14 Abstract

15 Particle acidity is a critical parameter that affects atmospheric chemistry. Concerns have been
16 raised about the exacerbating aerosol and rainfall acidity due to China's ongoing efforts to reduce
17 ammonia emissions. Therefore, it is urgent to clarify the changing trends in particle pH response to air
18 pollution control policies, especially in North China, which is significantly affected by dust aerosol.
19 12-years observational data in Zhengzhou reveal that the annual average PM_{2.5} concentration
20 decreased from $212 \pm 102 \mu\text{g}/\text{m}^3$ in 2013 to $60 \pm 41 \mu\text{g}/\text{m}^3$ in 2022, with the largest reduction in sulfate
21 (79%). Correspondingly, the annual particle pH increased by 0.11 units from 2013 to 2019. In addition,
22 the elevated particle pH in 2015 and 2018 was notably influenced by the increase in TNH_x (NH₃ +
23 NH₄⁺). Note that the crustal material concentrations and their proportions increased significantly
24 during 2019–2022, which might be responsible for the resuspension of surrounding soil dust. Even
25 though the TNH_x concentration was decreasing, the annual average growth rate of pH values increased
26 to 0.21 units from 2019 to 2022. This phenomenon is not unique to Zhengzhou, as major cities in the
27 North China Plain have also experienced a pronounced upward trend in coarse particles after 2019.
28 Therefore, the future ammonia reduction policies in North China may not lead to a rapid increase in
29 particle acidity buffering by the crustal materials.

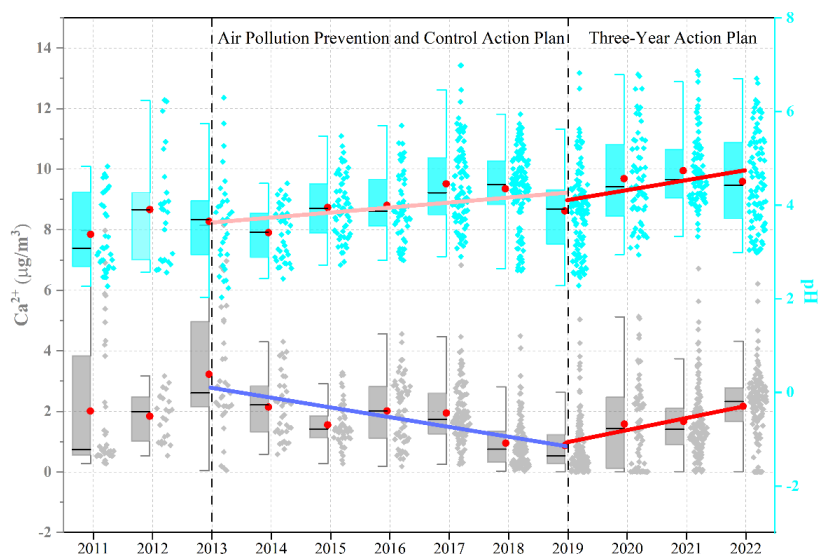

30 **Keywords:** Dust, aerosol acidity, sources, North China Plain, control measurement

31

32 **Synopsis:** The future ammonia reduction policies in North China may not lead to a rapid increase in
33 particle acidity in the presence of crustal materials., which further elevated the particle pH after 2019.

37

38 Highlights:

- 39 • Crustal material concentrations and their proportions increased significantly during 2019–2022;
- 40 • The resuspension of surrounding soil dust may determine the rebound of crustal material
- 41 concentrations;
- 42 • Rebound in crustal material further elevated the particle pH.

43

44 **1 Introduction**

45 Particle acidity is a critical parameter that affects atmospheric chemistry, such as the gas-particle
46 partitioning of semi-volatile and volatile species (Surratt et al., 2010; Guo et al., 2016), the solubility
47 of metals (Tao and Murphy, 2019), acid-catalyzed reactions (Rengarajan et al., 2011), and acid
48 deposition (Mao et al., 2009), thereby determining aerosol concentration and chemical composition,
49 as well as impacting human health, ecosystems, and climate (Li et al., 2017; Pye et al., 2020; Su et al.,
50 2020; Nenes et al., 2021). Generally, the global fine particulate matter (PM_{2.5}, aerodynamic diameter
51 $\leq 2.5 \mu\text{m}$) exhibits a bimodal pH distribution ranging from 1–3 (e.g., in the United States and Europe)
52 (Guo et al., 2015; Battaglia et al., 2017; Masiol et al., 2020; Zhang et al., 2021) and 4–5 (e.g., in East
53 Asia) (Kim et al., 2022; Sharma et al., 2022). The atmosphere rich in gaseous ammonia (NH₃) and
54 crustal material (CM) shows significant pH buffering effects (Wang et al., 2020; Zheng et al., 2020;
55 Karydis et al., 2021), which is a dominant factor that drives the high particle pH in East Asia (Karydis
56 et al., 2021; Zhang et al., 2021; Kim et al., 2022; Sharma et al., 2022).

