The origins of particles and trace gases involved in the rapidly changing polar climates remain unclear, limiting the reliability of climate models. This is especially true for particles involved in aerosol-cloud interactions with polar clouds. As detailed chemical fingerprinting measurements are difficult and expensive in polar regions, backtrajectory modeling is often used to identify the sources of observed atmospheric compounds. However, the accuracy of these methods is not well quantified.This study provides a first evaluation of these analysis protocols, by combining backtrajectories from the FLEXible PARTicle dispersion model (FLEXPART) with simulations of tracers from the Weather Research and Forecast model including chemistry (WRF-Chem). Knowing the exact modeled tracer emission sources in WRF-Chem enables precise quantification of the source detection accuracy. The results show that commonly used backtrajectory analysis are unreliable in identifying emissions sources. After exploring parameter sensitivities thanks to our simulation framework, we present an updated and rigorously evaluated backtrajectory analysis protocol for tracing the origins of atmospheric species from measurement data. Two tests of the improved protocol on actual aerosol data from Arctic campaigns demonstrate its ability to correctly identify known sources of methane sulfonic acid and black carbon. Our results reveal that traditional backtrajectory methods often misidentify emission source regions. Therefore, we recommend using the method described in this study for future efforts to trace the origins of measured atmospheric species.

1 Introduction

The warming rate of the Arctic is almost four times higher than the global average rate (Rantanen et al., 2022). In the austral hemisphere, the Antarctic ice sheet raises concern while its melting accelerates (Bronselaer et al., 2018). This polar amplification of warming raises concern across the entire climate sciences community due to its possible impacts on the atmospheric and ocean circulations (Serreze and Barry, 2011). Studying the rapidly changing polar climates is therefore a research priority.

Short-lived climate forcers, such as aerosols and ozone, play an important role for global and polar climates (IPCC, 2021). Polar regions are especially sensitive to local forcing (Stuecker et al., 2018), so understanding the origin of short-lived climate

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

forcers in these regions is especially important. Their climate impact is dominated by aerosol-cloud interactions, the effect of aerosols on cloud formation and evolution (Storelvmo, 2017). However, our understanding of aerosol forcing remains especially uncertain because of the complexity of their processes and the scarcity of measurements in the polar regions. Polar clouds could be even more sensitive to aerosols than in other regions, because clouds are usually more sensitive to aerosols in clean conditions (Carslaw et al., 2013). In addition, aerosol-cloud interactions are even more uncertain in ice-containing clouds, which are predominant in polar regions (Matus and L'Ecuyer, 2017) Controversies remain in the scientific community on the nature and sources of the atmospheric species implicated in these mechanisms. For instance, origins of particles acting as cloud condensation nuclei (CCN, necessary for liquid cloud droplet formation) or ice nucleating particles (INPs, involved in cloud ice formation) are sources of great debate (e.g., Zhao et al., 2024). Because modeling of CCN and INP species is often imprecise or even lacking in climate models (Morrison et al., 2020), an improved knowledge of their sources would help to fill the present gaps (Murray et al., 2021). In this context, being able to identify the sources of aerosols relevant for CCN and INP would be decisive in order to improve our understanding of their emissions, how to represent them in models, and how to quantify their impacts on polar clouds and climate.

In order to identify the origin of observed species, observational studies often rely on analyzing their detailed chemical composition and physical properties (Freitas et al., 2022; Parshintsev and Hyötyläinen, 2015; Shao et al., 2022), or their correlation with chemical tracers like carbon monoxide from biomass burning or fossil fuel combustion, or dimethyl sulfide from phytoplankton blooms. However these extra measurements are often expensive and not systemically present in measurement campaigns, and their interpretation is hardly straightforward.

Another way to identify the sources of observed species is to use backtrajectory modeling, tracking their atmospheric path all the way back to their emission sources through the use of dispersion modeling. This does not require extra experimental data and has the advantage of costing less than observational methods. For example, this kind of analysis is increasingly used and presented alongside the analysis of INP observations (Allen et al., 2021; An et al., 2014; Irish et al., 2019; Hartmann et al., 2020, 2021; Porter et al., 2022; Si et al., 2019; Wex et al., 2019; Yun et al., 2022), but presents several downsides. Indeed, the methods used vary from one study to another, and they often lack clear theoretical guidelines in how they should be setup and interpreted. For example, it is not clear how far back in time backtrajectories should be run, depending on the nature of the studied species, even though the choice of this cutoff can drastically change the interpretation of the air mass origin. Moreover, backtrajectory results are often presented without any quantitative analysis of their uncertainties.

The performances of backtrajectory sources identification methods have been evaluated comparatively with potential source contribution functions (PSCF) methods in Fang et al. (2018). Although the authors conclude PSCF are inferior to inverse modeling in locating sources of emissions, they dot not present a protocol of use capable to identify sources of the studied atmospheric species. To the best of our knowledge, no other study has quantitatively estimated the performances of reverse modeling detection methods.

In order to close this knowledge gap, the present study introduces a methodology for evaluating backtrajectory source identification methods, by analyzing backtrajectories from simulated observations in a regional model. Specifically, a widely used source identification method is tested to assess its ability to retrieve known sources of simulated emissions in the regional

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

Weather Research and Forecasting model including Chemistry (WRF-Chem) model (Sec. 2.1.2). We use this approach to evaluate the source identification method of Hirdman et al. (2010), based on the FLEXible PARTicle dispersion (FLEXPART) model (Sect. 2.3). We then conduct a sensitivity study on the parameters of the Hirdman et al. (2010) method, in order to improve its performance (Sect. 3). The method's sensitivities to its parameters are evaluated and thereby, the prerequisites for its application are identified (Sect. 4). Finally, a comprehensive example of the application to real-world observations of marine-sourced and land-sourced species are presented (Sect. 5), in order to demonstrate the improved method's performance on real cases.

2 Methods

Backtrajectory modeling consists in the computation of particles path back in time within a fluid. As Chemistry Transport Models (CTM) give information on the future path of particles or chemical species, a backtrajectory model helps to trace back the fluid parcels that contain the species of interest. For atmospheric studies, many models offer solutions for backtrajectory computation. Among the most used we find the HYbrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) (Stein et al., 2015), FLEXPART (Pisso et al., 2019), LAGRANTO (Sprenger and Wernli, 2015), and the Stochastic Time-Inverted Lagrangian Transport model (STILT) (Wen et al., 2012). Hirdman et al. (2010) developed a method based on statistical analysis of FLEXPART backtrajectories combined with ground based measurements to identify geographical origins of observed atmospheric species. This method has been used to identify the emissions sources of INPs (Irish et al., 2019; Si et al., 2019), atmospheric mercury (Hirdman et al., 2009), tropospheric ozone and black carbon (Hirdman et al., 2010). However, this method has never been validated yet. Instead, previous studies only verified that the identified emission zones corresponded to expected areas. As it is commonly used, the method is only able to confirm expected emission sources. Identifying unknown sources necessitates a further assessed method.

In this section we describe the models and methods we used to lead our study. The results are presented in Sect. 3.

2.1 WRF-Chem model for simulating concentration time series

In order to construct series of simulated concentrations at Arctic measurement sites with known emissions sources, we use the *Weather Research and Forecasting model including Chemistry* (WRF-Chem) regional model.

2.1.1 Model setup

The WRF-Chem model is a widely used non-hydrostatic numerical model of mesoscale meteorology and atmospheric chemistry (Skamarock et al., 2022; Grell et al., 2005). The version used here is optimized for high latitudes and presented in detail in Lapere et al. (2024) and Marelle et al. (2017).

