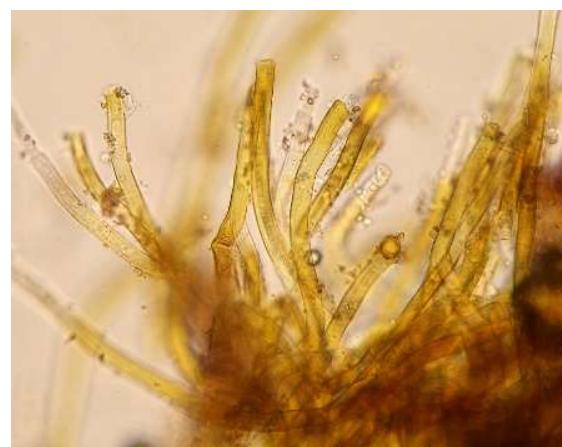

338 The biological communities on west-facing rock surfaces are primarily characterized by black
339 hairy, black membranous, yellow-green leathery, gray-black leathery, yellow-green, brown, and
340 gray-green appearances. The main species include *Scytonema* sp.1, mosses, *Schizothrix* sp.1,
341 *Myxosarcina* sp., *Asterocapsa* sp., *Gloeocapsa* sp.1, *Gomphosphaeria* sp., and *Gloeocapsa* sp.2 et
342 al (Fig. 10) . Among these, the dominant species are *Scytonema* sp.1 and mosses et al, accounting
343 for 28% and 20% of the relative biomass percentage respectively (Fig. 11) .

352 3.2.3 Characteristics of communities Distribution on North-facing Surfaces

353 The biological communities on north-facing rock surfaces are primarily characterized by gray-
354 brown membranous, brown, gray-black, yellow-green, black-brown, gray-white, brown crusty,
355 brown carpet-like, brown-black leathery, and brown-black membranous appearances. The main
356 species include *Myxosarcina* sp., *Gomphosphaeria* sp., *Gloeocapsa* sp.1, *Schizothrix* sp.1,
357 *Asterocapsa* sp., *Scytonema* sp.1, *Calothrix* sp., mosses, *Gloeocapsa* sp.2, *Microcoleus* sp.,
358 *Chroococcus* sp., *Gloeothecae* sp.1, *Lyngbya* sp., *Gloeocapsa* sp., *Scytonema* sp.2, and *Synechocystis*
359 sp. et al (Fig. 12) . Among these, the dominant species are *Myxosarcina* sp. and *Gomphosphaeria*
360 sp., accounting for 17% and 15% of the relative biomass percentage respectively (Fig. 13) .

371 3.2.4 Characteristics of communities Distribution on South-facing Surfaces

372 The biological communities on south-facing rock surfaces are primarily characterized by gray-
 373 green leathery, gray-white, gray-black membranous, black leathery, gray-black, brown-yellow, and
 374 green powdery layer appearances (Fig. 14) . The main species include *Scytonema* sp.1, *Nostoc* sp.,

375 *Asterocapsa* sp., *Myxosarcina* sp., *Phormidium* sp., *Gloeocapsa* sp.1, *Chroococcus* sp.1, *Schizothrix*
376 sp.4, *Microcoleus* sp., *Aphanocapsa* sp., *Chroococcus* sp.3, *Lyngbya* sp., *Gloeocapsa* sp.3, and
377 *Gloeocapsa* sp.4 et al (Fig. 15) . Among these, the dominant species are *Scytonema* sp.1 and *Nostoc*
378 sp., accounting for 25% and 20% of the relative biomass percentage respectively (Fig. 16) .

391

392 3.2.5 Comparison of communities on Different Orientations

393 The main aerophytic organisms on the rock surfaces include spherical cyanobacteria, small
394 filamentous cyanobacteria, and large filamentous cyanobacteria. Their distribution is primarily
395 influenced by the looseness of the substrate, sunlight, and moisture. From spherical cyanobacteria
396 to small filamentous cyanobacteria and then to large filamentous cyanobacteria, the requirement for
397 substrate looseness increases, the need for moisture decreases, and the requirement for sunlight
398 duration increases. Mosses, however, prefer shady and moist environments.

399 Although both the east and west-facing surfaces of the Hall of Prayer for Good Harvests in the
400 Temple of Heaven receive sunlight for half a day (Table 1), the east-facing surface receives sunlight
401 in the morning when the rock surface temperature is lower. Even with sufficient sunlight, the growth
402 of organisms on the east-facing surface is not as robust as on the west-facing surface. The west-
403 facing surface receives sunlight in the afternoon when the rock surface temperature is higher,
404 providing both water and heat conditions that are more favorable for biological growth. This results
405 in the presence of *Scytonema sp.1*, a cyanobacterium that prefers looser substrates, and more mosses,
406 leading to more severe weathering on the west-facing surface. The north-facing surface, being in
407 the shade, has slower evaporation rates and is mainly colonized by spherical cyanobacteria, resulting

408 in relatively weaker weathering. The south-facing surface receives more sunlight and weathers faster,
409 with the carved decorations on the rock surface completely destroyed (Fig. 14a). The matrix is
410 highly loose, and even large filamentous cyanobacteria like *Nostoc*, which typically prefer to live
411 in soil rather than on rock surfaces, are present. This indicates that the south-facing marble has
412 weathered severely, forming a loose, soil-like thick weathering layer. Additionally, *Scytonema* sp.1,
413 a species that thrives in sunny and dry environments and plays a significant role in bioweathering,
414 is also present. Mosses are not found on the south-facing side because they prefer shady and moist
415 environments. The orientation of the building, through differences in sunlight duration and
416 evaporation rates, creates a unique gradient of microhabitats, which in turn drives the differential
417 distribution of microbial communities and is accompanied by varying degrees of weathering
418 depending on the direction.