57 In recent years, the changing trends in particle pH have become a research hotspot, especially in
58 China, in response to air pollution control policies, i.e. Air Pollution Prevention and Control Action
59 Plan (2013–2018) and Three-Year Action Plan (2018–2020). The annual average PM_{2.5} concentration
60 in Beijing dropped by 64% from 89.5 $\mu\text{g}/\text{m}^3$ in 2013 to 32 $\mu\text{g}/\text{m}^3$ in 2023 (MEP, 2023), with a clear
61 downward trend of sulfate concentration, and nitrate surpassing sulfate as the primary component
62 (Zhai et al., 2019; Zhou et al., 2019; Li et al., 2023). In contrast, the NH₃ predominantly originates
63 from agricultural activities, whose concentration has been relatively steady. These patterns have

64 fostered a persistent belief that aerosols will tend to become increasingly neutral, transitioning the
65 inorganic aerosol composition from ammonium sulfate to ammonium nitrate (Pinder et al., 2007, 2008;
66 Heald et al., 2012; Weber et al., 2016). For instance, a significant increase in the nitrate-to-sulfate
67 molar ratio from 2014–2017 in Beijing resulted in the particle pH increasing from 4.4 to 5.4 (Xie et
68 al., 2020). Moreover, increased NH₃ concentrations raised particle pH by 0.3–0.4 units from 2014/2015
69 to 2018/2019 in Beijing (Song et al., 2019). Over Europe and North America, the pH has increased
70 strongly from about 2.8 and 2.2 during the 1970s to 3.9 and 3.3 in 2020 respectively, especially during
71 the 1990s, with significantly increasing NH₃ emission (Karydis et al., 2021). On the contrary, modeling
72 results indicate a continuous decline in pH in East Asia from 1970 to 2020 due to sharp increases in
73 SO₂ and NO_x emissions (Karydis et al., 2021). In addition, the PM_{2.5} pH showed a slight decrease of
74 0.13 from 2018 to 2022 summer in Beijing due to the change in total nitrate (NO₃⁻ + HNO₃) (Li et al.,
75 2023). Moreover, Zhou et al. (2022) found a decreasing pH trend from 2011 to 2019 in eastern China,
76 primarily influenced by temperature, followed by sulfate and non-volatile cations. Similarly, Nah et al.
77 (2023) observed a decreasing pH trend from 2011 to 2020 in Hong Kong, attributing it to temperature
78 and sulfate levels. Thus, concerns have been raised about the potential increase in the acidity of aerosol
79 and precipitation due to China’s ongoing efforts to reduce ammonia emissions, which pose severe
80 health risks and acid deposition (Liu et al., 2019; Shi et al., 2019).

81 In addition to NH₃, CM is another key alkaline substance, that buffers particle pH. Ca²⁺ can form
82 insoluble CaSO₄ with sulfate, reducing sulfate concentration in the aqueous phase of aerosol, and thus
83 lowering H⁺ and aerosol liquid water content (ALWC) concentrations and enhancing particle pH (Ding
84 et al., 2019; Karydis et al., 2021). Moreover, non-volatile cations can lower the molar ratio of ammonia

85 to sulfate, leading to an increase in particle pH (Zheng et al., 2022). Karydis et al. (2021) simulated
86 that CM directly increased aerosol pH from 4 to 7 in the Middle East. Wang et al. (2022) reported that
87 non-volatile cations accounted for approximately 8–17% of hourly aerosol pH variation. Li et al. (2023)
88 indicated that the buffering effect of cations was the major reason for the relatively small pH changes
89 from 2018 to 2022 in Beijing, emphasizing that reducing coarse particle emissions in the future could
90 significantly decrease particle pH. In addition, there was a rising trend in the contribution of CM to
91 particle pH in Tianjin, China (Shi et al., 2017). Therefore, it is evident that CM has a significant impact
92 on the variation of particle pH, especially in North China, which is significantly affected by dust
93 aerosol, but the trend of CM concentration and its long-term implication is still lacking unfortunately.

94 **2 Experiment and method**

95 **2.1 Instruments and Measurements**

96 Sampling was conducted on the fourth-floor platform at Zhengzhou University (34.75° N, 113.61°
97 E) in Zhengzhou, China. The sampling site (Fig. S1), approximately 14 m above the ground, is
98 primarily surrounded by residential areas with well-developed transportation networks and no
99 significant industrial sources. There are two highways located 3 km to the south and 7 km to the east.
100 Additionally, a coal-fired power plant located 6 km to the east was shut down in 2020, and a gas-fired
101 power plant is situated 3 km to the south.