WRF-Chem is guided by Final Operational Global Analysis data (FNL) from the American *National Center for Environmental Prediction*, with six hours time-steps. The simulation is run on a $10,000\ \mathrm{km} \times 10,000\ \mathrm{km}$ square domain centered on

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

Table 1. Tracer parameters in WRF-Chem-Polar.

Tracer name	Regional condition	Parameterization
Sea ice	Over ocean, with sea ice fraction larger than 0.5	Monahan et al. (1986)
Open ocean	Over ocean, with sea ice fraction smaller than 0.5	Monahan et al. (1986)
Continent	Over continental regions	Ginoux et al. (2001)

The parameterizations refer to the application of the condition on wind speed.

the north pole, with an horizontal resolution of 50 km and 72 vertical levels. The WRF version used for this study is 4.3.1. The detail of the options used for the simulations are described in Table A.

2.1.2 Tracer emission

The WRF-Chem model is used to simulate the emissions, transport and removal of three different tracers on a duration of 24 months (September 2019 to September 2021). The latter are short-lived particles with wind-dependent emissions. Each of them represents the emissions of surface type sources categorized as follow: continental, oceanic from ice-free regions, and oceanic from sea ice regions. The continental tracer could be assimilated to mineral dust or continental biogenic aerosols, the open ocean tracer corresponds to sea spray emissions, and the sea ice tracer to blowing snow emissions. We chose to focus on natural sources because they are not well constrained in the Arctic. In addition, their relative contributions to the emissions of CCN and INPs is still unclear (Burrows et al., 2013; Gong et al., 2023; Hartmann et al., 2021), which motivates us to study those types of particles. Nevertheless, the results of this experiment stay valid for other atmospheric species.

The emissions are led by processes relying on wind speed with surface type dependency. The detailed definitions are presented in Table 1. All the tracers have a lifetime defined as an exponential decay with a characteristic time of three days.

2.1.3 Tracer interpolation at Arctic sites

The concentrations of each tracer are daily interpolated at the coordinates of five Arctic stations: Alert (Canada), Ny-Ålesund (Svalbard), Tiksi (Russia), Utqiaġvik (Alaska) and Villum (Greenland). Series of simulated concentrations of the three tracers can therefore be set up. The five stations were chosen for their distribution around the Arctic basin (Fig. 1e). This distribution sets the conditions for assessing the spatial sensitivity of the method in this region. Furthermore, many measurement campaigns are conducted at these stations (e.g. the Ny-Ålesund Aerosol Cloud Experiment, NASCENT (Pasquier et al., 2022)).

Figure 1 presents the emission regions (panels a, b, c) of the three tracers through their integrated emissions over one year of simulation. Panel (d) shows an example of a reconstructed series of concentrations interpolated at the coordinates of the Svalbard station, Ny-Ålesund. A seasonal variability of the concentrations can be clearly detected, which is in accordance with actual observations of Arctic species. This variability is mainly due to seasonal variations of mesoscale atmospheric transport and to local wind speeds (both phenomenons reproduced by WRF). Variability in precipitation rates and therefore in wet removal should also be considered (Freud et al., 2017). Nevertheless, not all simulated concentration series show such a

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

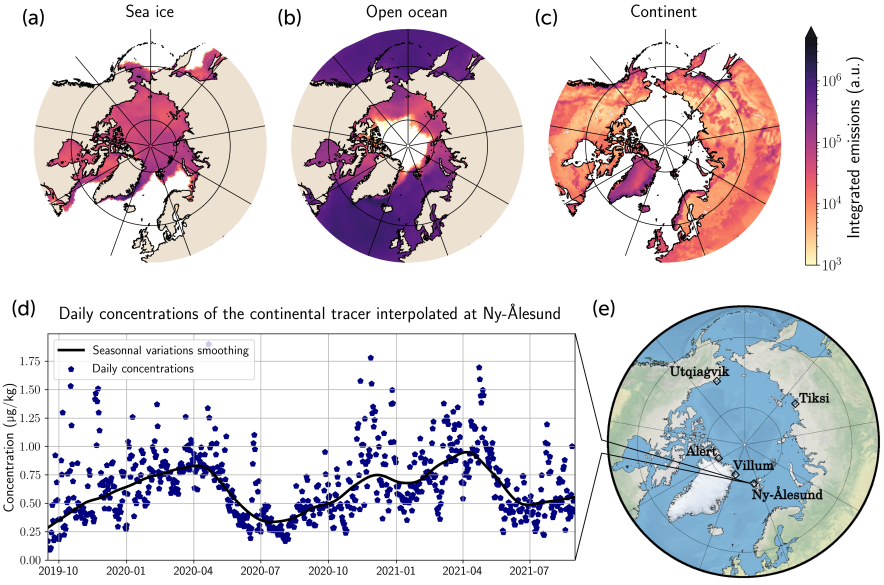

Figure 1. Overview of the tracers emissions in WRF-Chem and concentration series reconstructions. Regions of emissions of sea ice (a), open ocean (b) and continental (c) tracers. (d) Example of reconstructed series of daily concentrations interpolated at Ny-Ålesund. (e) Map of the Arctic with the locations of the five studied stations. Base map from Cartopy © British Crown copyright, 2016

variability, it depends of the tracer and the station. The strongest variability is found for the continental tracer; the lowest for the sea ice one. More broadly, the farther the emission source from the station, the weaker the observed variability.

Reproducing real concentrations series is not in the scope of this study. Therefore, even though the tracers have aerosol particles like properties, the interpolation of their concentrations does not mimic instrumentation used for this type of measurement. Consequently, it is important to note that these series can not be assimilated to actual concentrations of any atmospheric species.

The knowledge of the tracers emissions conditions peculiar to this experiment allows the evaluation of the method performances. Theoretically, a perfectly working method of tracking would point out the exact sources of emission that correspond to each tracer. Practically, the performances of backtrajectory methods are heterogeneous among tracers and from a station to another. Section 3.3 discusses the way the method should be applied in order to get the best performances and what parameters drive its success.

2.2 Backtrajectories plumes with FLEXPART-WRF

FLEXPART belongs to the family of Lagrangian Particle Dispersion Models (LPDMs). These are stochastic tools for the modeling of large amount of air tracers. The Lagrangian approach allows for reduced numerical diffusion (Cassiani et al.,

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

2016) which therefore leads to better capturing atmospheric diffusion than Eulerian models (Pisso et al., 2019). LPDMs also show the advantage of remaining independent of the model grid resolution since they use Lagrangian approach. This accounts for the recommended utilisation of LPDMs for the interpretation of backtrajectories in sources tracing (Stohl et al., 2002).

FLEXPART (Pisso et al., 2019) simulates emission, diffusion, and deposition processes (wet and dry) or time-based decay of atmospheric tracers. The emission is done through single or multiple volume sources, and the simulation can be run forward or backward in time. The path of the emitted tracers is followed through a plume representation expressed in terms of *Potential Emission Sensitivity* (PES) in seconds. It can be likened to the resident time of particles in each grid cell. This information surpasses the direction of origin commonly given by simple trajectories (Hirdman et al., 2009). The FLEXPART performances have been validated with multiple atmospheric tracers release experiments (Stohl et al., 1998). Furthermore, Hegarty et al. (2013) demonstrated the FLEXPART ability for reconstructing dispersion of atmospheric tracers.