419 To further understand the environmental differences and weathering conditions of the rock
420 surfaces at the Hall of Prayer for Good Harvests in the Temple of Heaven, temperature
421 measurements were taken on a sunny afternoon in April (Fig. 4). The rock surface temperatures
422 were found to be highest in the southwest and lowest in the northwest. The Hall of Prayer for Good
423 Harvests was divided into four natural sectors, each centered on a cardinal direction and covering
424 45° to either side: North (N): 315°-45°, centered on true north, covering from northwest to northeast;
425 East (E): 45°-135°, centered on true east, covering from northeast to southeast; South (S): 135°-
426 225°, centered on true south, covering from southeast to southwest; West (W): 225°-315°, centered
427 on true west, covering from southwest to northwest. The weathering degree of 100 Cloud Chi Heads
428 on the third layer was statistically analyzed in each sector. The results showed that 40% of the south-
429 facing Cloud Chi Heads decorations were completely weathered, indicating the most severe
430 weathering. The weathering degrees for the west, east, and north sectors decreased in that order.
431 This pattern is consistent with the distribution of biological organisms on the rock surfaces, as shown
432 in Table 1. The analysis of the weathering degree of 100 Cloud Chi Heads on the third layer showed
433 that 40% of the south-facing Cloud Chi Heads decorations were completely weathered, indicating
434 the most severe weathering. The weathering degrees for the west, east, and north directions
435 decreased in that order. This pattern is consistent with the differences in weathering in different
436 directions revealed by the distribution of biological organisms on the rock surfaces (Table 1).

Table 1

Environmental characteristics and dominant species of marble surface of the Hall of Prayer for Good

Harvests at the Temple of Heaven in Beijing, China.

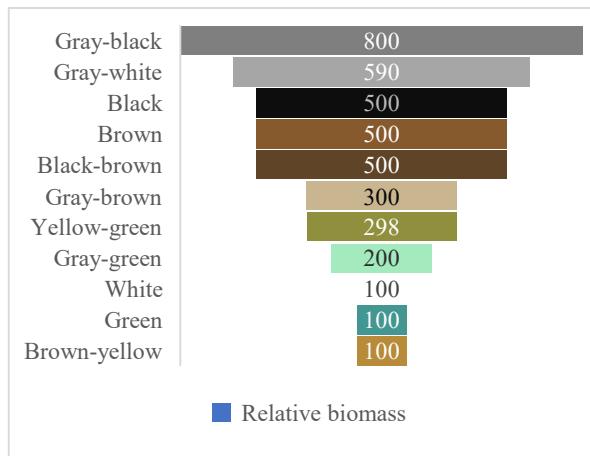

Marble Surface		Environmental Characteristics			Dominant Species	Weathering degree
Orientation	Sunlight	Moisture				
North-facing	None	Slow evaporation	Cold and humid		Spherical cyanobacteria	
East-facing	Half day	Rapid evaporation in the morning	Warm and humid		Small filamentous cyanobacteria, Spherical cyanobacteria	Weak
West-facing	Half day	Rapid evaporation in the afternoon	Hot and humid		Small filamentous cyanobacteria, Mosses	
South-facing	Full day	Rapid evaporation during the day	Hot and dry		Small filamentous cyanobacteria, Large filamentous cyanobacteria	Strong

442 **3.3 Relative Biomass of Different Colored Biological Communities on Rock Surfaces in the Study**443 **Area**

444 The colors displayed by organisms on rock surfaces differ from those observed under a
 445 microscope. In this paper, the former is referred to as the "visual color," while the latter is called the
 446 "microscopic color." The visual color is the community color presented when different populations
 447 aggregate together, whereas the microscopic color is the color of different species observed under
 448 magnification through a microscope. Often, communities of cyanobacteria with different
 449 microscopic colors appear mostly black or gray-black of visual color.

450 The visual colors of biological communities on rock surfaces in the study area can be
 451 categorized into gray-black, gray-white, black, brown, black-brown, gray-brown, yellow-green,
 452 gray-green, white, green, and brown-yellow. Their relative biomass is shown (Fig. 17) . The most
 453 common color is gray-black, followed by gray-white, black, brown, and black-brown. These are