102 Samples were collected using a high-volume sampler (TE-6070D, Tisch, USA) and air particulate
103 samplers (TH-16A, Tianhong, China) from April 2011 to December 2022. Two quartz filters and two

104 Teflon filters were used daily from 10:00 AM to 9:00 AM the next day, resulting in a total of 5848
105 samples. After excluding abnormal data due to instrument malfunctions, 4228 valid samples were
106 obtained. Detailed information on the samples is provided in Table S1. Organic carbon (OC) and
107 elemental carbon (EC) were analyzed using a carbon analyzer (Model 5L, Sunset Laboratory, USA).
108 Water-soluble inorganic ions (Cl^- , NO_3^- , SO_4^{2-} , Na^+ , NH_4^+ , K^+ , Mg^{2+} , and Ca^{2+}) were measured using
109 ion chromatography (ICS-90 and ICS-900 models, Dionex, USA) (Yu et al., 2017; Jiang et al., 2018).
110 Elements were analyzed using a wavelength dispersive X-ray fluorescence spectrometer (S8 TIGER,
111 Bruker, Germany) to determine concentrations of Fe, Na, Mg, Al, Si, P, S, Cl, K, Ca, Ti, V, Ni, Cu, Zn,
112 Cr, Mn, Co, Ga, As, Se, Sr, Sn, Sb, Ba, and Pb (Tremper et al., 2018). Meteorological conditions,
113 including temperature (T), relative humidity (RH), and wind speed (WS) were obtained using an
114 automatic weather station (Wang et al., 2019). Detailed analytical methods and quality control are
115 described in Refs (Jiang et al., 2018; Yang et al., 2020).

116 **2.2 Data Analysis**

117 **2.2.1 Mass reconstruction**

118 The calculation method for CM is as follows (Tian et al., 2016):

$$119 \quad [\text{CM}] = 1.89 \times [\text{Al}] + 2.14 \times [\text{Si}] + 1.4 \times [\text{Ca}] + 1.43 \times [\text{Fe}] \quad (1)$$

120 where [Al], [Si], [Ca], [Fe] and [Ti] represent the concentrations of the respective elements ($\mu\text{g}/\text{m}^3$),

121 but Ti was not measured.

122 2.2.2 Thermodynamic model

123 The particle pH was calculated using the ISORROPIA-II model (<http://isorro피아.eas.gatech.edu>).
124 Input data (excluding $RH \leq 30\%$) included SO_4^{2-} , TNO_3 ($HNO_3 + NO_3^-$), TNH_x ($NH_3 + NH_4^+$), Ca^{2+} ,
125 K^+ , Na^+ , Mg^{2+} , Cl^- , RH and T . The concentrations of hydrogen ions in air (H_{air}^+) and ALWC were
126 calculated using the aerosol equilibrium composition system $Na^+ - K^+ - Ca^{2+} - Mg^{2+} - NH_4^+ - SO_4^{2-} - NO_3^- -$
127 $Cl^- - H_2O$ H_{air}^+ (Fountoukis and Nenes, 2007). pH values were calculated using the following formula:

$$128 \quad pH = -\log_{10} H_{aq}^+ \cong -\log_{10} \frac{1000H_{air}^+}{ALWC_i + ALWC_o} \cong -\log_{10} \frac{1000H_{air}^+}{ALWC_i} \quad (2)$$

$$129 \quad ALWC_o = \frac{m_{org} \rho_w}{\rho_w} \frac{K_{org}}{\left(\frac{1}{RH} - 1\right)} \quad (3)$$

130 where $ALWC_i$ and $ALWC_o$ refer to the ALWC for inorganic and organic components, respectively.
131 m_{org} denotes the mass of organic aerosol, ρ_w is the density of water (1.0 g/cm^3), ρ_{org} is the density of
132 organic material (1.4 g/cm^3) (Guo et al., 2015), k_{org} is the hygroscopicity parameter for organic aerosol
133 (0.087) (Chang et al., 2010; Li et al., 2016). The ISORROPIA-II model operated under metastable
134 conditions in the forward mode. Due to the lack of measured data for gaseous HNO_3 and NH_3 , TNO_3
135 was represented solely by NO_3^- . The concentration of NH_3 was simulated based on a linear regression
136 equation proposed by Wei et al. (2023), who used the same data as this study from 2013 to 2020:

$$137 \quad NH_3 = 19.909 \times RH + 0.559 \times T - 0.35 \times NH_4 + 0.123 \times NO_3^- + 2.159 \times Cl^- - 0.224 \times SO_4^{2-} - 154.923 \quad (4)$$

138 where NO_3^- , SO_4^{2-} , NH_4^+ , and Cl^- correspond to their respective concentrations ($\mu\text{g/m}^3$).