When investigating ground emissions, it is common to introduce the footprint PES (FPES), defined as the PES of the first FLEXPART vertical level. The latter will be defined here as the first $100\ \mathrm{m}$ above ground level. Here we use the FLEXPART-WRF version of the model. It is optimized to use WRF output data (cf. Sect. 2.1), allowing the control of meteorological variables through WRF. In FLEXPART-WRF, several FLEXPART schemes are replaced by the WRF's ones (Brioude et al., 2013). FLEXPART-WRF set in backward mode is able to simulate the so called backtrajectories with particle diffusion all along the edges of the backtrajectory. It intends to give information on the particles origins. The accuracy of the transport patterns simulated by FLEXPART-WRF decreases with the augmentation of the backward simulation duration and relies on the accuracy of the initial WRF simulation in terms of meteorological variables.

2.2.1 Emission configuration in FLEXPART

The tracers in FLEXPART are characterized with five parameters (Table 2). First, we define the release time of the particles. In our case, the model emits on a whole day corresponding to the associated in situ measurement (Sect. 2.1.2). Then, we set the release box, which is defined as a $50\ \mathrm{km}$-wide grid cell, and the trajectories are computed backward in time for seven days before the time of release. An arbitrary value of $10,000$ particles released in that grid cell is chosen based on the parameter set by Raut et al. (2017) and Irish et al. (2019) for similar purpose. The sensitivity to the number of released particles is low; it only shifts the magnitude of the PES which does not impact the subsequent analysis. Finally, we can set different schemes for the tracers dry and wet deposition. For the experiment depicted in Sect. 2.1.2 we set an exponential decay similar to the WRF-Chem tracers used to construct the concentration time series.

The complete FLEXPART-WRF configuration file used here is available (cf. Data and Code availability). FLEXPART-WRF is run for every point of the concentration series (715 days at the 5 different locations) with the parameters described hereinabove. Finally, the ratio method (Sect. 2.3) is applied on the FLEXPART-WRF outputs, and the results are analysed for the three tracers (sea ice, open ocean, continent) independently.

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

Table 2. Emission parameters for FLEXPART-WRF.

Parameter	Description
Release period	Day of measurement (1 day)
Release box	50×50 km-wide and 100 m tall box covering the measurement site
Backtrajectory duration	7 days
Number of released particles	$10,000$
Deposition	Exponential decay with $\tau = 3$ days*

*Deposition parameters can be set differently depending on the studied species.

2.3 Statistical source identification method

In this study, we work on a statistical analysis method of backtrajectories inspired by Hirdman et al. (2010). The method is itself inspired by the analysis protocol introduced by Ashbaugh et al. (1985). Since then, this method has inspired several studies (e.g., Irish et al., 2019; Si et al., 2019) but has never been evaluated. In the following, we will stick to the methodology introduced in Hirdman et al. (2010) without the bootstrapping post analysis, like it is mostly applied in the studies that used it. It will be referred as the "ratio method".

The approach relies on both atmospheric species concentrations measurements and model outputs from FLEXPART-WRF. For each point of the concentration series, a FLEXPART-WRF simulation is run in backward mode. Then, the outputs of every run are sorted according to the measured particles concentration they are associated with. The great majority of earlier studies relying on backtrajectory analysis stop here without further analysis. Notwithstanding, at this step, we only have information on the direction of origin, with proximity bias near the measurement site. In the present study, we use a deeper analysis described as follows.

Let us consider S_t as the average of the FPES fields from a set of N FLEXPART-WRF runs:

$$S_\mathrm{t} = \frac{1}{N} \sum_{n=1}^{N} S(n) \tag{1}$$

where N is the number of model runs, and $S(n)$ the array of FPES associated with the measurement n.

S_t can be interpreted as the climatology of the origins of air masses that are associated with the particle concentrations series on the studied period. We can sort the concentrations in order to select the $P = \frac{x \times N}{100}$ highest and lowest concentrations, with x the percentage of selection. Thus, if S is the series of FPES fields sorted from the lowest to the highest measurement value, we can define S_h^x and S_l^x the climatologies of the origins of air masses associated with respectively the P highest and lowest

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

particle concentrations. These new fields are expressed as follow,

$$S_{\mathrm{h}}^{x} = \frac{1}{P} \sum_{n=N-P}^{N} S(n) \tag{2}$$

$$S_{\mathrm{l}}^{x} = \frac{1}{P} \sum_{n=1}^{P} S(n) \tag{3}$$

As the PES decrease with distance from the measurement site, a proximity bias is observed on these climatologies, giving the impression of mainly local sources. To eliminate that bias, we compute the ratio of S_{h}^{x} (respectively S_{l}^{x}) to the total climatology S_{t}. We thus can define R_{h}^{x} and R_{l}^{x}, the respective ratios of the "high" and "low" climatologies,

$$R_{\mathrm{h}}^{x} = \frac{P}{N} \frac{S_{\mathrm{h}}^{x}}{S_{\mathrm{t}}} \tag{4}$$

$$R_{\mathrm{l}}^{x} = \frac{P}{N} \frac{S_{\mathrm{l}}^{x}}{S_{\mathrm{t}}} \tag{5}$$

Values equal to $f = x/100$ indicate no deviation from the average field S_{t}. Consequently, the points where R_{h}^{x} is higher than f correspond to regions of likely origins for the studied particles. The same reasoning applied on R_{l}^{x} leads to the conclusion that the corresponding field indicates no longer sources but sinks of the studied species.

One should be aware that the significance of R_{h}^{x} and R_{l}^{x} is proportional to the value of S_{t}. Low values of S_{t} indicate few transport through the corresponding grid points and therefore can invalidate the statistical results of the ratios computation. Practically, too high values of the ratio can be suspected as spurious indications. However, if the percentage x is strict (i.e. low) enough or the total number N of runs is large enough, these excessively high values should not appear.

In the following, we will discuss furthermore how to define a threshold on FPES in order to prevent false interpretation of the ratio fields. Moreover, because the ratio method allows to get rid of the FLEXPART proximity bias, it can miss the detection of very local sources when applied on a large domain. However, this effect is only proportional to the domain size and resolution. Hence, it can be mitigated by either increasing resolution or downscaling the domain.

3 Results

3.1 Metric of evaluation

The main result of the ratio method is the ratio map associated with the highest concentrations of the studied series. By itself it gives qualitative information on the sources origin of the species. In order to get some quantification, we use the definition of the surface types that corresponds to the tracers emission (Table 1). Masking the ratio maps with continental, open ocean and sea ice masks and then summing the ratio values corresponding to these surface types, we get a quantification of the actual detection performed by the method. We call D the score of the surface type corresponding to the tracer. A perfect detection would be a full contribution of the surface type corresponding to the analysed tracer. For instance, the method applied on the concentrations of the continental tracer should lead to a detection of the continent, with a limited contribution of sea ice and

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

open ocean regions. In that case, D would tend towards 1. Practically, the ratio method gives various results. Therefore, a metric with five levels of success has been defined to catch the fluctuations of the method performances. Table 3 describes the metric levels. Good confidence is attributed to the results when level 2 is reached. Levels 0 and 1 call for special attention and map analysis.

Table 3. Definition of the criteria for the evaluation of the ratio method results.

Level of success	Criteria
0	D is not first contribution
1	D is first contribution
2	$D > 0.5$
3	$D > 0.5$ and second contribution < 0.25
4	$D > 0.8$

3.2 The standard ratio method

In this section, we use the ratio method as presented in Sect. 2.3. We apply it on the simulated data constructed with the numerical experiment presented in section 2.1.2. For clarity, we present one case: retrieving the sources of continental tracer emissions from the Ny-Ålesund simulated concentration series.