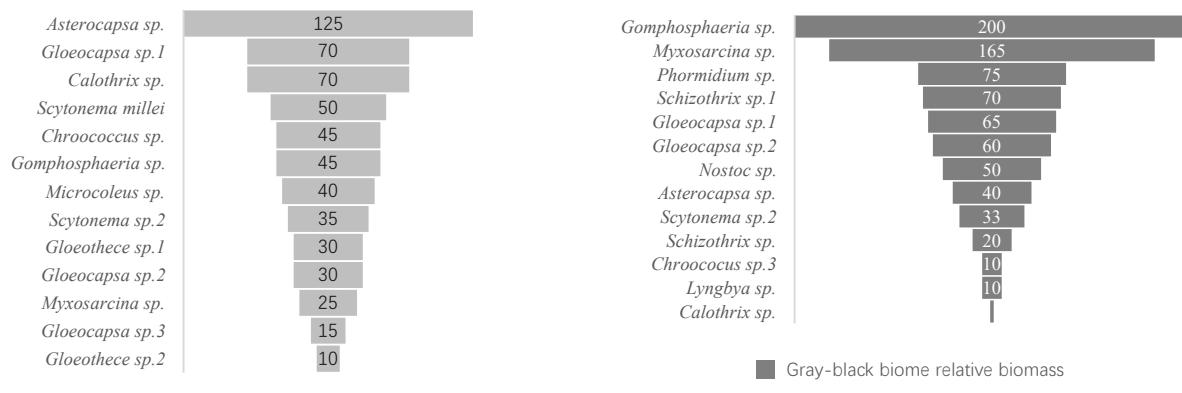

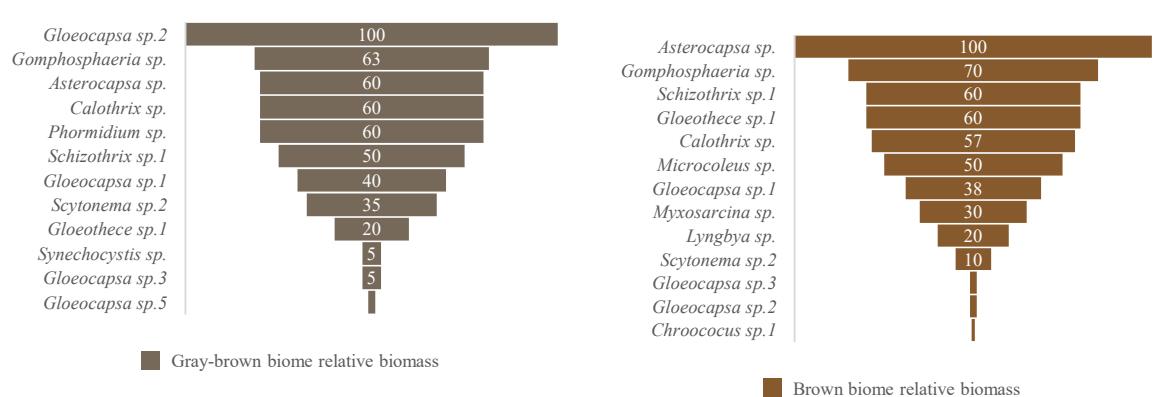

454 also typical colors exhibited by aerophytic cyanobacteria in the field, sometimes referred to as "ink
455 bands." For example, the Nine Horses Fresco Hill (Jiuma Huashan) in the Guilin landscape of China
456 is formed due to aerophytic cyanobacteria growing on the rocks, creating black ink-like bands.

457
458 **Fig. 17** Relative biomass of biomes with different colors on the marble surface of the Hall of Prayer for Good
459 Harvests at the Temple of Heaven in Beijing, China.

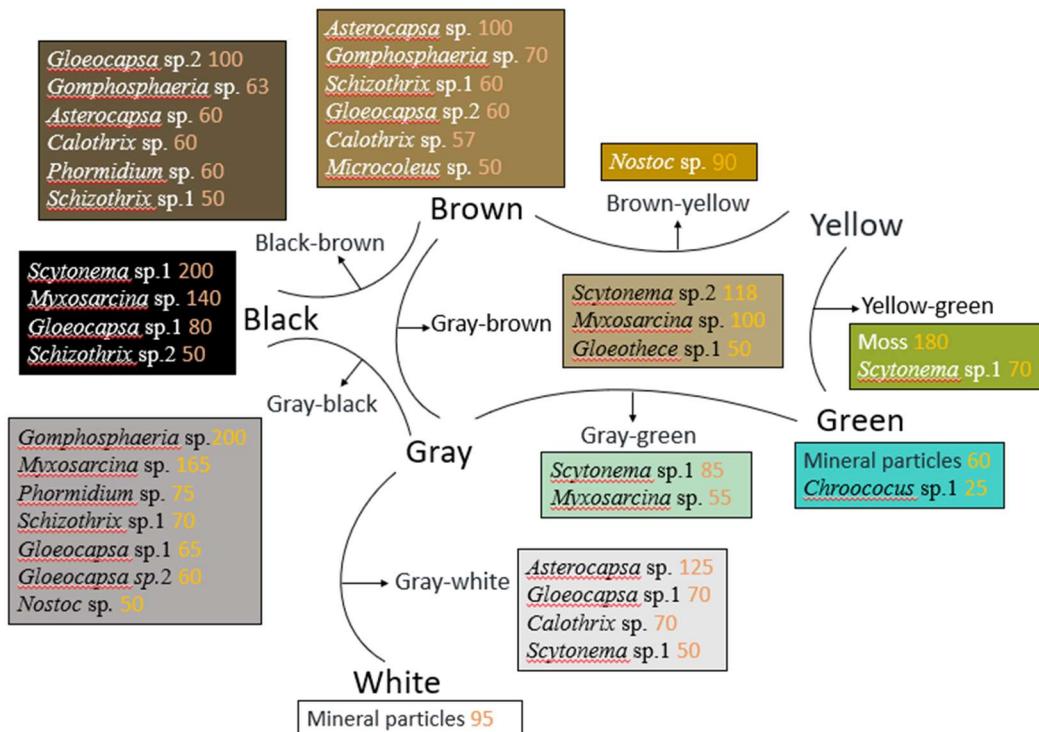

460
461 3.4 Relative biomass of communities' composition in different colored biological communities on
462 rock surfaces in the study area