139 2.2.3 HYSPLIT analysis

140 Backward trajectories were calculated using the mixed-particle Lagrangian integrated trajectory
141 method (HYSPLIT, [https:// www.ready.noaa.gov/HYSPLIT_traj.php](https://www.ready.noaa.gov/HYSPLIT_traj.php)). 24-h backward trajectories
142 were simulated for air masses above 1000 m above ground level in Zhengzhou. Subsequently,
143 trajectories from two periods, 2013–2018 and 2019–2022, were clustered separately to analyze the
144 variations between the two policy implementation periods.

145 3 Results and discussion

146 3.1 Temporal variations in chemical components

147 The long-term trends in PM_{2.5} concentrations and its chemical components from 2011 to 2022 are
148 depicted in Fig. 1, with annual average concentrations listed in Table 1. Over the past twelve years, the
149 Chinese government implemented the Air Pollution Prevention and Control Action Plans (2013–2018)
150 and the Three-Year Action Plan (2018–2020), gradually improving air quality in Zhengzhou. The
151 annual average concentration of PM_{2.5} decreased from 212 ± 102 µg/m³ in 2013 to 60 ± 41 µg/m³ in
152 2022, representing a reduction of approximately 72%. As for chemical components, the largest
153 reductions were observed in SO₄²⁻ (79%), decreasing from 38.0 ± 19.9 µg/m³ in 2013 to 7.9 ± 4.5
154 µg/m³ in 2022, followed by EC (76%). Additionally, the concentrations of NH₄⁺ and NO₃⁻ also
155 significantly decreased by 68% and 56%, respectively. The proportion of each component in PM_{2.5}
156 (Fig. S2) reveals a decrease in SO₄²⁻, K⁺, and Cl⁻, indicating effective control measures targeting coal
157 and biomass combustion (Lei et al., 2021). However, the proportions of NO₃⁻ and OC in PM_{2.5} rose

158 from 11% and 12% in 2013 to 13% and 17% in 2022, respectively, similar to the trend observed in the
159 North China Plain (Wen et al., 2018; Zhai et al., 2019; Li et al., 2023).

160 **3.2 Temporal variations in CM**

161 Notably, there is no clear declining trend in the CM concentration, with a rebound observed during
162 2020–2022 (Fig. 1i). Furthermore, the proportion of CM in PM_{2.5} exhibits a significant upward trend
163 (Fig. S2). To further analyze its trend, sampling data were divided into three periods corresponding to
164 governmental stages: 2011–2013, when no special control measures were implemented; 2013–2019,
165 coinciding with the implementation of the Air Pollution Prevention and Control Action Plan; and
166 2019–2022, coinciding with the Three-Year Action Plan. During these periods, Henan Province and
167 Zhengzhou City implemented several dust control policies summarized in Table S2. As shown in Fig.
168 2a and 2b, the mass concentration of CM peaked at $14.6 \pm 8.3 \mu\text{g}/\text{m}^3$ in 2013, accounting for 8% of
169 PM_{2.5}. From 2013 to 2019, the CM concentration notably decreased from 14.6 ± 8.3 to $8.5 \pm 7.8 \mu\text{g}/\text{m}^3$,
170 with an annual average decline rate of $0.81 \mu\text{g}/(\text{m}^3 \cdot \text{year})$. Seasonal trends (Fig. S3) indicate more
171 pronounced decreases in spring and summer compared to autumn and winter, possibly due to favorable
172 meteorological conditions such as higher WS promoting dust resuspension, where conventional dust
173 control measures (e.g., road sprinkling, sealed transport vehicles, and covering large piles) were more
174 effective. In autumn and winter with low WS, dust sources were likely dominated by primary releases,
175 such as demolition dust, which have no significant regulatory measures. (Wang et al., 2013, 2018). As
176 for the individual crustal elements in Fig. S4, Ca exhibited the highest average annual decline rate of
177 33% during 2013–2019, followed by Al. Si showed a less pronounced decline, attributed to its