Figure 2 illustrates the application of the ratio method on one of the tracers simulated in the idealized experiment (Sect. 2.1.2). Panel (a) shows the concentration series of the continental tracer interpolated at Ny-Ålesund over two years of simulation. Highest and lowest concentrations are flagged with respectively red and cyan colors. The second line of Fig. 2 is dedicated to the maps of FPES (panels (b) and (c)) and to the ratio map (panel (d)). The map (b) corresponds to the S_t defined in Sect. 2.3. It is the climatology of the origins of all the air masses ending at Ny-Ålesund over the two years of simulation. Similarly, (c) shows S_h^{10}, the climatology of the air masses origins that contained the 10% highest continental tracer concentrations of the series. Finally, (d) shows the ratio of S_h^{10} over S_t which has been presented as R_h^{10}. The result map, which is the ratio one, shows various regions of likely sources of continental series. Greenland and Canada ahead, there is also less continuous signal spots in Eurasia. Even though there is some signal overflow over the north Pacific, the Baffin bay and a small amount over the Arctic ocean, the quantification metric (defined in Sect. 3.1) gives to this case a score of 2. It means that the continental source is correctly detected.

The results for the continental tracer on the other stations (Alert, Tiksi, Utqiaġvik, excepted Villum) reach success (as it will be seen in Fig. 4a). Nevertheless, the application of the method on both sea ice and open ocean tracers gives poor results. Only Ny-Ålesund and Tiksi show a correct detection for the open ocean case. Otherwise, all the other detections fail, showing the continent as the main contributor (Fig. 4a). This observation questions the reliability of the continental tracer results. Indeed, a geographical bias strengthens the continental signal. We can identify two reasons for this behaviour. Firstly, the domain of simulation tends to over represent continental regions. Indeed, the continent accounts for 53% of the total surface area, when

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

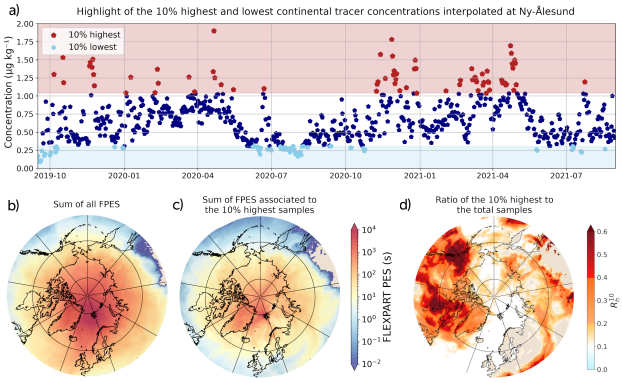

Figure 2. Application of the ratio method as it is depicted in Sect. 2.3. Panel (a) shows the reconstructed daily concentration series of the continental tracer interpolated at Ny-Ålesund on the two years of simulation. (b) is the climatology of the total air masses origins, (c) the climatology of the origins of air masses that brought the 10% highest concentrations, and (d) is the ratio of (c) on (b), noted R_{h}^{10}.

the open ocean and the sea ice regions represent on average 37% and 10% respectively. In the idealized situation of exact back-tracking of the air masses, this bias should not affect the detection results. However, dispersion modeling is innately imperfect. The computation of the ratio induces loss of information on FPES intensity. The latter is replaced by the ratio values which can reach its saturation value of one for regions where very few backtrajectory plumes passed. If an area is covered only by backtrajectory plumes associated with the highest concentrations of the measurement series, we get a saturation of the ratio. Thereby, regions of very low FPES can end up highlighted on the ratio map even though they are not statistically significant values. Consequently, irrelevant signals affect the detection, likely benefiting the predominant surface type, namely the continent in this Arctic situation.

Secondly, and to a lesser extent, the other reason for biased results is the seasonal variability of the concentration series. As described in Sect. 2.1.2, the simulated concentrations vary during the year, with maximum concentrations in winter/spring and low concentrations in summer and autumn, following the well known Arctic Haze seasonal cycle. The latter is due to efficient transport of air masses from land masses in the mid-latitudes during spring (Schmale et al., 2022). As a result, applying the ratio method on annual observations of short-lived pollutants in the Arctic produces a climatology of air mass origins in winter and spring, and is biased for lower latitude sources, over-representing continental sources as seen in our evaluation on Fig. 4a.

These implications suggest that the method, in its current state, is not suitable for studies involving real measurement data. The next section will present and discuss the improvements that make the method reliable for real case studies. In the following, we will talk about the *standard ratio method* (Sect. 3.2) and the *improved ratio method* (Sect. 3.3).

3.3 Improving the method

In Sect. 3.2, the standard ratio method gave ambiguous results. In this section, we present how one can improve the method in order to get more reliable source detection. In order to get rid of the seasonal variability bias, we sort the concentrations

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

upon their difference to the seasonal tendency of the series, rather than sorting them with their absolute values. Practically, we estimate the seasonal tendency by fitting the series and then subtracting it from the concentrations.

Concerning the over representation of the continental area, a cutting threshold on FPES is set in order to filter the less significant backtrajectories. The values of S_t, S_h and S_l under this threshold are removed for the ratio computation. The risk with this tuning is to loose information while filtering the lowest FPES values. We performed tests in order to identify the best threshold, using the idealized tracers experiment for the assessment. The details of the latter are discussed in Sect. 4. We get the best results for a variable threshold that filters the 2 % lowest FPES of the studied case. In this manner, we remove the majority of isolated backtrajectory plumes which are less statistically significant.

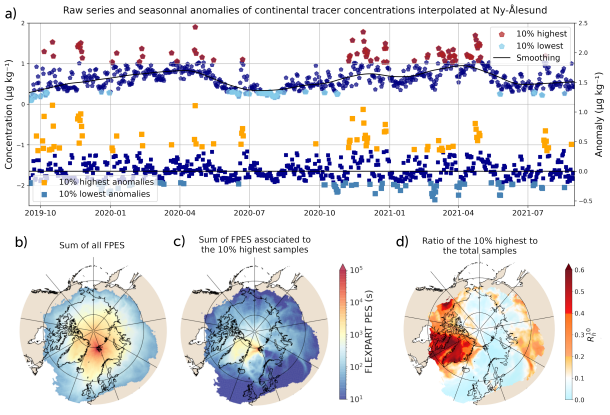

Figure 3. Application of the improved ration method. Similarly to Fig. 2, (a) shows the reconstructed daily concentration series of the continental tracer interpolated at Ny-Ålesund with the comparison of the standard sorting (top) and the seasonal sorting (bottom). (b) is the climatology of the total air masses origins, (c) the climatology of the origins of air masses that brought the 10 % highest concentrations, and (d) is the ratio of (c) on (b), noted R_h^{10}. In (b) and (c) the 2 % lowest FPES have been removed, as explained in Sect. 3.3.

These two modifications to the ratio method are illustrated in Fig. 3. Panel (a) displays the original concentration series with the classical sorting of high and low values (top), as well as the series constructed with the differences to the seasonal variations (bottom). The highest values of the latter are flagged in yellow. They are more evenly distributed along the simulation period than the raw concentrations. The effect is even clearer for the lowest concentrations; some of the lowest points happen in the cold season, which was never the case with the standard sorting method.

Panels (b), (c) and (d) highlight the effect of the filtering threshold on FPES. Indeed, removing the 2 % lowest FPES erased a corona of values clearly visible on the climatology maps. The ratio map of panel (d) presents a much smaller area of values above 0.1. The overflows over sea ice and open ocean regions are greatly reduced. The Baffin Bay is the region where incorrect signal remains. This shows that leaks can still happen, especially around regions of intense emissions. The north American and Eurasian signals decreased as well. Even though they correctly corresponded to continental emissions, their significance

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

is considered as low because they were due to regions of low FPES. The quantification of the detection indicates a level of success for this case of 3, when the standard method only gave a value of 2.