463 The relative biomass of different visual color biotic communities on the rock surface in the
464 study area is shown (Fig. 18). An analysis of the main population compositions of these biological
465 communities is presented (Fig. 19). The colors of biological communities on rock surfaces in the
466 study area are primarily composed of black, brown, gray, green, and yellow, as well as combinations
467 of these colors (gray-black, gray-white, black-brown, gray-brown, yellow-green, gray-green, and
468 brown-yellow). The correlation between color combinations and population composition is not very
469 apparent, which also indicates that determining microscopic color (population composition) through
470 visual color is a complex and difficult task. Nevertheless, some patterns can be observed: Species
471 like *Scytonema* sp.1, *Myxosarcina* sp., *Asterocapsa* sp., *Gomphosphaeria* sp., and *Gloeocapsa* sp.2
472 tend to make the community color darker, presenting as black, brown, gray, or combinations of these;
473 The parts that have a visual color of white are minerals, not biological organisms, under microscopic
474 observation; the areas with a visual color of green (mainly referring to the characteristic blue-green
475 of cyanobacteria) are mineral particles and *Chroococcus* sp.1; the areas with a visual color of
476 yellow-green are mainly mosses; the areas with a visual color of brown-yellow are mainly *Nostoc*

479 **Fig. 18.** Relative biomass of community composition of different colors on marble surface of the Hall of Prayer for
480 Good Harvests at the Temple of Heaven in Beijing, China.

485

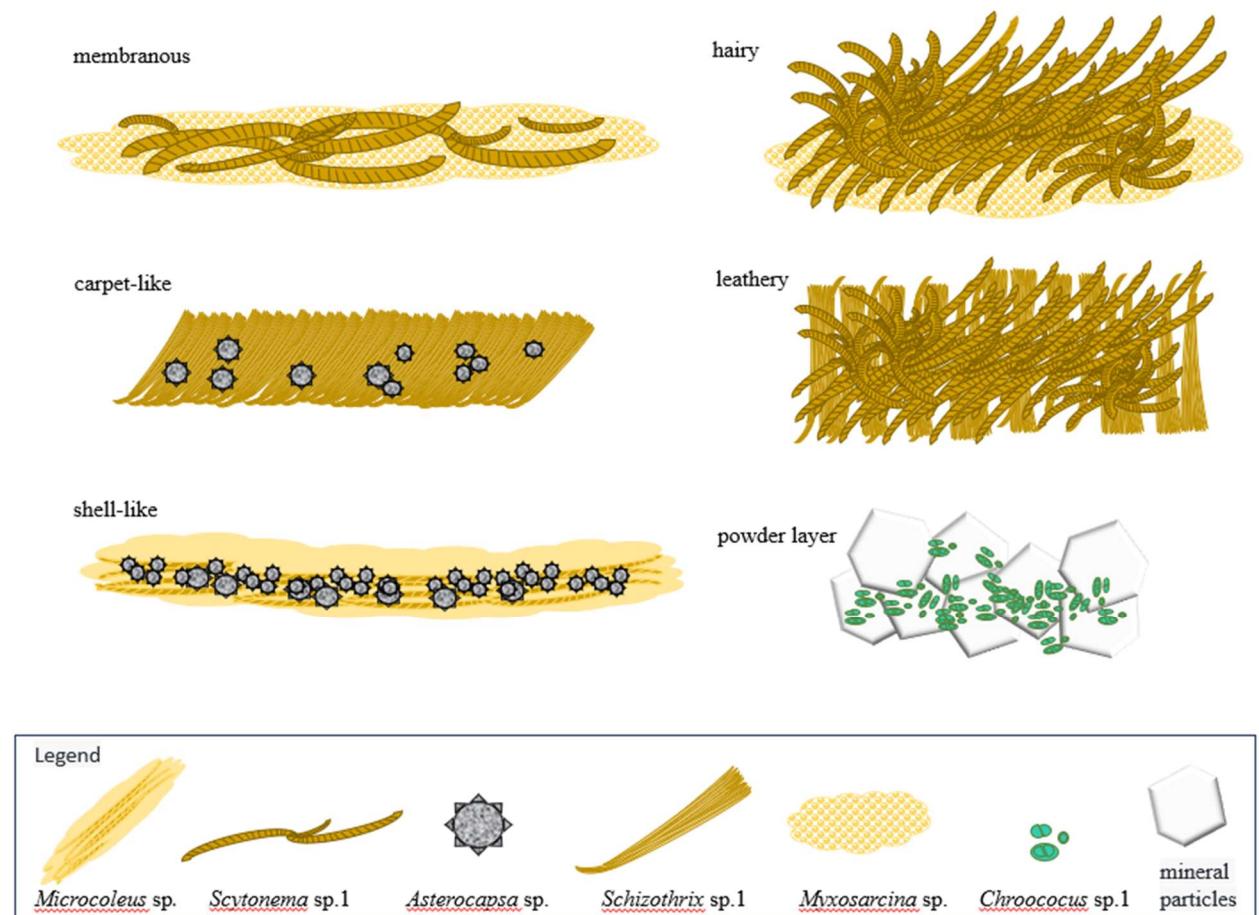

486 3.5 Relative biomass of communities composition in different morphological biological
487 communities on rock surfaces in the study area

488 The biological communities on rock surfaces in the study area exhibit different morphologies,
489 including membranous, hairy, carpet-like, leathery, shell-like, and powdery layers. Their relative

490 biomass of population composition is shown (Fig. 20). A conceptual diagram of the formation of
 491 these community morphologies is presented (Fig. 21).

