## ABSTRACT

Chlorinated and brominated polycyclic aromatic hydrocarbons (XPAHs) are emerging pollutants widely found in atmospheric particulate matter (PM). However, their environmental transformation mechanisms remain poorly understood. In this study, we collected PM samples of varying sizes over a year for XPAH analysis and found that the average concentrations of XPAHs peaked in winter and were dominated by the contribution of PM<sub>1</sub> (47.0%). Correlation analysis with relevant meteorological parameters showed strong associations between XPAH fluctuations and PM, temperatures, and humidity. Hence, controlled laboratory experiments were conducted to explore the influence of particle size, sunlight duration, temperature, humidity, and oxidant concentrations on XPAHs ~~transformation~~. Our results indicated that the transformation rates of XPAHs were influenced by the parent polycyclic aromatic hydrocarbon structures, with phenanthrene < fluoranthene < pyrene < benz[a]anthracene  $\approx$  anthracene < benzo[a]pyrene, as well as the substitution of halogens: chlorinated < brominated. Furthermore, the photo irradiation promoted the heterogeneous transformation of XPAHs ~~;~~ this process was with this process being accelerated by the increased concentrations of reactive oxygen species and elevated temperature, peaking at the humidity level of 45%. The transformation products were identified by nontarget analysis. Accordong to that, We-we then proposed phototransformation pathways for XPAHs, suggesting a mechanism involving ~~dechlorination~~ dehalogenation followed by oxidation. Predictions were made regarding the persistence, bioaccumulation, long-range transportation, and toxicities of XPAHs and their transformation products, showing a decrement in environmental risks as the transformation progressed. This study provides novel insights into the primary influencing factors for particulate XPAH variations and the mechanisms of heterogeneous phototransformation.

**KEYWORDS:** Photochemistry; Influencing factors; Heterogeneous phototransformation; Transformation mechanism; Transformation pathways;

## 1. Introduction

Chlorinated and brominated polycyclic aromatic hydrocarbons (CIPAHs and BrPAHs; ~~XPAHs~~), collectively referred to as XPAHs, are halogenated derivatives of polycyclic aromatic hydrocarbons (PAHs) that have ~~garnered~~ gained considerable attention in recent years due to their heightened persistence, toxicity, and bioaccumulation relative to their parent PAHs (Jin et al. 2017b; Ma et al. 2013; Nishimura et al. 2017; Ohura et al. 2013). At present, research on XPAHs primarily encompasses the following aspects: (1) Establishment of pre-treatment and instrumental methods (Jin et al. 2023; Liu et al. 2019b; Noro et al. 2023; Sei et al. 2021; Takikawa et al. 2023), (2) Environmental detection across various environmental media (Jin et al. 2020; Xie et al. 2021), and (3) Identification of anthropogenic sources. XPAHs have been reported to exist in the air (Jin et al. 2017c; Kakimoto et al. 2014; Nilsson and Ostman 1993), soil (Sun et al. 2013; Zhang et al. 2006), water (Shiraishi et al. 1985), sediment (Ohura et al. 2015), and organisms (Jin et al. 2017a; Liu et al. 2019b; Nishimura et al. 2017; Ohura et al. 2015; Xia et al. 2019). The sources, such as industrial thermal processes (Yang et al. 2022b), electronic waste decomposition (Wang et al. 2022), and vehicular emissions (Deng et al. 2023) have been identified, by means of detection of XPAHs in the stack gas and fly ash emitted from these sources (Jin et al. 2017b; Nishimura et al. 2017; Yang et al. 2022a). However, a significant aspect of research appears to have been overlooked: i.e. the environmental transformation. Variations in the transformation mechanisms of XPAH congeners in environmental matrices can result in differences in their environmental fate and associated risks.

The photochemical processes have been verified to represent a marked elimination pathway for organic substances affecting the atmosphere ~~atmospheric organic chemical species~~ (Hu et al. 2021; Laskin et al. 2015; Malecha and Nizkorodov 2016). For example, PAHs have been confirmed to undergo oxidation (Zhu et al. 2022), or thorough fragmentation (Hu et al. 2021; Zhang et al. 2024) under atmospheric photochemical reactions. Therefore, despite the absence of direct study, given their structural similarities to PAHs, XPAHs also possess the potential to undergo similar processes. ~~A study~~ Studies by Ohura et al. also confirmed the photochemical transformation of CIPAHs when being exposed to light in cyclohexane solvent (Ohura et al. 2008). Field observations provided additional evidence suggesting that the photochemistry plays a crucial role in atmospheric XPAH transformation. For instance, certain studies have shown that concentrations of CIPAHs in particulate matter (PM) were slightly higher during nighttime than during daytime (Ma et al. 2013; Ohura et al. 2013), indicating that

daytime photochemistry contributed to the transformation of XPAHs. For BrPAHs, although no direct nighttime versus daytime concentration comparison has been conducted, prior research indicated that BrPAHs might exhibit greater instability under photo irradiation than ClPAHs (Ohura et al. 2009).

Heterogeneous reactions were identified to be the key mechanisms driving the transformation of atmospheric organic compounds, e.g., PAHs (Jia et al. 2019), during these photochemistry processes (Zhang et al. 2023). Atmospheric PM acts as a significant carrier for both environmental pollutants and catalysts, serving as a medium for heterogeneous reactions. These reactions could be influenced by various environmental factors. For instance, the reactive oxygen species (ROS) have been identified to accelerate the phototransformation of polychlorinated naphthalene (PCNs), which are two-ring ClPAHs, on the surface of silica gel (Kang et al. 2021). In addition, the temperature and humidity have been noted to influence the lifetime of atmospheric organics (Shiraiwa et al. 2011). For example, the heterogeneous oxidation mechanisms of organophosphate flame retardants were found to be significantly affected by humidity (Liu et al. 2019a). In the case of particulate XPAHs, heterogeneous reactions may also play a crucial role in their transformation. However, the influencing factors, specific mechanisms, pathways, and products remain unclear, necessitating further exploration.

This study aims to unravel the mechanisms, influencing factors, pathways, and products of XPAH heterogeneous transformation on PM. To achieve this, we conducted field studies complemented by meticulously designed laboratory experiments and nontarget organic compound analysis. Initially, we collected year-range particle samples of various sizes along with relevant meteorological data. These samples were subsequently analyzed for XPAHs. Through multivariate parameter analysis, we explored XPAH fluctuations correlated with meteorological data to pinpoint key influencing factors. Subsequently, controlled laboratory experiments were designed and conducted to unveil the heterogeneous transformation of XPAHs under the influence of particle size, humidity, temperature, and atmospheric oxidant content. The persistence, bioaccumulation, long-range transportation, and toxicities of the transformation products were then assessed to determine the environmental risks associated with XPAH transformation. Therefore, the findings of this study contribute comprehensive insights into the mechanisms and environmental risks involved in the fate of XPAHs in the environment.

## **2. Materials and methods**

### **2.1 Experimental materials**

In this study, a comprehensive investigation was conducted on 41 XPAHs with 2 to 5 benzene rings,

99 along with an analysis of the corresponding parent PAHs. The parent PAHs are abbreviated as follows:  
100 Nap (naphthalene), Phe (phenanthrene), Ant (anthracene), Triph (triphenylene), Fluor (fluoranthene), Pyr  
101 (pyrene), BaA (benz[a]anthracene), and BaP (benzo[a]pyrene). The congeners in the C1PAH and BrPAH  
102 groups are described as Cl-, Cl<sub>2</sub>-, Cl<sub>3</sub>-, Cl<sub>4</sub>-, Br-, and Br<sub>2</sub>-, indicating the presence of monochlorinated,  
103 dichlorinated, trichlorinated, tetrachlorinated, monobrominated, and dibrominated PAH derivatives,  
104 respectively, with the numbers denoting the substituting positions. Specific names, abbreviations, and  
105 molecular structures of 20 C1PAHs and 21 BrPAHs are listed in **Table S1**. As reported in our previous  
106 study (Jin et al. 2017c), standards, isotopically labeled internal standards, and recovery standards for  
107 XPAHs and PAHs were commercially obtained.