In order to take maximum advantage of the ratio method, the information contained in the ratio associated with the lowest concentrations can also be used. Indeed, this ratio points the regions where the sources do not likely come from. Thus, its reverse $(1 - R_{\mathrm{l}})$ can be used as a mask applied on R_{h}. We use $R_{\mathrm{h}} = R_{\mathrm{h}}^{10}$ and $R_{\mathrm{l}} = R_{\mathrm{l}}^{33}$. Thus we get a composite ratio defined as follows,

$$R_{\text{10-33}} = R_{\mathrm{h}}^{10} \times (1 - R_{\mathrm{l}}^{\uparrow 33}) \tag{6}$$

Where $R_{\mathrm{l}}^{\uparrow 33}$ are the values of R_{l}^{33} above 0.33. We choose to use R_{l}^{33} rather than R_{l}^{10} and R_{l}^{5} because it considers more backtrajectories and thus it is a more statistically significant ratio. Additionally, unlike the ratio of high concentrations, we aim to select as many regions as possible that are detected as unlikely sources.

Testing the detection performances of the composite ratio showed improvement in six out of fifteen cases, and generally enhanced the values of the correct bars in 80 % of the cases. We therefore include the composite ratio as a final step for the improved ratio method.

3.4 Results comparison

The success levels allow easy comparison between the different ways the method is applied. Therefore, we can compare the performances of the standard method – as if we apply straight forward the ratio method described in Sect. 2.3 – with the results of the improved method presented above. Figure 4 illustrates these results.

As mentioned in Sect. 3.2, the assessment of the standard method (Fig. 4a) does not provide a level of confidence high enough to trust its results. The improved method performs better in ten out of fifteen tested cases, worse in one case, and equally otherwise. As expected, the overall contribution of the continental source decreased thanks to the FPES filtering threshold. The open ocean suffered the same effect. The improved method detects much more accurately the origins of the ocean, continental, and sea ice tracers, with correct attributions at 4/5 stations for the ocean tracer (3 in the original method), 3/5 for the ice tracer (0 in the original method), and 5/5 for the continental tracer (4 in the original). In addition, the quality of the detection score is improved or identical, degraded in only one case (open ocean tracer at Tiksi).

However, a few detection still fail. The source detection of the sea ice tracer at Alert is highly polluted by continental signal. The composite ratio maps of this case give insight on the reason for this fail, presenting an overflowing of the plume on the continental regions. The poor detection of the open ocean tracer at Alert and Utqiaġvik are due to hard shortening of the FPES from the threshold filtering. The plume mainly covers the regions of marginal sea ice. We observe the same thing for Tiksi, even though the map clearly shows the influence of both north Pacific and north Atlantic. Anyway, and for all cases, the composite ratio maps give great information on the region of origin.

3.5 Combination of stations

Some observations of atmospheric species are made within a measurement network composed of multiple experimental sites. The observations can therefore be simultaneous and equally distributed in time. This tends to draw a snapshot of the state of the atmosphere regarding the studied species or variables. An instance of this is the global network of daily radiosoundings that allows the adjustment of reanalysis and regional models (Hersbach et al., 2020).

We can envision that the species of interest we want to study are or will be part of an observational network. Therefore, how would the tracing method presented here take advantage of this? In order to answer that question, we compute the method combining the backtrajectories associated with the five Arctic stations previously described. Once again, we are in the presence of an idealized situation: the concentrations series are perfectly simultaneous and derived identically. True observational data might drift from these perfect conditions, however we believe this experiment can illustrate the potential of such an application of the method.

For the combination, we kept the sorting of high and low concentrations specific to each station. We did as well for the sorting of the corresponding backtrajectory plumes. The gathering is done at the step of ratio construction. S_h and S_l are computed as the sum of the corresponding ratios of every station. In the same way, the total climatology of the backtrajectory plumes, S_t, is now the sum of the PES plumes of the five stations. The ratios R_h and R_l are then calculated with equations 4 and 5.

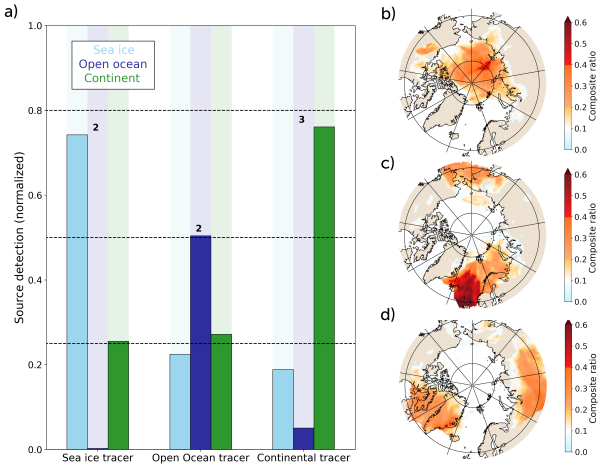

Figure 5. Results of the five stations combination. (a) shows the fraction of contribution of every surface type for the three tracers, and the associated success level. (b), (c) and (d) are the composites ratio maps for the sea ice tracer, the open ocean tracer and the continental tracer respectively.

The results show a successful source origin detection (Fig. 5). The continental sources are detected with a success level of 3, when the sea ice and open ocean get a success level of 2. This lower score for the open ocean could be explained by the geographical arrangement of the stations: open ocean regions are not well surrounded by the Arctic stations. When Villum and Ny-Ålesund are exposed to north Atlantic sea sprays, Utqiaġvik is hardly reached by these emissions. Conversely, the

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

north Atlantic stations do not get much signal from north Pacific emissions. More generally, sea ice and open ocean results are affected by some continental signal due to systematic coastal overflow. This effect leads to lower scores even though the composite ratio maps give clear insight on the origin regions. The existence of this unshrinkable surfeit of continental signal should be kept in mind when interpreting any results of similar application of the method.

Nevertheless, the combination of simultaneous observations of the same species has the potential to give precise clues on the regions of origins of the so called species. The implementation of data from mid-latitude stations could also improve the results by increasing the spatial coverage. Therefore, the present work encourages the development of observational networks.

3.6 Points for using a ratio methodology

Eventually, we did not test the improved ratio method against basic backtrajectory analysis. In order to get an idea on how they compare, Fig. 6 shows, through the example of the sea ice tracer for the Tiksi station, different visualisations of the FLEXPART-WRF backtrajectories. The first line shows the climatologies of the backtrajectories over the period of observation. These representations are the most commonly used in studies using backtrajectories (Fig. 6a and 6b). The second line shows the results of the ratio methods presented in this paper. What the figure reveals is that the sea ice origin of the tracer is only clearly found with the improved ratio method (6d and 6e). As a reminder, if the source detection was perfect, the light blue bar would reach one on Fig. 6e since the studied tracer was only emitted in sea ice regions. The climatologies, particularly Fig. 6b, provide general information about potential sources of the tracer. However, it does not allow for reliable quantification as seen in the corresponding column on Fig. 6e. Neither does the standard ratio method (6c), which gives – in this case – even worse quantification results than the climatology. Let us mentioned that weighting the backtrajectory plumes with the particles concentrations has also been tested, and did performed similarly as the climatology of the highest observed concentrations. Eventually, only the improved ratio method provides a clear map of the actual origins of the tracer (Fig. 6d compared to Fig. 1a) and enables unequivocal quantification of it.

