24

25 **Abstract.** The Marysvale volcanic field in southwestern Utah hosts three large volume gravity slides: the Sevier  
26 (SGS), the Markagunt (MGS), and the Black Mountains (BGS). The gravity slides are composed of lahar deposits,  
27 lava flows, and ash-flow tuffs erupted from former stratovolcanoes and other vents during the Oligocene and Miocene.  
28 The ash-flow tuffs are prime targets for dating to constrain the age of the gravity slides because some ash-flow tuffs  
29 are deformed within the slides, whereas others are undeformed and cap the slides. Furthermore, the gravity slides  
30 produced pseudotachylyte during slide motion, a direct indicator for the timing of each slide. This work provides new  
31  $^{40}\text{Ar}/^{39}\text{Ar}$  dates for several ash-flow tuffs and pseudotachylyte for the SGS, along with U/Pb zircon dates for one  
32 deformed tuff and overlying alluvium at the slide plane. Results show that the slide was emplaced at  $25.25 \pm 0.05$  Ma  
33 and was immediately followed by the eruption of the Antimony Tuff at  $25.19 \pm 0.02$  Ma. The model presented here  
34 suggests that the intrusion of magma related to the Antimony Tuff acted as a triggering mechanism for the slide, and  
35 that slide movement itself led to decompression melting and eruption of the Antimony Tuff. This sequence of events  
36 occurred on a geologically rapid timescale and may have been virtually instantaneous.

37

38 **Short summary.** The timing of an ancient gravity slide that originated in the Marysvale volcanic field (Utah) is  
39 constrained using  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of pseudotachylyte, a friction-induced glass that is generated during slide  
40 movement, and the volcanic tuffs that were displaced by the slide and those that overlie the slide mass. Our results  
41 suggest that the Sevier gravity slide occurred at 25.25 Ma. The removal of such a large volume of material likely  
42 allowed for the eruption of the Antimony Tuff at 25.19 Ma.

## 43 1 Introduction

44 Gravity slides are large volume mass movements that typically slide over  
45 shallowly dipping ( $\leq 3^\circ$ ) paleosurfaces. The Heart Mountain slide (Wyoming) and the  
46 recently described Markagunt Gravity Slide (Utah) were coeval with volcanism and  
47 displaced km-thick sheets of volcanic rocks (Biek et al., 2022; Malone, 1995; Malone et al., 2017). A characteristic  
48 feature of gravity slides is that they maintain the original stratigraphy within the allochthonous sheets. The presence  
49 of volcanic materials offers opportunities to constrain the emplacement age using several geochronological  
50 techniques. Furthermore, these megaslides are emplaced so rapidly that they can generate pseudotachylyte, a friction  
51 induced melt hypothesized to have formed from the rocks involved in sliding. Geochronology of the  
52 pseudotachylyte can directly constrain the age of the slide.

53 The Oligocene-Miocene Marysvale gravity slide complex (MGSC) in southwestern Utah is unique in that it  
54 contains multiple, gigantic individual gravity slides, including the Sevier gravity slide (SGS), the 23 Ma Markagunt  
55 gravity slide (MGS; (Holliday et al., 2022)), and the Black Mountain gravity slide (BGS) (Biek et al., 2019, 2022).  
56 Despite the coeval nature of the MGSC and the Marysvale Volcanic Field (MVF), the causality of gravity slide  
57 emplacement is still unclear. Slide initiation may be due to magmatic doming within the gravity slide's breakaway  
58 region, laccolith emplacement, or the accumulation of volcanic material on weak strata may overload the crust and  
59 stimulate widespread slope failure (Hacker et al., 2018). Recent work has improved the understanding about source

60 material and kinematics of these landslides (Braunagel et al., 2023; Hacker et al., 2023; Holliday et al., 2022;  
61 Zamanialavijeh et al., 2021). Notably, Holliday et al. (2022) obtained  $^{40}\text{Ar}^*/^{39}\text{Ar}$  dates on the ash-flow tuffs and  
62 pseudotachylyte from the MGS, then employed a novel Bayesian statistical optimization age model to constrain an  
63 emplacement age. This work builds upon the previous geochronology study of the MGS to determine the  
64 emplacement age of the SGS through  $^{40}\text{Ar}^*/^{39}\text{Ar}$  dating of pseudotachylyte formed during slide movement and of  
65 the bounding ash-flow tuffs. Our results unambiguously tie pseudotachylyte formation to slide emplacement,  
66 affirming the catastrophic nature of the slides, while simultaneously constraining the timing of slope failure relative  
67 to volcanic eruptions, which resolves outstanding questions surrounding causality of gravity slides.