## 108 **2.2 Sample collection and extraction**

109 Atmospheric particles of three sizes (PM<sub>1</sub>, PM<sub>2.5</sub>, PM<sub>10</sub>) were collected in Hangzhou from March  
110 2023 to February 2024 using medium-flow samplers (Wuhan Tianhong Instruments Co., Ltd., China).  
111 These samplers were positioned atop a school building at a height of approximately 15 meters above  
112 ground level. The sampling site (30° 8' 15" N, 120° 4' 17" E) was situated in the Xihu District of  
113 Hangzhou, with no industrial area within a five-kilometer radius. Samples were collected in monthly  
114 cycles, at a flow rate of 0.1 m<sup>3</sup>/min. Quartz fiber filters were employed to capture particles. Subsequently,  
115 samples were collected, dried, weighed, and stored at -18 °C.

116 Samples were extracted with a mixture of dichloromethane and hexane (1:4, v: v) by an auto-  
117 Soxhlet extractor (Universal Extractor E-800, Buchi, Germany). The extracted samples were then  
118 purified using an active silica column and concentrated to 50 µL using a rotary evaporator and nitrogen  
119 blower. Specific processes for the extraction and clean-up processes can be found in our previous study  
120 (Jin et al. 2017c).

## 121 **2.3 Experiments design for heterogeneous transformation of particulate XPAHs**

122 In this study, we designed a photo-transformation device that provided complete confinement and  
123 precise control over the experimental conditions. The reaction unit employed a xenon lamp (light  
124 intensity: 100 mW·cm<sup>-2</sup>) as the primary light source with an AM1.5 filter, which can achieve a good fit  
125 with the sunlight spectrum, effectively simulating the outdoor solar radiation (Cao et al. 2020; Wang et  
126 al. 2020). The entire photolysis reaction unit comprises a gas supply, mass flowmeters, a dryer (with  
127 molecular sieve and color silica gel), a bubbler containing Milli-Q water, a xenon lamp, an optical  
128 reactor, a quartz reaction vessel, a temperature control system, gas absorption bottles, and a relative

humidity monitoring component (**Fig. 1a**). To accurately emulate atmospheric conditions, model particles and a composite mixture comprising 41 XPAHs were meticulously prepared. Sequentially, 20  $\mu\text{L}$  of the XPAHs mixture (1 mg/L) or individual congener solution was deposited onto the surface of the prepared layer of silica particles ( $M_{\text{XPAHs}}: M_{\text{PM}} = 2\mu\text{g/g}$ ) (**Fig. 1b** and **Fig. S1**). The settings of the concentrations were based on previous studies on the XPAH concentrations per particle mass (Jin et al. 2017a; Jin et al. 2018). Specific information on the devices and experiments are described in **Text S1**.

To comprehensively explore the impact of various factors, including particle sizes (100 nm, 2  $\mu\text{m}$ , 10  $\mu\text{m}$ ), temperatures (10°C, 20°C, 30°C), humidity (RH=30%, 45%, 60%), oxidant concentrations (0% (+ tert-butyl alcohol; TBA), 0%, 1%, 3%, 5%, 10%), and irradiation duration (0 min, 10 min, 30 min, 60 min, 180 min), on the phototransformation mechanism of XPAHs, a series of experiments were conducted (**Text S1**). The reacted gas was directed into a toluene solution for analysis of XPAHs in the tail gas, with less than 1% of the XPAHs escaping through volatilization during the reaction time. Dark control groups were conducted in each experiment to ensure that the difference between the two sets of experiments was due to the transformation effect caused by photo irradiation. Upon completion of the reactions, the particle layer within the reaction vessel was sonicated with 200  $\mu\text{L}$  of toluene, followed by centrifugation of the supernatant. The resulting solution was then transferred into a centrifuge tube for subsequent product analysis.

## 2.4 Instrumental analysis

Analysis of the XPAHs and PAHs was conducted using gas chromatography coupled with magnetic sector high-resolution mass spectrometry (HRGC-HRMS, DFS, Thermo Fisher Scientific, USA) equipped with an electron ionization source. Specific information on the parameters for the oven and MS can be found in our previous study (Jin et al. 2017a). The analytical program and instrumental parameters for the analysis of PAHs were set according to “CalEPA Method 429”.

Non-target analysis of the transformation products of XPAHs was performed using a Trace 1310 GC coupled to a quadrupole-Orbitrap MS (Thermo Fisher Scientific, USA). Data were collected and processed using Thermo Scientific TraceFinder 5.1 software. High-resolution mass spectra of unknown compounds were deconvoluted into pure spectra using the Deconvolution Plugin of TraceFinder software and then verified against the standard mass spectra from the commercial library NIST 2014. Specific information on the non-target analysis was shown in **Text S2**.

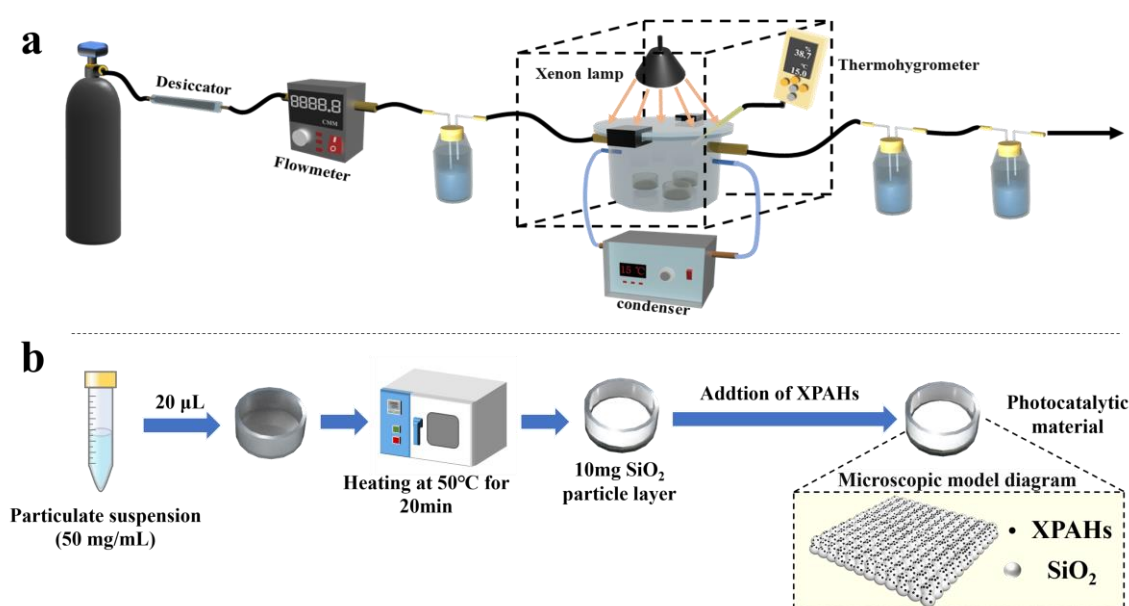

## 2.5 Environmental behavior and toxicity assessment of XPAHs and their transformation products

159 To assess the ecological risk and environmental characteristics—specifically, persistence, long-  
 160 range transport potential, and bioaccumulation—of transformation products of XPAHs, this study  
 161 employed the KOWWIN, KOAWIN, BCFBAF, and Level III fugacity models within EPI Suite 4.1 to  
 162 compute various physicochemical properties of compounds. Essential environmental parameters,  
 163 including molecular weight, octanol-water partition coefficient (Kow), air-water partition coefficient  
 164 (Kaw), and half-lives in air, water, and soil, were subsequently introduced into the Pov-LRTP tool  
 165 (Concha and Manzano 2023). Subsequently, the P-B-LRTP score is developed based on persistence  
 166 (Pov), characteristic travel distance (CTD), and transfer efficiency (TE) values to prioritize the screened  
 167 compounds. The respiratory toxicity model in ProTox 3.0(Banerjee et al. 2024) was used to predict the  
 168 toxicity of the products, assessing their median lethal dose (LD50) and toxicity class.