4 Discussion on sensitivities

In this section, we investigate the sensitivity of our improved ratio method to key parameters: the sorting percentiles, the data series duration and frequency, and the filtering threshold on FPES.

4.1 Sorting percentiles

The standard ratio method uses the 10^{th} percentile to sort the highest and lowest points of the measurements series. A higher threshold would address more points which can be needed for statistical representativeness when the series is short. Some studies use percentiles of 33^{rd} or 36^{th} percentile to define what are the highest measurements (Irish et al., 2019; Si et al., 2019). On such short series, selecting the highest third of measurement amounts to look at a few particular backtrajectories, and the benefits of computing the ratio appears to be poor. On longer time series, using 33^{rd} percentile to define the highest measurements casts too widely among the observations and makes the ratio unable to identify the sources of emissions. With

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

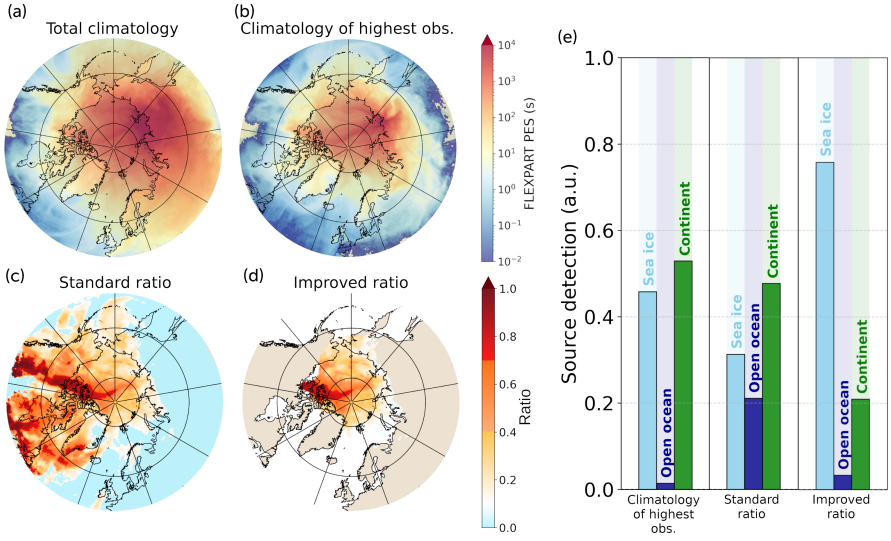

Figure 6. Panel of backtrajectory visualisations and analysis for the sea ice tracer at the Tiksi station. (a) and (b) are the climatologies of respectively the total backtrajectories and the trajectories associated to the 10 % highest observations (S_h^{10}). (c) and (d) are the ratio maps of the two versions of the ratio method (R_h^{10} for respectively the standard and improved versions). (e) is the quantification of the detection results for the climatology associated to the highest observation and for both versions of the ratio method.

such a high percentile, the method detects also some of the high concentration events due to particular atmospheric patterns, as well as some events of lower concentrations. This dims the source identification and makes it inefficient. Actually, the tests performed on the idealized tracers (Sect. 2.1.2) with a 33rd percentile for selecting the highest concentrations, show that the method is never able to retrieve the emissions sources of the tracers. Conversely, the 5th percentile does not select enough data points, leading to a miss detection of some of the main source regions. Finally, the 10th percentile, used by the standard ratio method, gives the best performances when used with one or two years long series of daily measurements.

4.2 Series duration

The original experiment had a duration of twenty-four months which corresponds to a complete double seasonal cycle. The sensitivity of the method to the duration and frequency of the concentration series is tested by reducing the number of points of the series. First, in order to test the sensitivity of the method to the time series duration, the experiment is reproduced on two periods of twelve months: on the first year and then on the second one. Then, in order to test the sensitivity of the method to the concentration sampling frequency, the concentration series is cropped to keep only one concentration point every two days. In other words, the number of points is divided by two keeping the same time extent than the original experiment (half frequency). Finally, only one point is kept every week (frequency divided by seven).

The results show that two years analysis does not improve the precision of the method compared to one year experiment. However, a difference is observed when measurements are only performed every two days: the success level loses one point

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

on average. Furthermore, lowering the frequency of measurement down to one every week causes to loose one additional level of success. In conclusion, increasing the time resolution enhances the method's performances. The sampling frequency should always be considered when applying the improved ratio method.

4.3 FPES filtering

The improved ratio method (Sect. 3.3) includes a filtering of the grid cells with the lowest FPES in order to remove the least significant model results near the domain boundaries. In practice, FPES values are filtered by a threshold determined after a percentage of the total FPES in the domain for a given case. The threshold should be kept as low as possible in order to avoid information loss. Nevertheless, when it is too low, some insignificant information may remain. In order to evaluate the effect of this FPES threshold on the performances of the sources detection method, seven thresholds are tested, from no filter to filtering 6 % of the lowest FPES values. Increasing the level of filtering shrinks the studied region around the starting point of the backtrajectories, i.e. the measurement station. Therefore, and because the selected stations are located around the Arctic basin, as the filtering level increases, the representation of the sea ice regions get stronger. In terms of success level of detection, it improves the scores for the sea ice tracer, but tends to lower them for the open ocean (Fig. 7a). Because the tests are performed on simulated tracers (Sect. 2), it is possible to use these findings to calibrate what threshold may give the most reliable and meaningful results for all tracers. In Sect. 3.1, the detection is rated as successful when the D score is superior or equal to two. On Fig. 7b, one is counted for every detection that satisfies the above condition (i.e. $D \geq 2$). Therefore, a given tracer can have a maximum overall score of five (i.e. a successful detection for the five stations). The evolution of the scores on Fig. 7b shows that a filtering of 2 % is the optimal compromise. It is the lowest threshold for which the total score plateaus. Although the scores for sea ice and continent reverse at a 3 % filter, this does not affect the total score, making it preferable to maintain the lowest possible filtering threshold. Consequently, for the Arctic domain studied in this paper, we recommend to use a 2 % filtering threshold.

5 Application examples on aerosol observational datasets

The improved ratio method presented in Sect. 3.3 has shown its capabilities in identifying the type (sea ice, open ocean, continent) of the emission sources of simulated atmospheric tracers. In this section, the method is applied to two observational datasets in order to test it under real conditions. The origin of the species observed in both datasets is well-defined: the first is continental, and the second is oceanic. This knowledge allows for a critical evaluation of the method's results. Discussing the results will provide clarity on how to apply the method correctly and accurately interpret its findings.