492 **Fig. 20.** Relative biomass of different forms of community on marble surface of the Hall of Prayer for Good
 493 Harvests at the Temple of Heaven in Beijing, China.
 494

510 intertwines, with *Schizothrix* sp.1 interspersed within (Fig. 21). The dominant species in the shell-
511 like biological communities are mainly *Microcoleus* sp. and *Asterocapsa* sp. The former accounts
512 for a relative biomass of 50, while the latter accounts for 30 (Fig.20). *Microcoleus* sp. has well-
513 developed sheaths, with multiple algal filaments inside each sheath. The sheaths of multiple
514 *Microcoleus* sp. aggregate to form a mucilaginous layer, with *Asterocapsa* sp.1 dispersed within.
515 When the mucilaginous layer dries, it cracks into numerous small pieces. The edges of each piece
516 detach from the rock surface and curl up, forming a shell-like structure (Fig. 21 and Fig. 22) . The
517 powder layer is a severely weathered surface (Fig. 14d). Under microscopic observation, it mainly
518 consists of mineral particles and *Chroococcus* sp.1, with the former accounting for 60 and the latter
519 for 20 of the relative quantity (Fig. 20). *Chroococcus* sp.1 is distributed on the surface and in the
520 crevices of mineral particles (Fig. 15a and b). The color of the community appears as a mixture of
521 the green color of *Chroococcus* sp.1 (or the blue-green color characteristic of cyanobacteria) and the
522 white color of mineral particles.

523

524 3.6 Bioweoathering on Rock Surfaces in the Study Area

525 The growth distribution of aerophytic organisms on rock surfaces in the study area is closely
526 related to the surface smoothness and texture of marble (Table 2). If the marble surface is uneven or
527 has a non-uniform texture, the aerophytic organisms' communities will be distributed in a spotted
528 pattern (Fig. 22a). Dissolution forms solution pits and cavities (Fig. 22b), which further expand into
529 solution basins (Fig. 22c, d). If the marble surface has linear textures or non-uniform texture with
530 joint stripes, the aerophytic organisms' communities will be distributed in a linear pattern (Fig. 22e).
531 Dissolution forms solution marks and grooves (Fig.22f), which further expand into solution
532 channels (Fig. 22g). If the marble surface is smooth and has a uniform texture, the aerophytic
533 organisms' communities will be distributed in a planar pattern (Fig. 22h). Dissolution forms a
534 weathering layer or spalling layer (Fig. 22i).

535

536 **Table 2**

537 Characteristics of the Marble Surface of the Hall of Prayer for Good Harvests in the Temple of
538 Heaven, Beijing, China, and the Process of Biological Erosion on Its Surface.

Marble Characteristics	Biological Community		Resulting Dissolution	Development
	Distribution	Forms		Process
Uneven surface or non-uniform texture	Spotted distribution		Solution pits, cavities, and basins	
Surface with linear textures or non-uniform texture with joint stripes	Linear distribution		Solution marks, grooves, and channels	
Smooth surface with uniform texture	Areal distribution		Weathering layer, spalling layer

541 **Fig. 22** Bioweathering forms on the marble surface of the Hall of Prayer for Good Harvests in the Temple of
542 Heaven, Beijing, China.

543

544

545 The spotted distribution of biological communities gradually expands into linear distribution,
546 and then into areal distribution. Solution pits, basins, and cavities also further enlarge their
547 dissolution forms, developing into solution marks, grooves, and channels. For example, in the study

548 area, the weathering process of white marble “Cloud Chi Head” begins with the accumulation and
549 growth of organisms in the low-lying areas of the cloud patterns (Figures 23a, b). These areas retain
550 more moisture, so they are the first to undergo bioweaethering, forming deeper solution cavities and
551 channels. The communities then gradually spread to the surrounding areas, developing into linear
552 distributions, and then areal distributions, leading to flaking of the rock surface (Fig. 23c). This
553 partially destroys the pattern structure, further expanding the area and depth of dissolution, forming
554 a loose powder layer (Fig. 14a, d; Fig. 15a, b; Fig. 4b, c; Fig. 23d, e).

555

557 Heaven, Beijing, China.

558

559 **4 Discussion**

560 (1) This study focuses on the cyanobacterial and bryophyte communities that can be observed
561 using biological microscopy. The current scope of the research has not yet covered other microbial
562 groups. To determine whether other bacterial groups exist on the surface of stone cultural relics and
563 to understand their ecological functions, further systematic verification through subsequent studies
564 is still needed. At the methodological level for the classification and identification of cyanobacteria,
565 traditional morphological identification, although it may lead to taxonomic deviations at the genus
566 and species levels, molecular biology methods also face technical bottlenecks. For special samples
567 like biofilms on stone cultural relics, molecular testing typically requires microbial samples with a
568 high purity of more than 0.2 grams. However, in actual sampling, due to restrictions on cultural relic
569 protection, sometimes only trace amounts of less than 0.01 grams can be obtained. While such low
570 sample quantities are sufficient for morphological identification under a biological microscope, they
571 pose significant challenges for molecular biology methods. Low DNA extraction efficiency and
572 significant amplification bias from such small samples can result in decreased taxonomic resolution.
573 Furthermore, there has been long-standing controversy in the taxonomy of cyanobacteria. The
574 conflict between traditional morphological classification and molecular systematics has led to a
575 dynamic revision of the taxonomic framework. This makes it difficult to match taxonomic
576 information when annotating environmental samples using 16S rRNA gene sequence databases
577 (Lefler, et al., 2023). Future research should aim to construct a multidimensional identification
578 system, integrating microscopic observation, culturomics, and metagenomics, to gradually establish
579 classification standards and databases suitable for the study of microorganisms in cultural heritage.
580 This will be an important direction for the development of methodologies in this field.