169 
$$P - B - LRTP \text{ Score}_i = \text{LogPov} + \text{LogBAF} + \text{LogTE}$$

## 170 2.6 Quality assurance and quality control

171 For the analysis of actual atmospheric PM samples, the recovery rates of internal standards ranged  
 172 from 52% to 105%. In laboratory simulation experiments, the recovery rates of XPAHs ranged from  
 173 78% to 115%, while those of PAHs ranged from 53% to 120%. These recovery rates met the  
 174 requirements for the detection and analysis of persistent organic pollutants. The detection limits (LODs)  
 175 ranged from 0.17 to 1.9 fg/m<sup>3</sup> for ClPAHs, and from 0.23 to 1.6 fg/m<sup>3</sup> for BrPAHs. A blank sample was  
 176 analyzed together with each batch of samples, and the relative concentrations of all XPAH congeners  
 177 were below the detection limits.

178

### 3. Results and discussion

#### 3.1 Occurrence levels and congener profiles of particulate XPAHs

During the sampling period, PM concentrations ranged from 41.5 to 652.7  $\mu\text{g}/\text{m}^3$ , with an average concentration of  $130.0 \pm 167.6 \mu\text{g}/\text{m}^3$  (**Fig. S2a**).  $\text{PM}_1$  had the highest proportion, with an average of  $47.0\% \pm 13.5\%$ , while the proportions of  $\text{PM}_{1-2.5}$  and  $\text{PM}_{2.5-10}$  were comparable. Notably, the peak concentration was recorded in April 2023. This surge coincided with a dust storm originating from the north, leading to heightened levels of suspended dust in the atmosphere and a significant spike in PM levels. Barring exceptional weather conditions, PM concentrations in other seasons were approximately twice as high as those observed in the summer and autumn.

The concentrations of  $\sum_{21}\text{CIPAHs}$  in the particles ranged from 0.6 to 61.5  $\text{pg}/\text{m}^3$  (mean:  $12.1 \pm 16.9 \text{ pg}/\text{m}^3$ ), while those of  $\sum_{18}\text{BrPAHs}$  ranged from N.D. to 5.4  $\text{pg}/\text{m}^3$  (mean:  $0.6 \pm 1.5 \text{ pg}/\text{m}^3$ ) during the sampling period (**Fig. 2a**). These values are lower than those reported in previous studies, such as Beijing, China ( $\sum_{19}\text{CIPAHs}$ :  $128.8 \pm 102.6 \text{ pg}/\text{m}^3$ ,  $\sum_{19}\text{BrPAHs}$ :  $9.5 \pm 13.8 \text{ pg}/\text{m}^3$ ) (Jin et al. 2017a); Ulsan, South Korea ( $\sum_{11}\text{BrPAHs}$ :  $1.62 \text{ pg}/\text{m}^3$ ) (Vuong et al. 2020); and Shizuoka, Japan ( $\sum_{20}\text{CIPAHs}$ :  $133.0 \pm 53 \text{ pg}/\text{m}^3$ ) (Ohura et al. 2013). For distribution in particles of different sizes, CIPAHs had the highest fraction in  $\text{PM}_1$  (mean: 45.4%, range: 29.4–65.9%) and comparable proportions in  $\text{PM}_{1-2.5}$  (mean: 28.1%, range: 13.0–52.0%) and  $\text{PM}_{2.5-10}$  (mean: 26.5%, range: 8.46–3.5%). Conversely, BrPAHs showed no significant variance across the three particle size ranges, with concentrations of  $\text{PM}_1$  (mean: 35.9%, range: 12.5–68.2%),  $\text{PM}_{1-2.5}$  (mean: 35.7%, range: 14.3–55.2%) and  $\text{PM}_{2.5-10}$  (mean: 28.4%, range: 1.25–59.2%) (**Fig. 2b**). In total, over 70% of XPAHs were bound to particles with diameters smaller than 2.5  $\mu\text{m}$ .

Concentration trends of XPAH homologue groups were as follows: ClFluor > ClBaP > ClAnt > ClPyr > ClPhe > ClBaA (**Table S2**); BrPyr > BrPhe > BrAnt > BrTriph > BrBaA > BrFluor (N.D.) (**Table S3**). The distribution profiles of XPAH congeners in  $\text{PM}_{10}$  in Hangzhou are shown in **Fig. S2b**, **Fig. S2c**, and **Table S4**. Among CIPAHs, 2-ClPhe/9-ClPhe, 1,5-Cl<sub>2</sub>Ant/9,10-Cl<sub>2</sub>Ant, 1-ClPyr, 3-ClFluor, 3,8-Cl<sub>2</sub>Fluor, and 6-ClBaP were found to be predominant throughout the year. This distributions aligned with findings of prior studies (Jin et al. 2017a; Kitazawa et al. 2006; Ma et al. 2013). It is worth noting that 6-ClBaP, characterized by the highest molecular weight and highest toxic equivalent factor investigated within CIPAHs investigated in our study, demonstrated the highest concentration proportion. BrPAHs are predominantly constituted by 2-BrPhe, 9-BrPhe, 7-BrBaA, and 1,6-~~Br<sub>2</sub>Byr~~Br<sub>2</sub>Pyr. This