178 association with soil dust, where control measures for exposed soil are lacking (Zhang et al., 2020). In
179 addition, the Ca^{2+} concentration as depicted in Fig. 2c decreased from $3.2 \pm 2.1 \mu\text{g}/\text{m}^3$ in 2013 to 2.2
180 $\pm 1.1 \mu\text{g}/\text{m}^3$ in 2019, with an approximate annual average decline rate of $0.3 \mu\text{g}/(\text{m}^3 \cdot \text{year})$, further
181 demonstrating the decline in dust source. Apart from control measures, WS exhibited a declining trend
182 (Fig. S5), with a decrease rate of 43%, while RH showed an increasing trend at a rate of 8% from 2013
183 to 2019, under which conditions that were unfavorable for dust resuspension (Wang et al., 2013, 2018).
184 It was worth noting that the proportions of CM, Ca, Al, Fe, Si, and Ca^{2+} in $\text{PM}_{2.5}$ have shown
185 consecutive annual increases from 2013 to 2019, with CM proportion increasing from 8% in 2013 to
186 14% in 2019, indicating that CM reduction lagged behind $\text{PM}_{2.5}$ reduction efforts in Zhengzhou during
187 this period. Additionally, both concentration and proportion of Ca^{2+} in 2022 ($2.2 \pm 1.1 \mu\text{g}/\text{m}^3$ and 14%)
188 were higher than in other cities of China, such as Beijing ($1.0 \mu\text{g}/\text{m}^3$ and 2.8%), Tianjin ($0.5 \mu\text{g}/\text{m}^3$ and
189 1.4%), and Xiamen ($0.48 \mu\text{g}/\text{m}^3$ and 1.5%) (Shi et al., 2017; Xu et al., 2025; Zhang et al., 2021). These
190 results indicate that CM remained an important component of $\text{PM}_{2.5}$ in Zhengzhou City.

191 During 2019–2022, both CM and Ca^{2+} concentrations exhibited significant rebounds, with annual
192 growth rates of 0.24 and $0.4 \mu\text{g}/(\text{m}^3 \cdot \text{year})$, respectively, and their proportions increased from 14% and
193 2% in 2019 to 22% and 5% in 2022. CM concentrations rebounded in all seasons, particularly in winter
194 (Fig. S3). Changes in meteorological conditions may be a significant factor contributing to these
195 concentration rebounds, accompanied by the average WS increased by 0.14 m/s and RH decreased by
196 7% from 2020 to 2022 (Fig. S5), facilitating dust resuspension. Furthermore, the lack of more effective
197 dust control measures, as indicated by the absence of significant changes in the dust control policies
198 from the Air Pollution Prevention and Control Action Plan and Three-Year Action Plan, may be another

199 important factor contributing to the rebound of dust.

200 **3.3 Sources of CM**

201 Elemental ratios were employed to characterize the sources of CM, with the Ca/Al ratio widely
202 recognized as a reliable indicator of sandy origin (Zhang et al., 2017). In addition, significant variations
203 in Ca/Si ratios (Table S3) were observed among different dust sources (Road, Construction, Piles, Soil).
204 Fig. 3a illustrates the trend in Ca/Si ratios from 2011 to 2022. After 2013, Ca/Si ratios showed a
205 declining trend annually, with the average ratio decreasing from a peak of 1.6 in 2016 to a lowest of
206 0.4 in 2022. Compared with Ca/Si ratios from different types of dust sources, the effect of road and
207 construction dust on CM has gradually decreased. This may be attributed to the implementation of dust
208 control measures such as enclosure, shielding, and dust suppression at construction and demolition
209 sites, as well as dust control on ground surfaces and roads (Table S3). During 2019–2022, the average
210 Ca/Si ratio remained below 1, with a mean of 0.4 in 2022, indicating that soil dust predominantly
211 contributed to CM. Currently, measures for controlling soil-suspended dust are limited, primarily
212 relying on long-term strategies such as afforestation and increasing urban green coverage, thus
213 requiring a longer process and sustained investment.

214 Sand dust transport serves as a significant source of CM in the North China Plain (Zhang et al.,
215 2024). The Ca/Al ratio from 2016 to 2022 (Fig. 3b) shows minimal variation, with annual averages
216 ranging between 1.5 and 2.5, indicating no significant changes in the source regions of sand. The
217 transport trajectories reveal that the predominant pathways for long-distance transport of sand dust
218 originated from Inner Mongolia, passing through Shaanxi and Shanxi provinces. Compared to 2013–

219 2018 (45%), the influence of long-distance transport decreased to 25% during 2019–2022. In contrast,
220 local transport within Henan province and short-distance transport from Shandong province showed a
221 noticeable increase. These findings suggest that the rebound in CM concentrations during 2019–2022
222 in Zhengzhou might be responsible for the resuspension of surrounding soil dust.

223 **3.4 Long-term trend of particle pH**

224 Are shown in Fig. 4, pH values showed a clearly increasing trend after 2014. From 2013 to 2019,
225 the annual pH increased by 0.11 units, reaching a maximum median value of 4.45 (Mean: 4.35) in
226 2018. Note that the annual average growth rate of pH values increased to 0.21 units from 2019 to 2022,
227 with a maximum median value of 4.42 (Mean: 4.51) in 2022. Seasonally, pH values showed increasing
228 trends in spring, summer, and autumn, and notably increased in winter from 2020 to 2022 (Fig. S6).
229 The increasing trend in pH values observed in this study is similar to the findings in Beijing (Song et
230 al., 2019; Xie et al., 2020), but differs from those reported in Shanghai and Hong Kong (Nah et al.,
231 2023; Zhou et al., 2022).