5.1 Aerosol absorption coefficient

The first dataset is a series of aerosol absorption coefficient measured at the Mount Zeppelin Observatory (Ny-Ålesund, Svalbard) at an altitude of 475 m above sea level, between January 2019 and September 2022 (Eleftheriadis, 2019). For the application we chose a two years period (September 2019 to August 2021), identical to the period on which the evaluation

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

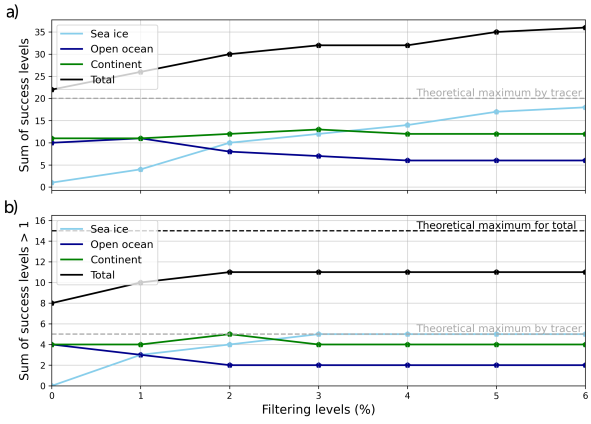

Figure 7. Evolution of the success levels sum for different levels of low FPES filtering. On (a), the sum is performed on the scores of the five studied stations (Alert, Ny-Ålesund, Tiksi, Utqiaġvik, Villum) independently for the three tracers (sea ice, open ocean, continent). The total success level is shown in black line. Panel (b) takes only the success levels superior or equal to 2 and sets it to 1. Dashed-lines represent the theoretical maxima of the individual tracers score (gray) and of the total score (black).

experiment has been held (Sect. 2.1.2). Aerosol absorption coefficient measured at 550 nm is known to be mostly driven by black carbon (BC) concentrations as it is by far the strongest absorbing aerosol species in the visible spectrum (Bond et al., 2013; Kirchstetter et al., 2004). Consequently, we consider the aerosol absorption coefficient as a marker of BC. BC is a great candidate for a first application of the method because its sources are relatively well known. Ninety percent of the BC emissions are produced by continental sources, mainly biomass burning and incomplete combustion of fossil fuels from traffic and industrial activities (Bond et al., 2013).

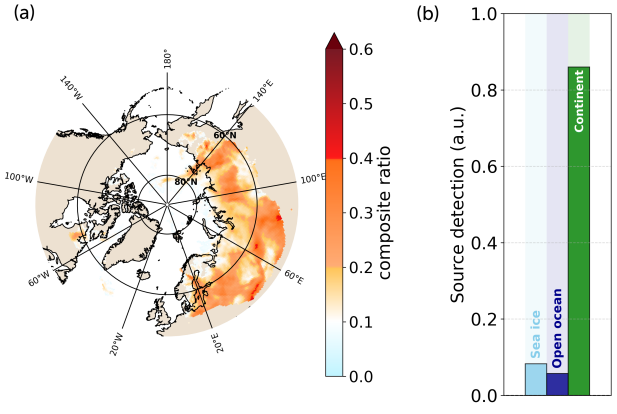

Figure 8. Results of the improved ratio method when applied on a data series of absorption coefficient measured at the Zeppelin Observatory (Ny-Ålesund, Svalbard). (a) is the ratio of the improved method that highlights the likely regions of origins. (b) is the quantification of the surface types contributions to the three sources (sea ice, open ocean, continent).

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

Figure 8 shows the ratio of the improved method as presented in Sect. 3.3 alongside the contribution of sea ice, open ocean and continental regions to the detection signal. Panel (a) highlights a strong Eurasian signal spreading from Northern Europe all the way to eastern Siberia. Panel (b) confirms the continental origin showing that more than 80 % of the signal comes from continental regions. Figure 4b showed that the detection of a continental originated species at Ny-Ålesund could give spurious signal of oceanic regions (sea ice and open ocean). Therefore, the weak oceanic signals showed on panel (b) can be considered as detection noise. The application of the improved ratio method to this series of BC measurements at Zeppelin station unequivocally leads to the conclusion of a continental origin of the observed BC in Svalbard. This finding corroborates the results described in Gilardoni et al. (2019) and Hirdman et al. (2010), i.e. BC observed at high-altitude sites comes from remote locations, mainly associated with Eurasian emissions.

5.2 Methanesulfonic acid

Methanesulfonic acid (MSA) is an organosulfuric compound. Its presence in the atmosphere is due to the emissions of dimethylsulfide (DMS). DMS is produced by marine bacteria and phytoplankton activity and can be oxidized into MSA in the atmosphere (Saltzman et al., 1983; Hopkins et al., 2023). Therefore, MSA measurements are expected to be associated with air masses of marine origins. Here, the dataset is a series of MSA particle phase measurements performed in the context of the Ny-Ålesund Aerosol Cloud Experiment (NASCENT) campaign held in Svalbard between September 2019 and August 2020 (Pasquier et al., 2022). The measurement series used in this study extends from January to December 2020. However, data is missing between July and August due to an instrument failure (Siegel et al., 2023). Similarly to the BC measurements (Sect. 5.1), the MSA measurements have been done at the Zeppelin Observatory.

The analysis of the results shown in Fig. 9 is non-trivial and should be taken as a textbook case of source identification by the ratio method. Panels (b) and (c) show the results for the analysis of the complete dataset extending on the whole 2020 year, while panels (d) and (e) show the results for the measurements between April and early July 2020. Panel (c) shows that, for the whole period of measurements, the main contribution is oceanic, but followed closely by the continental signal, while the sea ice regions contribution amounts to almost zero. The ratio map shown on panel (a) indicates that two main spots stand out. The western one shows strong signal on the Baffin Bay, Labrador Sea and Greenland Sea. Despite some overflow on continental areas, this spot mainly contributes to the oceanic signal. The second spot spreads over Northern and Eastern Europe. Signal comes from the regions of the North Sea and Baltic Sea which are both regions of high chlorophyll-*a* (Chl-*a*) concentrations. Nevertheless, the main signal of this spot is over continental areas. A part of it may be ascribed to overflows, but the eastern strip has to be considered as an actual signal. It points toward the north of the Caspian Sea, where the phytoplankton might be important (Eker, 2005). However, no study reports DMS or MSA emissions from this region, and it would be speculative to conclude on a contribution of Caspian Sea origins for the MSA observed at Zeppelin Observatory during this period.

Alternatively, the analysis of the individual backtrajectory plumes teaches that this eastern continental spot is due to three consecutive dates in mid-October (Fig. 9a). Despite the fact that they correspond to low measurement values regarding the observed MSA summer peak, they happen to be flagged as high seasonal anomalies in the measurement series. This is due to

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

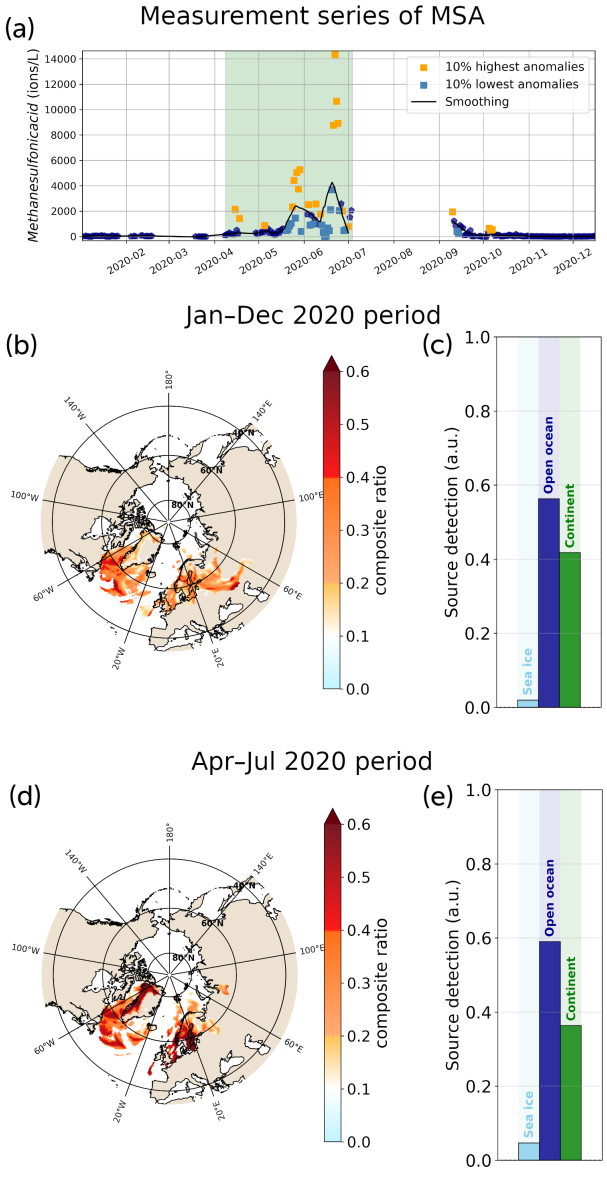

Figure 9. Results of the improved ratio method when applied on the data series of Methanesulfonic acid (MSA) measured at Zeppelin Observatory. (a) is the measurement series of MSA over 2020. The points corresponding to the 10 % strongest anomalies are represented in orange (high anomaly) and light blue (low anomaly) squares. (b) and (c) show the results for the complete series of measurements (January to December 2020). (d) and (e) show the results for a period of continuous measurements of the dataset (April to early July).

the very low levels of MSA observed after mid-September. The absence of measurements over July and August produces a lack of representativeness for the high summer values, which explains why these three dates stand out.