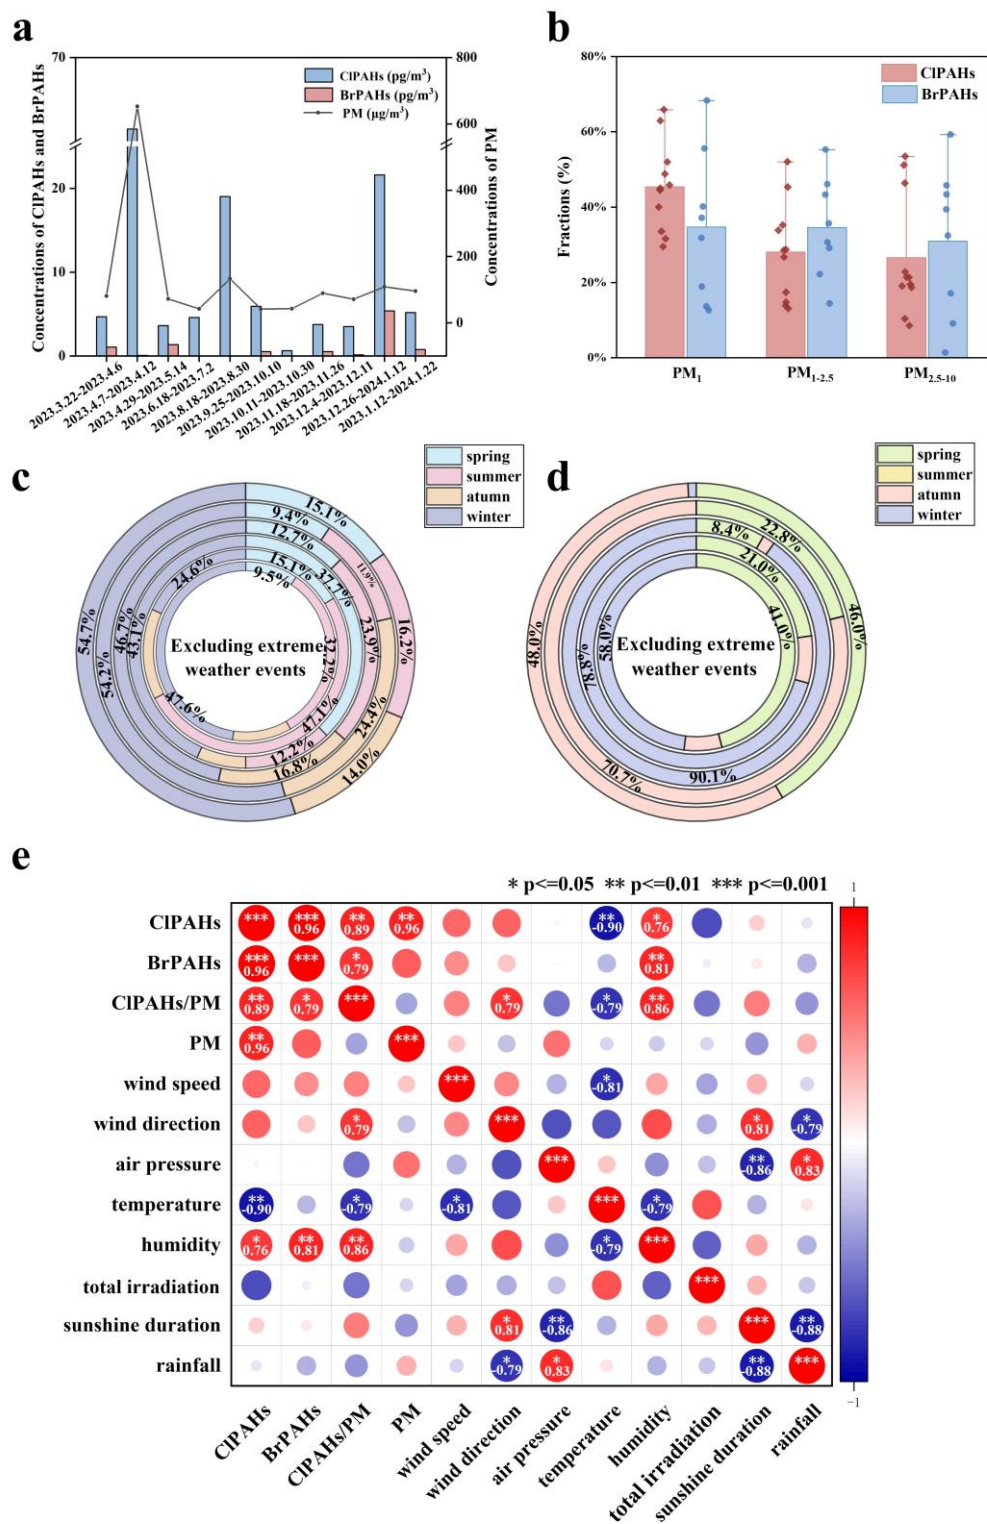

presented-represented a notable departure-difference from previous literature which predominantly identified 3-BrFluor, 1,8-Br<sub>2</sub>Ant, and 1-BrPyr as the primary congeners of BrPAHs in atmospheric PM in Beijing (Jin et al. 2017a). This disparity underscores variances in their respective sources or transformations.

### 3.2 Key environmental factors influencing temporal variations of particulate XPAHs

Extreme weather events such as sandstorms and prolonged light rainfall have been excluded in the following discussion. The average concentrations of PM and BrPAHs reached nadirs during summer and autumn while showing higher levels in the spring and the winter (Fig. S2d). Conversely, ClPAH concentrations remained relatively stable during the spring and the summer, decreased in the autumn, and peaked in the winter. The seasonal characteristics of ClPAHs with different parent PAH structures also varied (Fig. 2c). Except for ClBaA, the remaining ClPAHs reached their highest concentrations during the winter. ClFluor showed elevated concentrations in both the spring and the winter, whereas ClAnt demonstrated higher concentrations in the autumn and the winter. ClPhe maintained relatively consistent concentrations across the remaining three seasons. The seasonal characteristics of ClPAHs and BrPAHs (Fig. 2d) also differed. Concentrations of BrPAHs varied significantly with the seasons, with no congener detected in the summer and high concentrations of BrPhe, BrAnt, and BrPyr in the spring and the winter, likely influenced by climatic conditions such as temperature and sunshine. This disparity can be attributed to the ease of generation from sources and greater atmospheric stability of ClPAHs, while BrPAHs may be subjected to influences from atmospheric processes (Ohura et al. 2009).

Eight meteorological parameters were collected throughout the sampling period: wind speed, wind direction, air pressure, temperature, humidity, total irradiation, sunshine duration, and rainfall. Details are listed in Table S5, and the results of multifactor correlation analysis are shown in Fig. 2e. Pearson correlation analysis revealed significant positive correlations between ClPAHs and BrPAHs ( $P < 0.001$ ,  $R = 0.96$ ), PM ( $P < 0.01$ ,  $R = 0.96$ ), and humidity ( $P < 0.05$ ,  $R = 0.76$ ). BrPAHs exhibited a significant positive correlation with humidity ( $P < 0.01$ ,  $R = 0.81$ ). The impact of humidity was notably significant, as an increase in humidity tended to facilitate the upward adsorption of XPAHs onto PM. However, a previous study (Vuong et al. 2020) from Ulsan, South Korea has reported a negative correlation between humidity and XPAHs. This observation suggested that the relationship between XPAHs and humidity varied across different regions. Additionally, ClPAHs shew a significant negative correlation with temperature ( $P < 0.01$ ,  $R = -0.90$ ), suggesting that higher temperatures corresponded to lower ClPAH

240 concentrations. This further elucidated the phenomenon of lower CIPAH levels observed during the  
 241 summer and autumn seasons. Other meteorological factors didn't show significant correlations with  
 242 CIPAHs or BrPAHs ( $P > 0.05$ ), possibly due to the intricate interplay of multiple factors under natural  
 243 conditions. Hence, the specific roles of meteorological conditions such as sunlight intensity, duration of  
 244 sunshine, temperature, and humidity warranted further investigation.

**Fig. 2.** (a) The fluctuations of concentrations of PM ,  $\Sigma_{21}$ CIPAHs, and  $\Sigma_{19}$ BrPAHs in the atmosphere. (b) The proportions of CIPAHs and BrPAHs across different PM diameters. (c-d) Seasonal distributions of CIPAH (c) and BrPAH (d) congeners, excluding events of extreme conditions, arranged from outermost to innermost layers: ClPhe, ClAnt, ClPyr, ClFluor, ClBaA, and ClBaP; BrPhe, BrAnt, BrPyr, BrTriph, and BrBaA. (e) Pearson correlation analysis between CIPAHs、BrPAHs and CIPAHs/PM with meteorological parameters (wind speed, wind direction, air pressure, temperature, humidity, total radiation, sunshine duration, and rainfall) under non-extreme weather conditions.

### 3.3 General transformation mechanisms of particulate XPAHs under photo irradiation

According to both preliminary research(Li et al. 2023) and the experimental results mentioned above, it is evident that meteorological conditions can significantly impact the concentrations and distributions of XPAHs on PM. Controlled laboratory experiments were conducted in this study to unveil the heterogeneous transformation mechanisms of XPAHs.

The transformation ratios of XPAHs were calculated based on the ratios of **transformed** **transformed** XPAHs to the initial concentration ( $(C_0-C_t)/C_0$ ). With the increase of irradiation time, a general trend of transformation was observed across XPAH congeners (**Fig. 3**). Overall, the transformation rates of CIPAHs appeared to follow the sequence: ClPhe < ClFluor < ClPyr < ClBaA  $\approx$  ClAnt < ClBaP (**Fig. S3**). This pattern aligned with the previously reported trends in PAH photolysis rates (Phe < BaA < Ant  $\approx$  BaP) (Zhao et al. 2017), indicating strong influence by the parent PAH structures. In a combined consideration of CIPAHs and their parent PAHs, shown as “CIPAHs+PAHs” in **Fig. S3**, we also observed the formation of PAHs and decreases of total concentrations of CIPAHs and PAHs. This indicated that there were dechlorination of CIPAHs and simultaneous fragmentation of parent PAH structures during the transformation of CIPAHs.