232 Sensitivity analyses were conducted to explore the dominant factors driving the elevated particle
233 pH in Zhengzhou by giving a range for one parameter and average values for other parameters input
234 into the ISORROPIA-II model. Are shown in Fig. S7, particle pH increases with the cation
235 concentrations (e.g., TNH_x , K^+ , Ca^{2+} , Mg^{2+} , and Na^+) and decreases with anions concentrations (e.g.,
236 SO_4^{2-} and NO_3^-). Additionally, RH does not significantly affect pH, whereas an increase in T leads to
237 a noticeable decrease in particle pH.

238 The changes in pH (ΔpH) between adjacent years are illustrated in Fig. 5, with the differences in

239 influencing factors listed in Table S4. Obviously, the decline in SO_4^{2-} from 2013 to 2018 was the
240 primary cause of the increase in particle pH, as it decreased H^+ and ALWC concentrations (Fig. S8) in
241 aerosol (Ding et al., 2019; Zhang et al., 2021). The average SO_4^{2-} concentration decreased by 14.6 and
242 $5.3 \mu\text{g}/\text{m}^3$, resulting in a pH increase of 0.43 and 0.35 units from 2013 to 2014 and 2016 to 2017,
243 respectively, which was comparable to an increased rate of 0.3 units in East Asia due to SO_2 emission
244 controls since 2016 (Karydis et al., 2021). As another acidic ion, the decrease in nitrate concentration
245 did not significantly contribute to the pH increases, consistent with findings from Ding et al. (2019)
246 and Zhang et al. (2021). This is primarily because nitrate ions decline more slowly compared to sulfate
247 ions and exceeded sulfate concentrations after 2016, under which conditions that nitrate-rich particles
248 can absorb twice the amount of water that sulfate-rich particles, leading to an increase in ALWC
249 concentration and inhibiting pH decline (Lin et al., 2020; Xie et al., 2020). On the other hand, increases
250 in particle pH in 2015 and 2018 were notably influenced by changes in TNH_x with concentrations
251 increased by 5.5 and $1.3 \mu\text{g}/\text{m}^3$, respectively. Increased TNH_x concentrations could react with SO_4^{2-}
252 $/\text{NO}_3^-$ and consume a substantial amount of H^+ , thereby raising particulate matter pH values (Seinfeld
253 et al., 1998; Zhang et al., 2021). Substantial decreases in T in 2015 (4.2°C), 2017 (4.9°C), and 2018
254 (2.8°C), favoring NH_3 partitioning into the particle phase and reducing H^+ concentrations, drove
255 increases in particle pH (Tao and Murphy, 2019).

256 During the period from 2020 to 2022, the influence of SO_4^{2-} on particle pH gradually decreased,
257 with a decrease in concentration from 0.3 to $2.3 \mu\text{g}/\text{m}^3$ only bringing about a pH decrease of 0.03 to
258 0.14. Moreover, a rebound in SO_4^{2-} concentration to $7.9 \pm 4.5 \mu\text{g}/\text{m}^3$ in 2022 even resulted in a decrease
259 of 0.11 units in pH instead. On the other hand, TNH_x began to show a slight annual decline (0.9 to 2.2

260 $\mu\text{g}/\text{m}^3$), resulting in a significant decrease in pH (0.21–0.35). Consequently, the increase in pH values
261 was closely related to the rise in Ca^{2+} concentration. Ca^{2+} is less volatile and competes preferentially
262 with NH_3 to neutralize anions such as SO_4^{2-} to form insoluble CaSO_4 , which precipitates from the
263 aerosol aqueous phase (Ding et al., 2019; Karydis et al., 2021), thereby reducing H^+ concentrations
264 (Fig. S8) and subsequently lowering particle acidity. Specifically, increases of 0.7 and 0.5 $\mu\text{g}/\text{m}^3$ in
265 Ca^{2+} concentrations led to pH increases of 0.13 and 0.09 units in 2020 and 2022, respectively, making
266 Ca^{2+} a primary controlling factor for pH elevation.