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

On Fig. 9d and Fig. 9e, the method is applied on the three months period of high MSA activity between April and early July (green period on Fig. 9a). Oceanic regions previously identified remain and are even better highlighted (Fig. 9d). Consequently, the contribution from open ocean regions increases while the continental signal decreases (Fig. 9e). The latter is now mainly due to overflows over Greenland. Although they are spatially limited, such overflows are associated with strong signal values, which is significantly boosting the continental contribution because the statistical representativeness dropped due the series cropping. Let us remind that the detection of oceanic source at Ny-Ålesund can be polluted by 25 % of spurious continental signal (Fig. 4b). Additionally, some Northern Russia signal spots remain. They could be associated with the Barents Sea high phytoplankton coastal activity. But their size and strength do not allow such conclusion since the method does not present high enough spatial precision.

Eventually, the results presented in Fig. 9d and Fig. 9e suggest an oceanic origin of the MSA measured at Zeppelin Observatory between January and July 2020. We identified two main source regions: the western North Atlantic (Greenland Sea, Labrador Sea and Baffin Bay), and the North Sea/Baltic Sea, which is in great accordance with the results of Pernov et al. (2024) for the corresponding season. Furthermore, these conclusions are consistent with the Chl-*a* observations during the studied period (NASA Ocean Biology Processing Group, 2022).

6 Conclusions

This study aimed to introduce an enhanced and evaluated methodology for tracing the sources of atmospheric species using backtrajectory modeling, with a focus on the Arctic region. We adapted the method presented by Hirdman et al. (2010), taking advantage of the FLEXPART backtrajectory plume representation to provide deepened information on the potential sources than classical single backtrajectory analysis would do. Named after its principal characteristic, the ratio method relies on the identification of the deviation of the air masses origins associated with the highest observed concentrations, divided by the climatology of air mass origins for a given measurement station and time period.

To get insight of the performances of the ratio method, we analyzed simulated data of idealized tracers emitted within WRF-Chem from three different surface types : the Arctic sea ice, and the open ocean and continental regions. The complete knowledge of the simulated tracers emissions allowed to continuously assess the performances of the source detection method, along with its sensibility to a set of parameters. This context made it possible to refine the methodology.

Testing the approach of the standard ratio method on simulated data showed it is unreliable for the identification of the simulated tracers origins, and therefore for identifying source regions of short-lived atmospheric species. The reasons for this lack of reliability and the responses we have tested are listed hereinbelow, by order of decreasing importance.

- The results are highly dependent on the percentile threshold used to sort the concentrations between the highest and lowest measurements. While the 33^{th} percentile has been used in the literature without being strictly evaluated (Irish et al., 2019), our results shows that such a high threshold can not be used to identify likely sources with confidence. We recommend to select the 10 % highest values, which implies to have sufficiently long series. Although some conclusions of previous works may be right, they should be re-evaluated with the improved ratio method presented here.

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

- The results of the standard ratio method are influenced by the geographical layout, with an over-representation of the continental areas in the detected sources. We introduced a filter on the lowest backtrajectory values in order to get rid of the less statistically significant ones. It led to a better representation of the three surface types, which resulted in a dramatic improvement of the detection results.

- The standard ratio method can either seek the sources or the sinks regions of a studied species, but the results stay independent. With the improved ratio method, we introduced a composite ratio that takes advantage of the information contained in the detection signal associated to both the highest and the lowest measurements.

- We found that sorting the raw concentrations between highest and lowest values was seasonally biased by the underlying annual cycle. We updated the method to instead sort concentration anomalies after subtracting the low-frequency annual cycle.

A limitation inherent to our evaluation protocol is the choice of the backtrajectory duration. We set up FLEXPART-WRF to follow the air masses pathways seven days back in time, which was coherent with the lifetime of our simulated tracers. Therefore, the improved method we developed is optimized for short-lived atmospheric species. Using the method thus implies to make assumption on the lifetime of the studied species. An extended evaluation would explore how the ratio method performs with long-lived species, which was not in the frame of this study. In a similar way, our evaluation has been specific to the Arctic region. Consequently, some parameters of the improved ratio method – especially the FPES filter – are set for best performance in the northern high latitudes. For other regions, with different geographical layouts, the FPES filtering may need to be adjusted with an other simulated experiment, similar to the one presented in this study. We recall that the FPES filter is mainly used to restore balance to the representations of the different surface types (sea ice, open ocean, continent) in the domain. In lower latitude domains, the FPES filter could be of less importance. Regarding the limitations of the backtrajectory approaches, the intrinsic uncertainties of the backtrajectory model can not be cleared of. Since backtrajectories rely on simulated meteorological fields, the precision of the source detection suffers from both the errors of the backtrajectory model and those of the weather model or reanalysis. However, we got rid of the latter in our evaluation experiment since we use the same model to produce the data and to feed the backtrajectory model. The tests performed on this advanced ratio method showed it can give useful information on the origins of atmospheric species, even though this kind of approach has inherent limitations. The results presented here allow to estimate the magnitude of these limitations in order to adopt a critical look on any result from real applications of the method.

The assessment of the method time resolution (frequency of measurement points) sensitivity showed that series of daily measurements give better results than series of lower frequency, and therefore should be privileged for applying the method. Combining simultaneous observations of the same species at different locations can also help to give more precise source detection, and should be encouraged for future campaigns.

The evaluation led in this study allowed with a unique modeling approach to quantify the source detection performances of the ratio method inspired by Hirdman et al. (2010), and as it has been used in several research articles (eg. Irish et al., 2019;

https://doi.org/10.5194/egusphere-2024-2839
Preprint. Discussion started: 11 October 2024

Si et al., 2019). Although this standard ratio method is more advanced than widely used inverse modeling analysis (Allen et al., 2021; An et al., 2014; Hartmann et al., 2021; Lu et al., 2012; Porter et al., 2022; Raut et al., 2017; Wex et al., 2019; Winiger et al., 2016), the assessment results shown that its performances are insufficient for identifying unknown emission sources of atmospheric species. Conversely, our improved ratio method is able to retrieve the source regions of an observed atmospheric species with an unprecedented precision. The demonstrated performances instill confidence to use the method in order to identify unknown sources and to confirm presumed ones.

Because reverse modeling analysis for source identification is widely used, the results presented here impact many past and future studies. The new analysis protocol for emission origins detection presented alongside the performance evaluation may find its application in a wide range of atmospheric studies. Here we show an Arctic application, but the conclusions should be general for short-lived atmospheric species in other regions. Therefore adoption and testing of this method in other regions is recommended.