In addition, the substitution numbers in the structures had a strong influence on the transformation of CIPAHs: with increment of the substitution numbers, the transformation ratios progressively decreased (**Fig. 3**). For example, after 1 h of irradiation, transformation ratios were approximately 20% for 3-ClPhe and 2-ClPhe/9-ClPhe, while 10% for 9,10-Cl<sub>2</sub>Phe. An exception was observed for ClAnt congeners (1,4-Cl<sub>2</sub>Ant or 1,5-Cl<sub>2</sub>Ant/9,10-Cl<sub>2</sub>Ant < 1-ClAnt/2-ClAnt or 9-ClAnt < 1,5,9,10-Cl<sub>4</sub>Ant. This difference could be attributed to the fact that the investigated low-chlorinated ClAnts are dechlorination products of high-chlorinated ClAnts. While the substitution position had some impact, it was not as significant as the number of chlorines. For instance, both 2,5-Cl<sub>2</sub>Fluor and 3,8-Cl<sub>2</sub>Fluor demonstrate

comparable photolysis extents, with approximately 20% transformation after 30 min of irradiation, and transformation ratios of 68.8% and 49.4% after 3 h of irradiation, respectively.

For BrPAHs (**Fig. S4**), the overall transformation ratio ranked as follows: BrPhe < BrAnt < BrPyr  $\approx$  BrFluor < BrBaA < BrBaP. The transformation ratio ranking between BrPAHs and ClPAHs exhibited disparities, implying that distinct halogen substitutions might yield diverse transformation effects. BrPAHs degraded more rapidly than ClPAHs. For example, BrPyr degraded by 60% after 30 min of irradiation, while ClPyr only degraded by less than 40%. Additionally, the increase in degree of bromination degree didn't appear to have a notable effect on the transformation rate of BrPAHs, which differed from ClPAHs.

**Fig. 3.** The relationships between transformation ratios of ClPAHs and photo irradiation time.

### 3.4 Influencing factors for heterogeneous transformation of particulate XPAHs

The influencing factors, i.e., particle size, relative humidity, reactive oxygen species content, and temperature on XPAH transformation have been investigated (**Text S1**). Although previous studies have revealed variations in XPAH concentrations on particles of different sizes (Jin et al. 2017a; Lara et al. 2022; Ma et al. 2013), the influence of particle size (100 nm, 2  $\mu$ m, and 10  $\mu$ m) on transformation efficiency was found to be not notably significant in simulated experiments (**Fig. S5 and Text S3**).

The influence of humidity varied among ClPAHs with different parent structures (**Fig. 4a**). For instance, the transformation of ClPhe and ClFluor slowed down with increasing humidity, whereas the

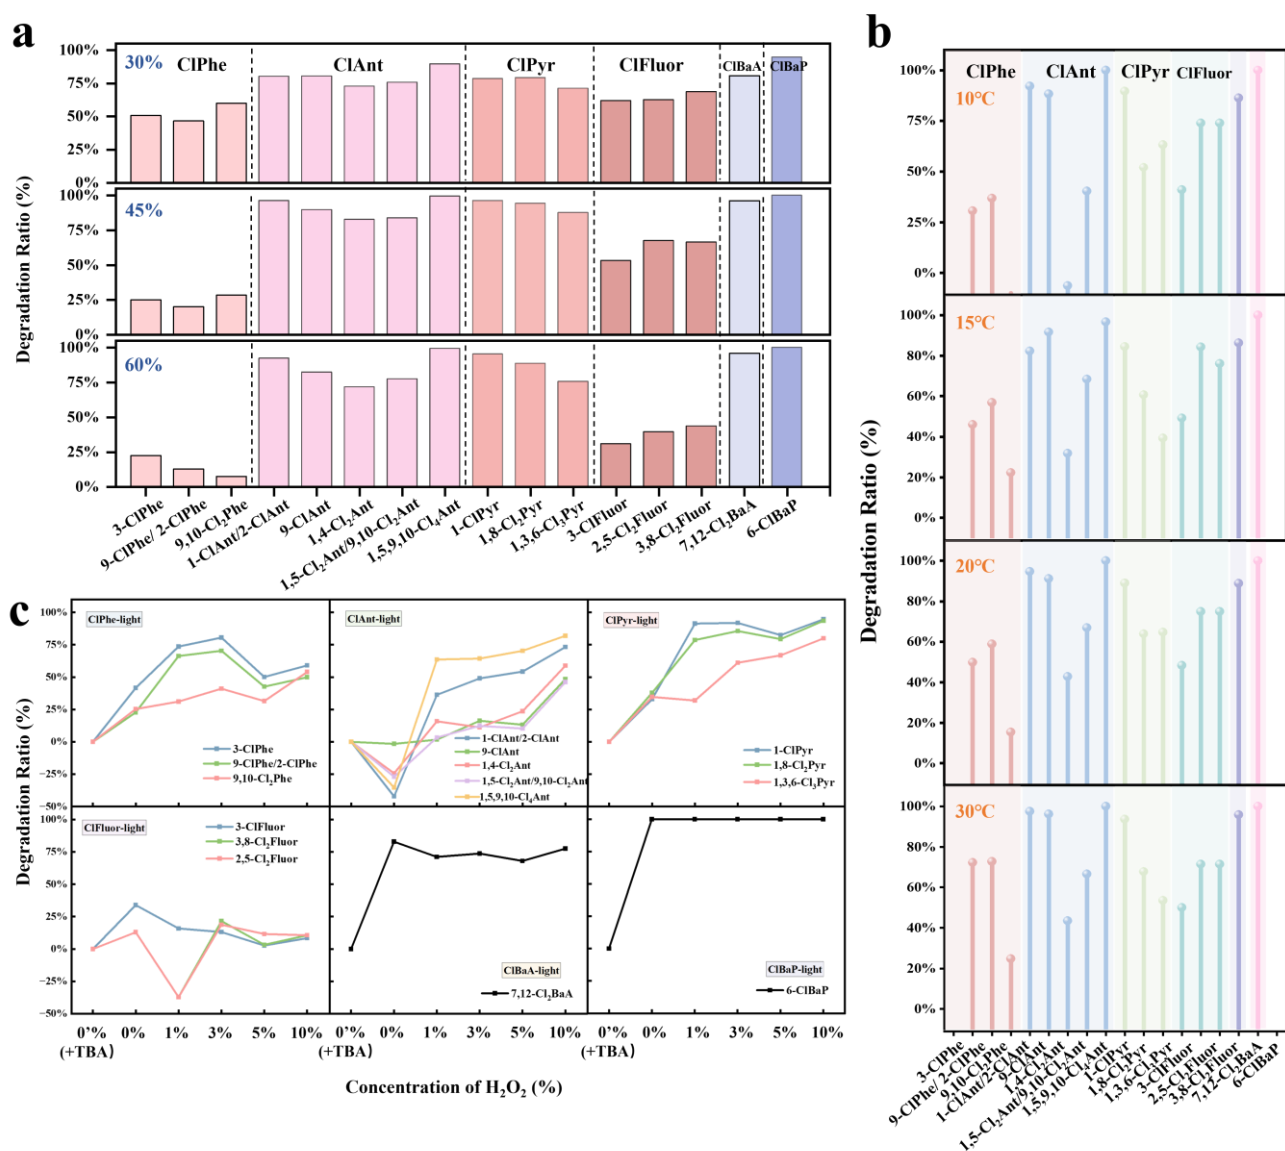

transformation of ClAnt, ClPyr, ClBaA, and ClBaP increased with higher humidity levels, with the highest transformation ratio observed at 45% humidity. Additionally, we found that the impact of humidity on transformation was not consistent for ClPAH congeners in the same homologue groups. For example, transformation of 9,10-Cl<sub>2</sub>Phe decreased more sharply than the other ClPhe congeners with the increment of humidity. The combined influence of photo irradiation and humidity enhanced the transformation of individual ClPAHs (**Fig. S6**). For example, under 45% humidity, ClPyr exhibited an average transformation of 50% in darkness, while this rate increased to 75% under photo irradiation. Possible reasons could be that the addition of photo irradiation drove the formation of hydroxyl radical ( $\cdot\text{OH}$ ), which could ~~participate in~~ the breakdown of molecules (Zhang et al. 2023). In contrast, the acceleration of transformation with increasing humidity was relatively universal for BrPAHs, with the most significant effects observed within the 30-45% humidity range (**Fig. S6c** and **Fig. S6d**).