267 **4 Conclusions**

268 The annual average $\text{PM}_{2.5}$ concentration in Zhengzhou decreased from $212.4 \pm 101.5 \mu\text{g}/\text{m}^3$ in
269 2013 to $59.5 \pm 41.2 \mu\text{g}/\text{m}^3$ in 2022, with the largest reduction in SO_4^{2-} . As for CM, their concentrations
270 notably decreased from 2013 to 2019, because of effective dust control measures, as well as decreased
271 wind speed and increased relative humidity. However, the proportions of CM in $\text{PM}_{2.5}$ have shown
272 consecutive annual increases. In addition, CM concentrations and their proportions increased
273 significantly during 2019–2022, which might be responsible for the resuspension of surrounding soil
274 dust. Correspondingly, the annual pH increased by 0.11 units from 2013 to 2019 mainly due to the
275 decline in SO_4^{2-} , increased TNH_x , or decreased temperature. During the period from 2020 to 2022, the
276 annual average growth rate of pH values increased to 0.21 units from 2019 to 2022, which was
277 determined by the rise in Ca^{2+} concentration.

278 **5 Implication**

279 Control measures implemented by the Chinese government have proven effective in reducing dust,
280 but this study reveals that the crustal materials in PM_{2.5} rebounded after 2019. This phenomenon is not
281 unique to Zhengzhou, as major cities in the North China Plain have also experienced a pronounced
282 upward trend in coarse particles after 2019 (Fig. S9). Thus, crustal materials remain a significant
283 component of atmospheric aerosols in North China, maintaining particle pH at higher levels. The
284 research predicted that China's next phase of reducing ammonia emissions would significantly
285 aggravate precipitation acidification, which poses severe health risks and acid deposition (Liu et al.,
286 2019; Shi et al., 2019). However, the presence of crustal material in the North China Plain, which is
287 difficult to reduce from soil dust, can play an important role as buffering substances to prevent quickly
288 rising acidity. Therefore, the future ammonia reduction policies in North China may not lead to a rapid
289 increase in particle acidity, but it is necessary to consider synergistic control with dust sources.

290 **Data availability**

291 All the data presented in this article can be accessed through
292 <https://doi.org/10.5281/zenodo.14032007> (Zhang, 2024).

293 **Supporting Information**

294 Additional data, figures, and tables, some of which are referenced directly within the manuscript,

295 and detailed descriptions of field measurements and samples.

296 **Author contributions**

297 Shenbo Wang designed this study. Hongyu Zhang and Zhangsen Dong analyzed the data and
298 prepared the manuscript with the contributions of all coauthors. Xiao Li conducted measurements.
299 Ruiqin Zhang provided funding acquisition. All authors have read and agreed to the published version
300 of the manuscript.