581 (2) The differential weathering characteristics of the Cloud Chi Heads on the Hall of Prayer for
582 Good Harvests, as well as the directional differences in the spatial distribution of organisms on the
583 rock surface, show significant consistency. This correspondence confirms the scientific validity of
584 the visual analysis method based on the relative volume and the relative volume percentage
585 determined by microscopic observation. This method, through the analysis of micro-scale biotic
586 community features, can effectively reflect the differences in weathering processes in the macro-

587 environment, providing an important reference for establishing the correlation between micro-
588 observation indicators and macro-environmental factors.

589 (3) The bioweathering process of the marble at the Hall of Prayer for Good Harvests in the
590 Temple of Heaven is controlled by both macro-hydrological dynamics and micro-surface
591 topography: On a macro scale, in areas with low flow during heavy rain (raised areas), water quickly
592 drains away, resulting in sparse biofilms and weak bioweathering. In high-flow areas during heavy
593 rain (water-collecting grooves), the extended water retention time leads to the formation of "ink
594 bands" rich in cyanobacteria, resulting in strong bioweathering. On a micro scale, the micro-
595 topographic features of the rock determine the colonization patterns of organisms by regulating local
596 hydrological conditions—irregular rough surfaces induce point-like biological aggregation due to
597 discrete water films, leading to the development of solution pores and pits; linear decorations or
598 joint surfaces promote linear biological expansion due to directional water storage, forming solution
599 marks and grooves; smooth and dense surfaces support planar biological growth due to uniform
600 water film coverage, ultimately leading to the overall peeling of the weathered layer. This coupled
601 mechanism reveals that, in addition to the different sunlight exposure on the rock surface caused by
602 orientation, the synergistic regulation of spatiotemporal water distribution and rock surface
603 characteristics is also an important reason for the different distribution of biological communities
604 on stone cultural relics. Some studies also suggest that the type of stone, its position on the building,
605 and the surface roughness of the stone greatly influence biological growth (Korkanç and Savran,
606 2015). Some organisms (such as cyanobacteria and lichens) also bore into the marble, forming a
607 hard, black, porous layer (Golubić, et al., 2015). The biological black crust on marble is often
608 attributed to physical and inorganic chemical causes such as dust, which also need to be taken into
609 account.

610 (4) The connections and issues between different research levels, methods, and results in this
611 paper.

612 Connections and issues between different research levels, methods, and results in this paper.
613 This paper studies the aerophytic organisms on rock surfaces in the research area in terms of
614 biological community population composition, community color and morphology, and community
615 distribution characteristics (Table 3). The spotted, linear, and planar distributions of biological
616 communities on rock surfaces in the study area are composed of many microcommunities. These

617 microcommunities exhibit different morphologies, including membranous, hairy, carpet-like,
618 leathery, shell-like, and powder layers. Spotted, linear, and areal distributions of biological
619 communities may be composed of one type of microcommunity or multiple types.
620 Microcommunities are further composed of multiple populations, and a population consists of
621 multiple individual organisms of the same species.

622 Community distribution characteristics are observed with the naked eye, without
623 magnification. Community color and shape are observed through stereomicroscopes and the naked
624 eye, magnifying objects 8-56 times (or no magnification if observed with the naked eye). Biological
625 community population composition is identified through biological microscope observation,
626 magnifying objects 40-1000 times. This represents three stages of research with increasing
627 magnification of the research object: 1) Distribution area; 2) Community; 3) Population. Research
628 at each stage is relatively easy to conduct, but the connections between stages are challenging and
629 represent a key focus of this paper. For example, to accurately correlate different colored and shaped
630 communities with their precise population compositions (i.e., connecting the community stage with
631 the population stage) requires statistical analysis of numerous specimens to improve accuracy.
632 Additionally, for outdoor observations of communities, which involve the transition between the
633 distribution area stage and the community stage, the primary method is still visual observation with
634 the naked eye. Only a small number of observations are conducted using stereomicroscopes because
635 detailed stereomicroscopic observations that require photography must be done indoors. Sampling
636 of cultural relics in scenic areas is extremely limited and must be carried out without damaging the
637 relics. To address this issue, one approach is to enhance the performance of observation equipment
638 to allow for in situ biological community observations outdoors without sampling, or to perform
639 minimal sampling.

640 **Table 3**

641 Analysis of Research Levels in the Study on aerophytic organisms on marble of the Hall of Prayer for Good
642 Harvests in the Temple of Heaven, Beijing, China.