Transformation ratios of XPAHs increased as temperatures rose, with the most significant transformation observed at 30 °C (**Fig. 4b**), indicating that the elevated temperature promote the transformation of XPAHs. The transformation ratio of each congener gradually increased with temperature compared to dark conditions (**Fig. S7a**). Under photo irradiation at the same temperature, the transformation ratios of nearly all XPAH congeners increased by more than 50% compared to dark conditions. This indicated that the breakdown of XPAH molecules was enhanced by the photo irradiation. In both photo irradiation and dark conditions, the transformation ratios of BrPAHs (**Fig. S7c** and **Fig. S7d**) exceeded those of ClPAHs. This phenomenon can be attributed to the differences in bond strength (the bond energy of C-Br is lower at 291 kJ/mol, whereas the bond energy of C-Cl is 345 kJ/mol) (Ohura et al. 2009) and atomic size (the radius of the Cl atom is approximately 99 pm, while the radius of the Br atom is around 114 pm) (Shannon 1976). ~~This phenomenon can be attributed to the lower bond energy of C-Br (291 kJ/mol) compared to C-Cl (345 kJ/mol), which is consistent with the findings of previous studies by Ohura et al (Ohura et al. 2009).~~

Adding H<sub>2</sub>O<sub>2</sub> to the reaction system simulates the effects of oxidants present in the atmosphere on the impact of XPAH transformation under photochemical conditions. The transformation of ClPAHs accelerated with the increase of H<sub>2</sub>O<sub>2</sub> concentration (**Fig. 4c** and **Fig. S8**). TBA was introduced to eliminate the  $\cdot\text{OH}$  effect in the control group. Under 1-hour photo irradiation conditions, the transformation rate ranking of ClPAHs is as follows: ClBaP > ClBaA > ClPyr > ClPhe > ClAnt >

326 ClFluor. The transformation of ClFluor showed no significant change with H<sub>2</sub>O<sub>2</sub> content, indicating  
 327 relative stability. Additionally, compared to monochlorinated compounds, the overall transformation  
 328 ratios of polychlorinated compounds are relatively slower and less influenced by H<sub>2</sub>O<sub>2</sub> (except for  
 329 1,5,9,10-Cl<sub>4</sub>Ant). This also suggested that the dechlorination process was more pronounced in high-  
 330 chlorinated compounds, while the transformation of low-chlorinated substances was mainly due to ring-  
 331 opening reactions. The situation was similar for BrPAHs, with transformation rates faster than those of  
 332 ClPAHs.  
 333

334  
 335 **Fig. 4.** Transformation ratios of ClPAHs under varying (a) humidity levels, (b) temperature conditions and (c)  
 336 H<sub>2</sub>O<sub>2</sub> concentrations, with photo irradiation.

### 337 3.5 Heterogeneous transformation pathways of XPAHs under photo irradiation

According to the results above, there are dechlorination, direct ring-opening, or ring-opening induced by oxidation processes involved in the breakdown of XPAHs. To elucidate the specific transformation pathways of XPAHs, we conducted photolysis experiments on highly chlorinated XPAHs, including 1,4-Cl<sub>2</sub>Ant, 9,10-Cl<sub>2</sub>Phe, 1,8-Cl<sub>2</sub>Pyr, 2,5-Cl<sub>2</sub>Fluor, 7,12-Cl<sub>2</sub>BaA, and 6-ClBaP, individually. Non-target analysis was then employed to recognize the transformation products of these congeners. Specific mass spectrums can be found in **Fig. S9**, and the relative compounds are listed in **Table S6**. The predominant products were quinones, ketones, hydroxyl-bearing compounds, and ring-opened products, consistent with previous findings on PAH phototransformation products (Jia et al. 2019; Zhao et al. 2017). Surprisingly, no chlorinated oxides were detected. Further analysis of the products from experiments on both ClPAHs and BrPAHs revealed no significant differences. As a result, we confirmed a hypothesis proposed in previous studies (Ohura et al. 2009) that the transformation of XPAHs underwent dehalogenation to form PAHs before oxidation.

The transformation pathways are presented in **Fig. 5**. According to the non-target analysis results of the photolysis products, the primary products for most ClPAHs, with the exception of ClFluor, were the parent PAHs in the initial step. And for ClFluor, the initial step involved not only the dechlorination, but also ring-opening, resulting in the generation of 2,7-dichlorofluorene and 9-chlorofluorene. Research findings suggested that in the atmosphere, the primary reactions for the destruction of aromatic compounds were the addition or substitution with ·OH (Dang et al. 2014). At the same time, the substitution of H or Cl in the main structures of ClPAHs or PAHs by the ·OH could influence the products of the next steps. Therefore, the subsequent steps might include ring opening, oxidation, or hydrolysis.

Specifically, there were three potential pathways for the transformation of 1,4-Cl<sub>2</sub>Ant (**Fig. 5a** and **Fig. S9a**). In the first pathway, 1,4-Cl<sub>2</sub>Ant could undergo substitution by ·OH to form A2 (1,4-dihydroxyanthracene, C<sub>14</sub>H<sub>10</sub>O<sub>2</sub>), which further oxidized to produce A3 (1,4-anthraquinone, C<sub>14</sub>H<sub>8</sub>O<sub>2</sub>). For the second and third pathways, 1,4-Cl<sub>2</sub>Ant underwent dechlorination to yield A1 (Ant, C<sub>14</sub>H<sub>10</sub>). The subsequent steps were then similar to those of Ant, with oxidation leading to the formation of A4 (9,10-Anthracenediol, C<sub>14</sub>H<sub>10</sub>O<sub>2</sub>), and further oxidation to A5 (9,10-Anthraquinone, C<sub>14</sub>H<sub>8</sub>O<sub>2</sub>) as the second pathway. In the third pathway, ring-opening occurred to form A6 (2-Methylnaphthalene, C<sub>11</sub>H<sub>10</sub>), followed by subsequent chain-breaking ring-opening to form A7 (Nap, C<sub>10</sub>H<sub>8</sub>), A8 (1,2,3,4-Tetrahydronaphthalene, C<sub>10</sub>H<sub>12</sub>), and A9 (2-Methoxyphenol, C<sub>7</sub>H<sub>8</sub>O<sub>2</sub>), ultimately yielding A10 (3-