301 **Competing interests**

302 The authors declare that they have no conflict of interest.

509 **Figures**

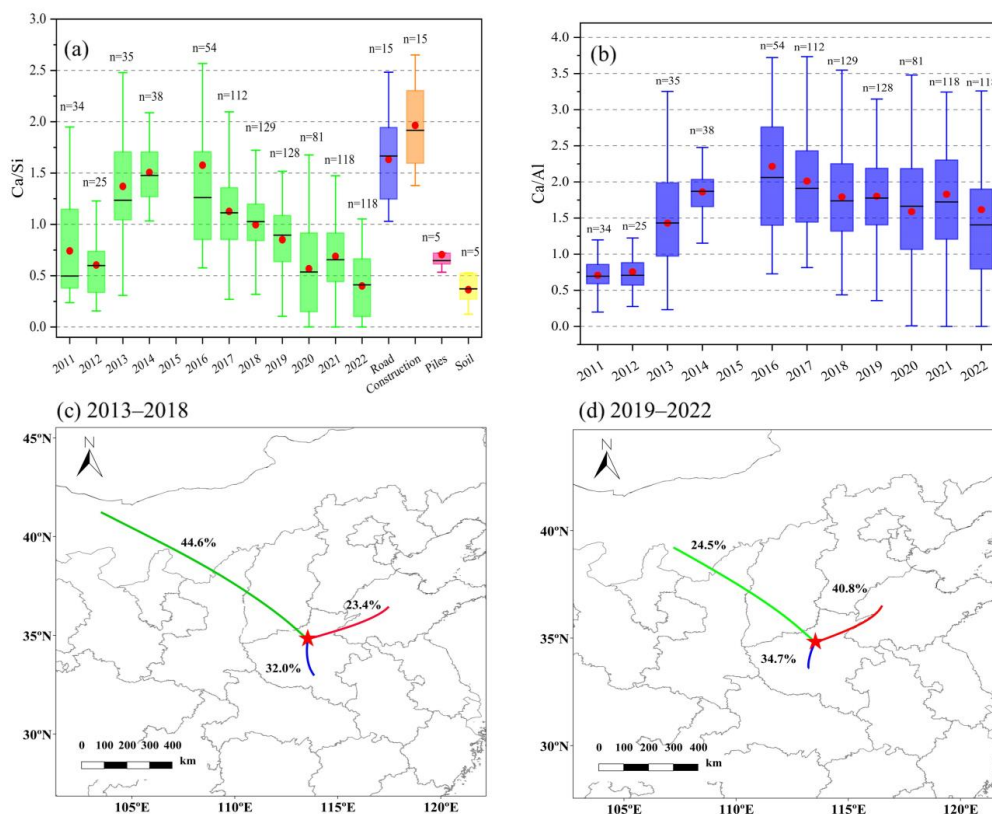

510

511 Figure 1. Long-term trends in the concentrations of PM_{2.5} and its chemical components in from 2011
512 to 2022 in Zhengzhou. Box plots depict annual averages (red dots) and medians (black lines), the
513 top, middle, and bottom lines represent the 75, 50, and 25 percentiles of statistical data, respectively,
514 and the upper and lower whiskers represent the 90 and 10 percentiles of statistical data, respectively.

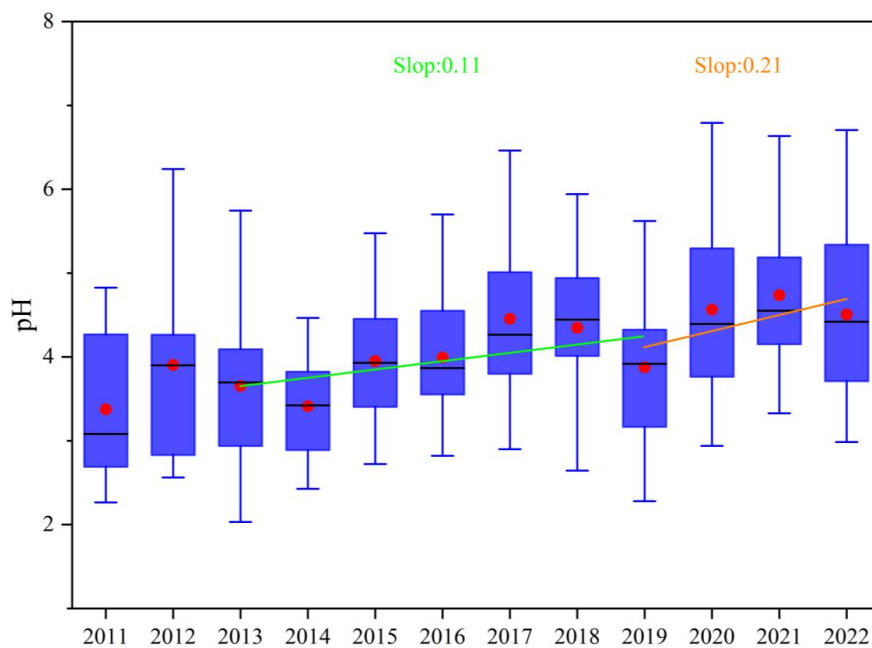

515

516 Figure 2. (a) and (c) Long-term trends in CM and Ca^{2+} concentrations in Zhengzhou from 2011 to
517 2022, respectively. Box plots depict annual averages (red dots) and medians (black lines), with red,
518 blue, and orange lines indicating annual growth rates for CM concentrations during 2011–2013,
519 2013–2018, and 2019–2022, respectively. (b) and (d) Long-term trends in the proportions of CM and
520 Ca^{2+} in $\text{PM}_{2.5}$, respectively.

521

522 Figure 3. (a) The annual Ca/Si ratios in Zhengzhou from 2011 to 2022 compared with those in
 523 various dust sources (specific values and references in Table S3). The red dots and black lines in the
 524 box plots represent the annual averages and medians, respectively, with n indicating the sample size.
 525 (b) The Ca/Al ratios in Zhengzhou from 2011 to 2022. The red dots and black lines in the box plots
 526 represent the annual averages and medians, respectively, with n indicating the sample size. (c) and
 527 (d) The transport pathways of CM during 2013–2018 and 2019–2022, respectively.

528

529 Figure 4. The time series of particle pH in Zhengzhou from 2011 to 2022. In the boxplots, red dots
530 and black lines represent the annual mean and median values, respectively. Green and orange lines
531 depict the annual average increase rates of particle pH from 2013 to 2018 and from 2019 to 2022,
532 respectively.

533

534 Figure 5. Contribution of each component to the changes in pH (ΔpH) between adjacent years. The
 535 difference between component concentrations and meteorological parameters between adjacent years
 536 is listed in Table S4.

537 **Table**

538 Table 1. Annual average concentrations of PM_{2.5} and its components from 2011 to 2022 in Zhengzhou,
539 China (µg/m³).

Years	PM _{2.5}	EC	OC	NO ₃ ⁻	SO ₄ ²⁻	NH ₄ ⁺	CM	Ca ²⁺
2011	161.9±81.4	5.1±2.1	13.6±8.6	16.2±11.2	29.6±14.3	13.8±8.3	9.3±7.3	2.0±2.2