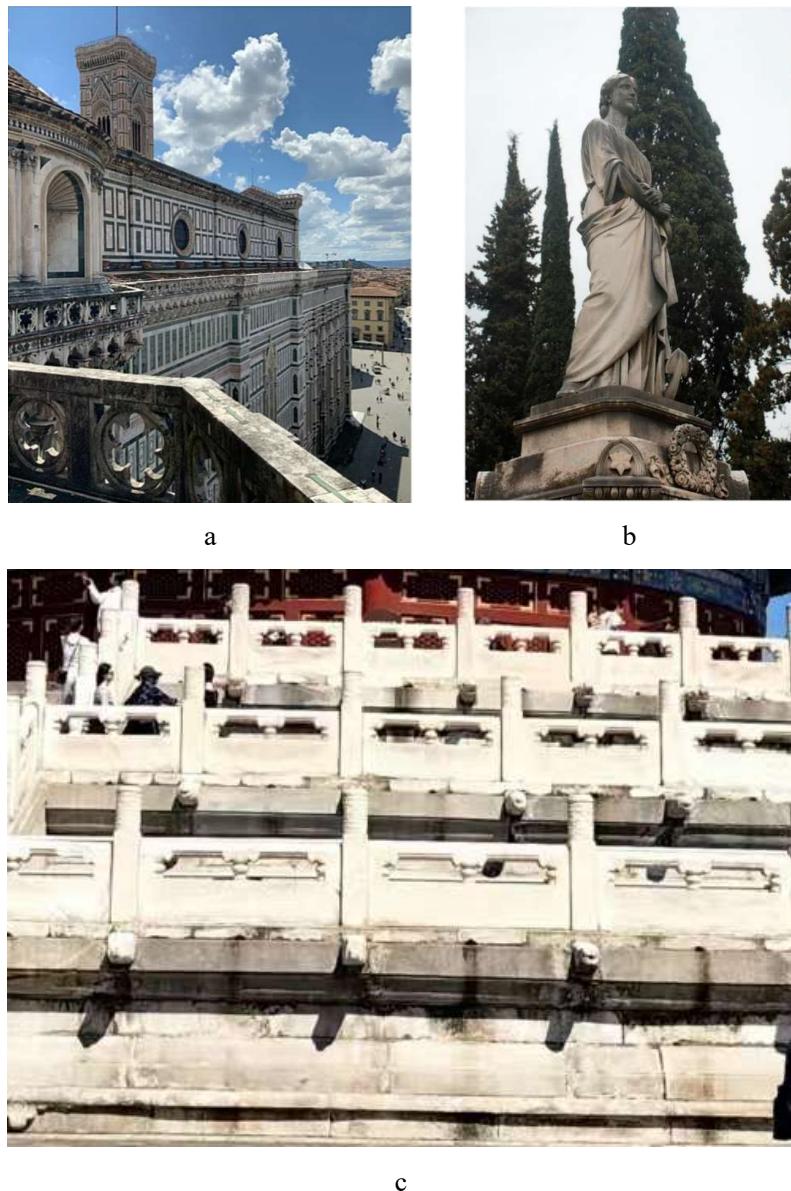

Research Level	Distribution Area	Community	Population
Observation Method	Naked eye	Stereomicroscope, naked eye	Biological microscope
Magnification	0	8-56, 0	40-1000

		11 colors:		
		gray-black, gray-white,		
		black, brown, black-brown,	30 genera and	
		gray-brown, yellow-green,	species :	
	3 distribution characteristics	gray-green, white, green,	<i>Myxosarcina</i> sp.,	
Classification	(point, linear, and areal distribution)	brown-yellow	<i>Gomphosphaeria</i> sp.,	
		6 morphologies:	<i>Asterocapsa</i> sp.	
		membranous, hairy, carpet-	and so on (Fig.5)	
		like, leathery, shell-like, and		
		powder layer		
	Composition	Composed of multiple communities	Composed of multiple populations	Composed of multiple individuals of a single species

643

644 (5) In this study, the weathering intensity of the Hall of Prayer for Good Harvests in the Temple of
 645 Heaven is south-facing > west-facing > east-facing > north-facing, while the metabolic activity of
 646 the microbial communities on the southeast side of the marble in Florence Cathedral is higher than
 647 that on the northwest side (Checcucci, et al., 2022). It is evident that the weathering of stone cultural
 648 relics exhibits directional differences, and these directional differences vary in different climate
 649 zones. When studying the microenvironment of rock surfaces, temperature is relatively easy to
 650 measure, but humidity is difficult to measure accurately due to the significant influence of wind
 651 disturbances, which can lead to measurement failures. Therefore, more effective methods are needed
 652 to address this issue. Another comparison can be made between the marble relics of the Cathedral
 653 of Santa Maria del Fiore in Florence, Italy, and the Speranza statue (the Cathedral of Santa Maria
 654 del Fiore was completed in 1887 and is 135 years old; the Speranza statue was built in 1863 and is
 655 158 years old). The growth of black biofilm on these structures is significantly more extensive and
 656 faster than that on the Hall of Prayer for Good Harvests at the Temple of Heaven in Beijing (built
 657 in 1420 and 605 years old). The primary reason for this difference is the climate. Florence has a
 658 Mediterranean climate with high rainfall (about 850 mm) (Venturi et al., 2020), while Beijing has a
 659 temperate monsoon climate with low annual rainfall (During the period from 2009 to 2024, the

660 multi-year average annual total rainfall was 610 mm, according to data from the National
661 Meteorological Science Data Center Website.). Therefore, water is the primary factor determining
662 the growth rate and distribution area of the black biofilm on marble. Additionally, the different
663 physical properties of marble in the two locations should also be considered.

664 Fig. 24: Comparison of Black Biofilm Growth on Marble Relics in Florence and Beijing

665 a. Cathedral of Santa Maria del Fiore in Florence (façade completed in 1887, 138 years old, using white, green, and pink marble), with a
666 large area covered by black biofilm (Santo, 2023);
667 b. Speranza statue in Florence (built in 1863, 158 years old, using white marble), with a large area covered by black biofilm (Mascalchi,
668 2018);
669 c. The Hall of Prayer for Good Harvests at the Temple of Heaven in Beijing (built in 1420, 605 years old, using white and bluish-white

670 marble), with a small area covered by black biofilm, mainly distributed in areas with high runoff from sudden rain.

671 (6) The species in the study area, such as *Scytonema* sp.2, are also common aerophytic cyanobacteria

672 found on limestone surfaces (Tian, et al., 2002; Tian, et al., 2003; Tian, et al., 2004). They prefer

673 calcareous environments, are drought-resistant, grow slowly, and have extremely strong vitality.