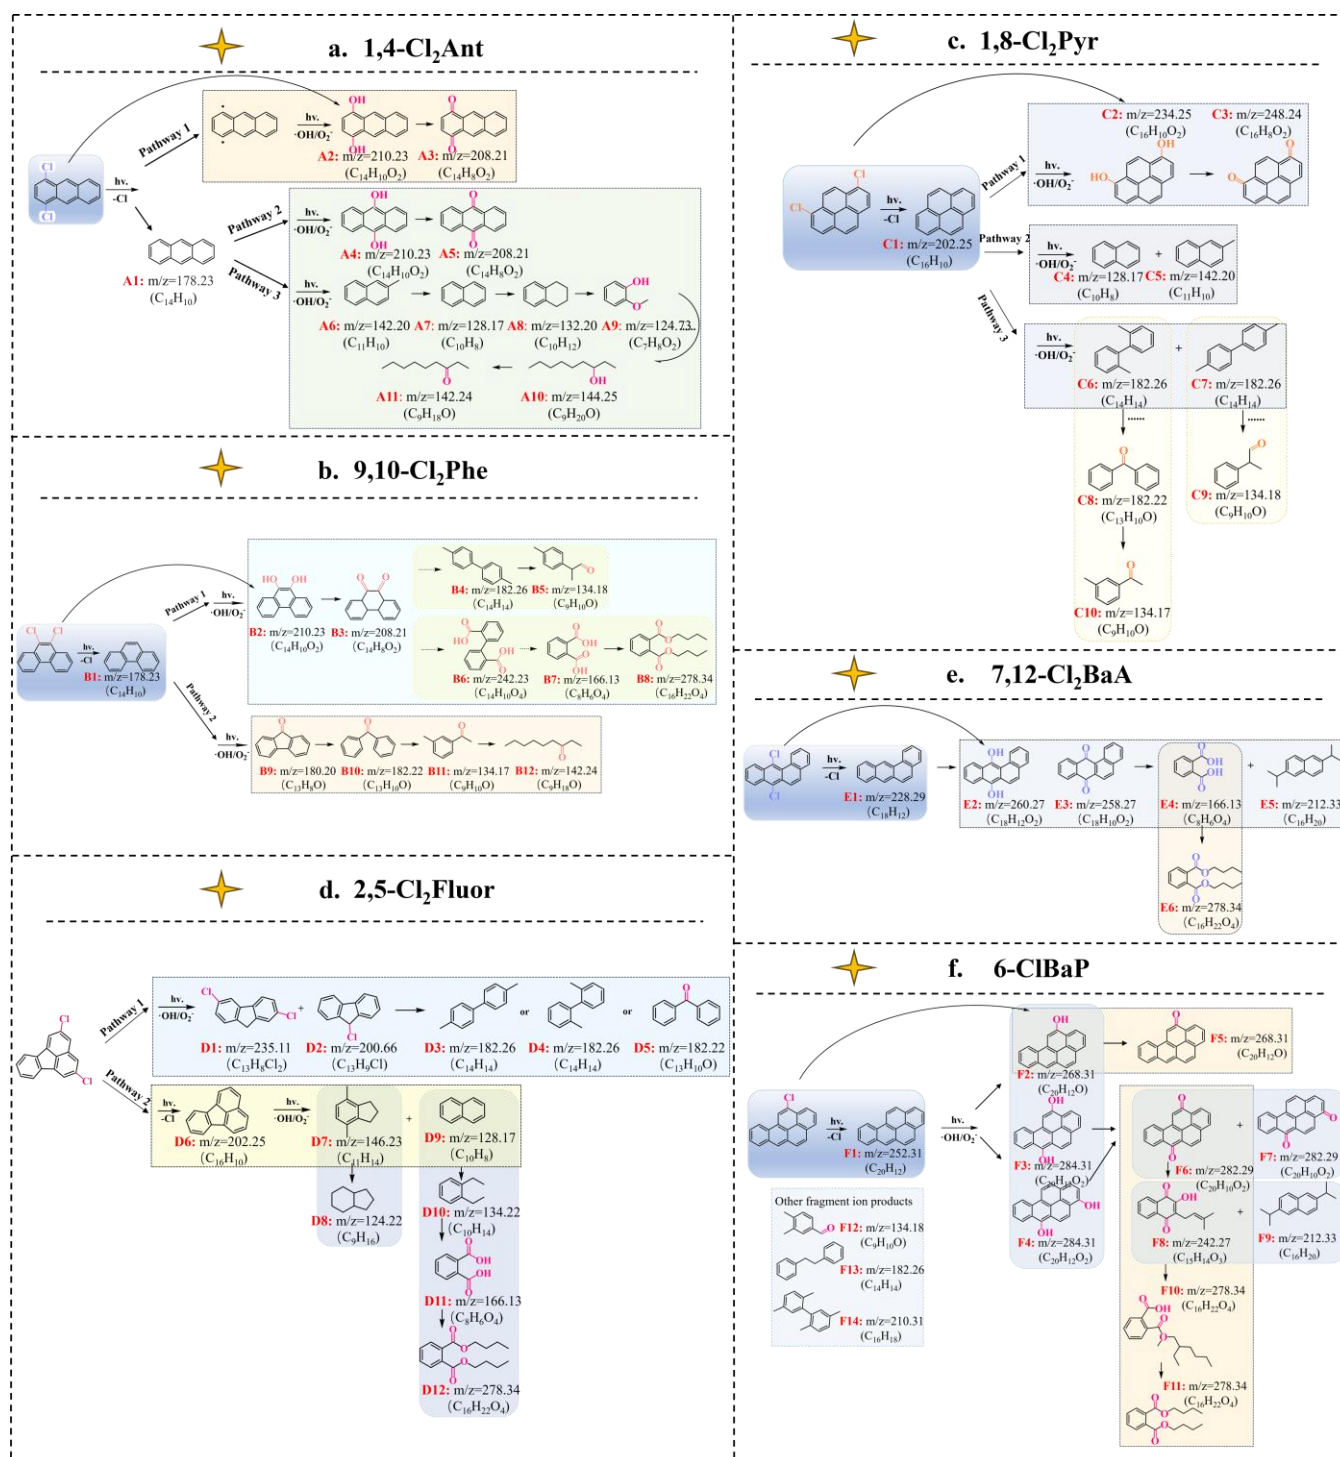

Nonanol, C<sub>9</sub>H<sub>20</sub>O) and A11 (3-Nonanone, C<sub>9</sub>H<sub>18</sub>O). Similar transformation pathways were observed for 9,10-Cl<sub>2</sub>Phe (**Fig. 5b** and **Fig. S9b**), 1,8-Cl<sub>2</sub>Pyr (**Fig. 5c** and **Fig. S9c**), and 7,12-Cl<sub>2</sub>BaA (**Fig. 5e** and **Fig. S9e**), involving dechlorination to generate PAHs, followed by attack by ·OH to produce phenols, further oxidizing to form quinones, acids, and esters. Additionally, 9,10-Cl<sub>2</sub>Phe exhibited an additional oxidation pathway involving ring-opening oxidation, yielding B9 (9-Fluorenone, C<sub>13</sub>H<sub>8</sub>O), followed by a series of chain-breaking ring-opening reactions to sequentially generate B10 (Benzophenone, C<sub>13</sub>H<sub>10</sub>O), B11 (3'-Methylacetophenone, C<sub>9</sub>H<sub>10</sub>O), and B12 (3-Nonanone, C<sub>9</sub>H<sub>18</sub>O). 1,8-Cl<sub>2</sub>Pyr also had two additional potential transformation pathways. In the first pathway, uniform cleavage occurred both above and below the pyrene molecule, generating C4 (Nap, C<sub>10</sub>H<sub>8</sub>) and C5 (2-Methylnaphthalene, C<sub>11</sub>H<sub>10</sub>). In the second pathway, diagonal cleavage resulted in the identification of two products: C6 (2-(2,5-dimethylphenyl)-1,4-dimethylbenzene, C<sub>14</sub>H<sub>14</sub>) and C7 (4,4'-Dimethyldiphenyl, C<sub>14</sub>H<sub>14</sub>). C6 underwent attack by ·OH/O<sub>2</sub><sup>-</sup> radicals to ultimately form C8 (Benzophenone, C<sub>13</sub>H<sub>10</sub>O), followed by further ring-opening cleavage to produce C9 (3'-Methylacetophenone, C<sub>9</sub>H<sub>10</sub>O). Similarly, C10 (2-Phenylprocpionaldehyde, C<sub>9</sub>H<sub>10</sub>O) was formed by oxidation-induced chain-breaking of C8.

For ClFluor (**Fig. 5d** and **Fig. S9d**), the initial step involved ring-opening, generating D1 (2,7-Cl<sub>2</sub>Fle, C<sub>13</sub>H<sub>8</sub>Cl<sub>2</sub>) and D2 (9-ClFle, C<sub>13</sub>H<sub>9</sub>Cl). Subsequent dechlorination and ring-opening led to the formation of D3 (4,4'-Dimethyldiphenyl, C<sub>14</sub>H<sub>14</sub>), D4 (2-(2,5-dimethylphenyl)-1,4-dimethylbenzene, C<sub>14</sub>H<sub>14</sub>), and D5 (Benzophenone, C<sub>13</sub>H<sub>10</sub>O) in the samples. In the second pathway, the initial dechlorination process resulted in the formation of D6 (Fluor, C<sub>16</sub>H<sub>10</sub>), which yielded D7 (1H-Indene, 2,3-dihydro-4,7-dimethyl-, C<sub>11</sub>H<sub>14</sub>) and D9 (Nap, C<sub>10</sub>H<sub>8</sub>). D7 underwent bond cleavage to form D8 (1H-Indene, octahydro-, C<sub>9</sub>H<sub>16</sub>), while D10 (1,2-Diethylbenzene, C<sub>10</sub>H<sub>14</sub>) was the ring-opening product of D9. Further oxidation (alcohol to aldehyde) sequentially yielded D11 (1,2-Dicarboxybenzene, C<sub>8</sub>H<sub>6</sub>O<sub>4</sub>) and D12 (Dibutyl phthalate, C<sub>16</sub>H<sub>22</sub>O<sub>4</sub>).

6-ClBaP, as a mono-chlorinated compound (**Fig. 5f** and **Fig. S9f**), exhibited the highest phototransformation ratio among all ClPAH congeners. After dechlorination, the initial step generated F1 (BaP, C<sub>20</sub>H<sub>12</sub>). Among them, positions 3, 6, and 12 of BaP were particularly reactive, and ·OH attacks led to the formation of F2, F3, and F4 (6-Benzo[a]pyrenol, 6,12-Dihydroxybenzo[a]pyrene, and 9,12-Dihydroxybenzo[a]pyrene, C<sub>20</sub>H<sub>12</sub>O), subsequently further generated F5, F6 and F7 (6-Benz[a]pyrenone, Benzo[a]pyrene-6,12-dione, and Benzo[a]pyrene-3,6-dione, C<sub>20</sub>H<sub>10</sub>O<sub>2</sub>). Under light exposure, F6 underwent further oxidation and ring-opening to produce F8 (Lapachol, C<sub>15</sub>H<sub>14</sub>O<sub>3</sub>), F9 (2,6-

Diisopropylnaphthalene, C<sub>16</sub>H<sub>20</sub>), and F11 (Dimethyl phthalate, C<sub>16</sub>H<sub>22</sub>O<sub>4</sub>), as reported by S. Zhao et al (Zhang et al. 2023). The exploration of XPAH transformation is limited by the absence of quantification of the products. Further studies are necessary to elucidate the specific molecular assignments.

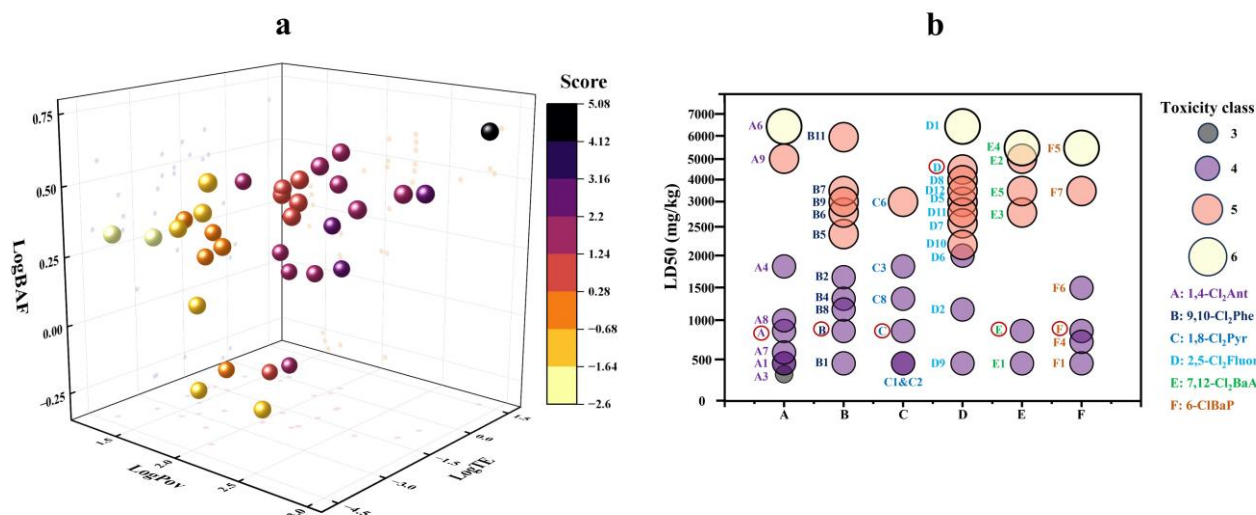

**Fig. 5.** (a-f) The transformation pathways and relative products of CIPAHs. ((a) 1,4-Cl<sub>2</sub>Ant; (b) 9,10-Cl<sub>2</sub>Phe; (c) 1,8-Cl<sub>2</sub>Pyr; (d) 2,5-Cl<sub>2</sub>Fluor; (e) 7,12-Cl<sub>2</sub>BaA; (f) 6-ClBaP).

### 3.6 Assessments of persistence, bioaccumulation, long-range transportation and toxicities of

## 405 XPAHs and their transformation products

406 Studies have suggested that transformation products of organic pollutants might exhibit distinct  
407 environmental behaviors and heightened ecological toxicity (Zhang et al. 2023). For the assessed P-B-  
408 LRTP scores of XPAHs and their transformation products in this study (**Fig. 6a** and **Table S6**), it could  
409 be observed that as the transformation pathways progressed, the scores of the transformation products  
410 decreased. For instance, the score of 9,10-Cl<sub>2</sub>Phe was 5.07, which decreased to 2.13 after dechlorination,  
411 and further oxidation products have even lower scores ranging from 1.65 to -1.27 (9,10-  
412 Difluorenquinone to 1,2-Benzenedicarboxylic acid). However, there were also transformation products  
413 with relatively high scores, such as B9 (9H-Fluorene-9-one, score: 1.57) and B10 (Benzophenone, score:  
414 1.81), which warrant special attention in future studies.

415 To further investigate the toxicities of these transformation products, the lethal doses (LD50) and  
416 toxicity levels (**Fig. 6b** and **Table S7**) were predicted by the respiratory toxicity model in ProTox 3.0  
417 (Banerjee et al. 2024). The findings indicated that as the transformation pathways progressed, the LD50  
418 values of the products generally increased, except for 2,5-Cl<sub>2</sub>Fluor, indicating a general toxicity  
419 decrement alongside XPAH transformation. For instance, the LD50 of 9,10-Cl<sub>2</sub>Phe was 886 mg/kg with  
420 a toxicity level of 4. Among its transformation products, only B1 (Phe) had an LD50 (316 mg/kg, level 4)  
421 lower than that of 9,10-Cl<sub>2</sub>Phe, while the toxicities of other oxidation and ring-opening products were  
422 lower. However, previous studies on the aryl hydrocarbon receptor activities of XPAHs in yeast assays  
423 reported the opposite results on toxicities of 9,10-Cl<sub>2</sub>Phe and Phe: the relative equivalent potency of  
424 9,10-Cl<sub>2</sub>Phe was found to be much higher than Phe. In the case of 2,5-Cl<sub>2</sub>Fluor, its inherently high LD50  
425 (4220 mg/kg, level 5) resulted in most of its products having higher toxicity levels compared to the  
426 parent compound. Overall, most transformation products have toxicity levels lower than their precursors.  
427 However, given the disparities between model predictions and experimental results, further toxicity  
428 experiments are needed to substantiate the changes in toxicity during the transformation process of  
429 XPAHs.

**Fig. 6.** (a) Prediction of environmental behaviors of XPAHs and their transformation products. (b) Respiratory toxicities (LD50) of XPAHs and their transformation products predicted by ProTox 3.0 model.

#### 4. Conclusion

In summary, this study elucidated the mechanisms, influencing factors, pathways, and products involved in the conversion of XPAHs on PM through comprehensive field sampling and laboratory simulations. Experimental findings revealed that the molecular structures of PAHs exerted a significant influence on the conversion process, with dehalogenation and cleavage of the parent ring structure being prominent features of XPAHs conversion. The number and position of substituents further modulated the conversion dynamics. Key environmental parameters, including humidity, temperature, and H<sub>2</sub>O<sub>2</sub> concentration, were identified as critical factors impacting conversion efficiency. The resulting conversion products and pathways were systematically hypothesized and confirmed, indicating a progressive decrease in environmental risks associated with the products as conversion advanced. This study provided novel insights into the heterogeneous conversion mechanisms of XPAHs on particulate matter, offering valuable contributions to the understanding of their environmental behavior and impact.