674 The mechanism of dissolve rocks primarily involves the biological need to obtain inorganic

675 nutrients such as calcium and magnesium ions from the rock. Aerophytic organisms can secrete

676 organic acids, which release calcium and magnesium ions from the rock, providing the inorganic

677 nutrients necessary for their growth and development. Through this acid dissolution process,

678 aerophytic organisms can "eat away" at the rock, forming small hemispherical dissolution pits. This

679 process damages the surface structure of the rock, leading to the formation of an underlying

680 weathering layer (Tian, et al., 2004). In addition, various forms of cyanobacterial communities in

681 extremely arid environments, such as on rocks, develop thicker exopolysaccharide (EPS) sheaths to

682 retain intracellular water. The EPS sheath undergoes contraction and expansion in response to

683 changes in weather conditions, accelerating the disintegration of rock particles on the surface of

684 rocks. This process is very similar to microbial weathering in the Atacama Desert (Jung, et al., 2020).

685 Both processes involve the swelling of the EPS due to water absorption, leading to the deformation

686 of the biofilm and the detachment of the rock surface at the community scale. This results in the

687 expansion of patchy weathering into a more extensive weathering layer (such as the Atacama

688 terrestrial protopedon or the powdery layer at the Temple of Heaven) at the landscape scale. The

689 mechanism involves the tensile stress generated by the swelling of the EPS exceeding the local

690 tensile strength of the rock, initiating cracks (such as grain boundary cracking in the Atacama and

691 mineral particle detachment at the Temple of Heaven). These cracks provide pathways for chemical

692 and biological erosion, leading to an expanded pore/crack network, increased water retention time,

693 enhanced biological activity, and further swelling, creating a self-reinforcing weathering loop. It is

694 clear that the swelling effect plays a crucial role as a "physical engine" in microbial bioweathering.

695 Future research should focus on cross-scale mechanical modeling: scaling up the swelling force of

696 microbial EPS (at the nN level) to the point of rock fracture (at the MPa level) to reveal the

697 mechanisms of scale transition; quantifying the impact of changes in fog/rain patterns under global

698 warming on the frequency of biological swelling, to warn of accelerated weathering risks; and

699 recognizing that swelling not only acts as a "trigger" for rock destruction but also serves as a key

700 link between biological activity and surface processes. Its universality across different environments
701 provides a new perspective for understanding the evolution of the Earth's critical zone.

702

703 5 Conclusion

704 (1) The most dominant species on marble surfaces in the study area is *Myxosarcina* sp., followed
705 by *Gomphosphaeria* sp., *Asterocapsa* sp.1, *Gloeocapsa* sp.1, and *Scytonema* sp.1. These
706 aerobic cyanobacteria prefer calcareous environments, are drought-tolerant, slow-growing, and
707 extremely resilient.

708 (2) The biological population composition on marble surfaces facing different directions of the Hall
709 of Prayer for Good Harvests in the Temple of Heaven varies due to differences in sunlight
710 exposure. The east-facing side, warm and humid, mainly hosts small filamentous and spherical
711 cyanobacteria such as *Scytonema* sp.2 and *Gomphosphaeria* sp. The west-facing side, hot and
712 humid, primarily features *Scytonema* sp.1 and mosses, with *Scytonema* sp.1 being small
713 filamentous cyanobacteria. The north-facing side, cold and humid, mainly supports spherical
714 cyanobacteria like *Myxosarcina* sp. and *Gomphosphaeria* sp. The south-facing side, hot and dry,
715 primarily hosts small or large filamentous cyanobacteria such as *Scytonema* sp.1 and *Nostoc*
716 sp.. The observed weathering intensity in different directions is: south > west > east > north,
717 which is entirely consistent with the varying degrees of weathering reflected by the Cloud Chi
718 Heads in each direction. This indicates that the visual analysis method based on the relative
719 volume and relative volume percentage of species, as determined by microscopic observation
720 and statistical analysis, is scientifically valid.

721 (3) Rock surface biological communities in the study area display various colors, with gray-black
722 being the most common, followed by gray-white, black, brown, and brown-black. Gray-black
723 communities are mainly composed of *Myxosarcina* sp. and *Gomphosphaeria* sp.

724 (4) Rock surface biological communities in the study area exhibit different morphologies, including
725 membranous, hairy, carpet-like, leathery, shell-like, and powder layers. Different morphologies
726 correspond to different population compositions.

727 (5) In addition to sunlight exposure, the growth of aerial organism on the rock surfaces in the study
728 area is also controlled by macro-hydrological dynamics and micro-surface topography. On a
729 macro scale, in areas with low flow during heavy rain, the biofilm is sparse, and the

730 bioweathering effect is weak. In areas with high-flow areas during heavy rain, "ink bands" rich
731 in cyanobacteria form, leading to strong bioweathering. On a micro scale, the microtopographic
732 features of the rock regulate local hydrological conditions, determining the colonization
733 patterns of the organisms: On uneven or heterogeneous marble surfaces, aerial organism
734 communities are distributed in patches, leading to the formation of solution pores, cavities, and
735 pits; On marble surfaces with linear patterns or heterogeneous textures with joint lines, aerial
736 organism communities are distributed in linear patterns, leading to the formation of solution
737 marks, grooves, and channels. On flat and homogeneous marble surfaces, aerial organism
738 communities are distributed in a planar pattern, leading to the formation of weathering layers
739 or spalling layers. The thicker exopolysaccharide (EPS) sheath of aerophytic cyanobacteria can
740 undergo contraction and expansion, thereby accelerating the disintegration of rock particles on
741 the surface of rocks. Preventing or reducing the growth of aerial organism is key to slowing
742 down the bioweathering process of the marble at the Hall of Prayer for Good Harvests in the
743 Temple of Heaven.