## 68 **2 Geologic background**

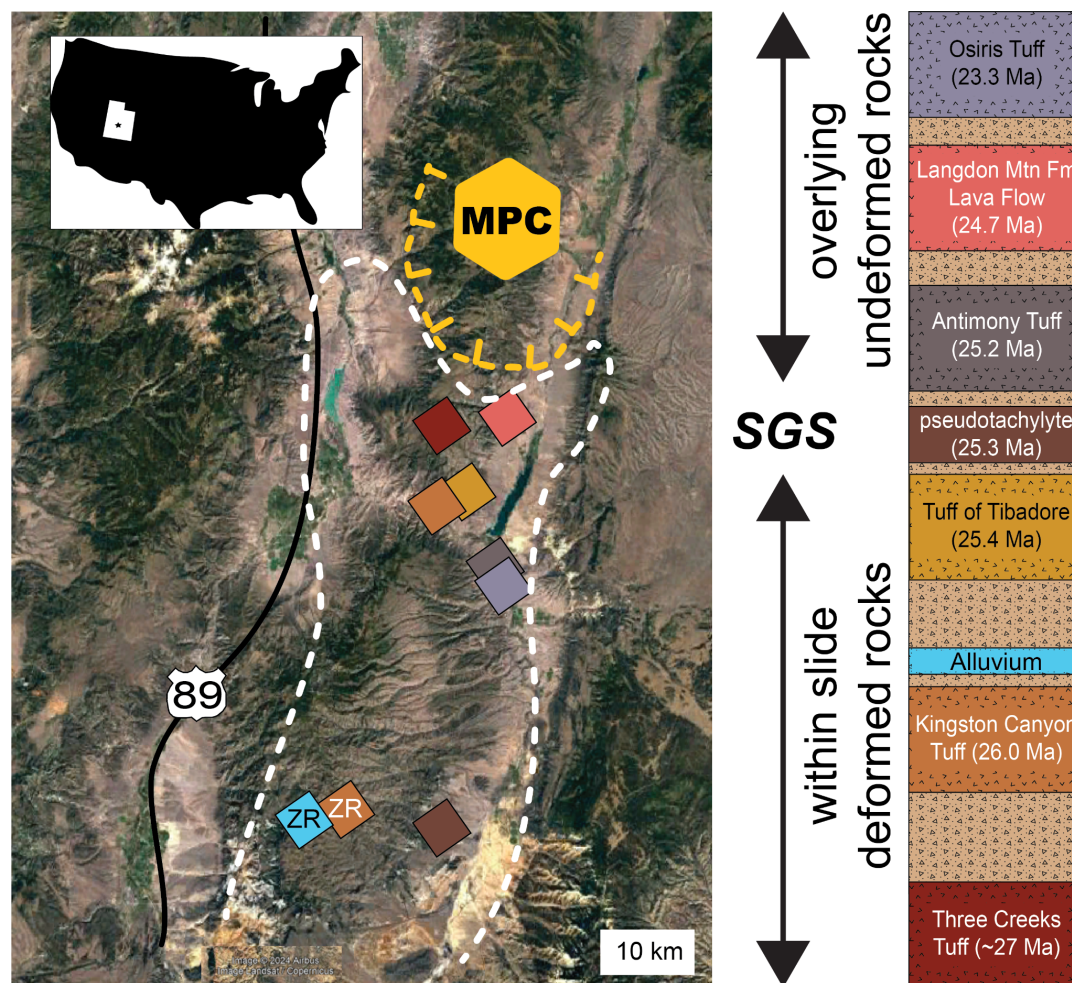

69 Early investigations in the MVF have provided the foundation for the discovery of the MGSC and  
70 unraveling the associated stratigraphy as described in Biek et al. (2019). Geochemical investigations of the volcanic  
71 units led to the identification of the calc-alkaline nature of the older rocks and bimodal basalt and high-silica rhyolite  
72 younger rocks (Rowley et al., 1975; Steven et al., 1977; Wender and Nash, 1979), and extensive mapping initiatives  
73 were undertaken to unravel the geology, mineral resources, and economic potential of the region (e.g., Steven et al.,  
74 1977; Cunningham and Steven, 1979; Steven et al., 1984; Palmer and Walton, 1990; Rowley et al., 1994; Rowley et  
75 al., 1998; Granger and Bauer, 1950; Taylor et al., 1951; Kerr et al., 1957; among many others). This foundational  
76 body of work contributes to understanding the spatial distribution of the volcanic centers and the stratigraphic  
77 relationships between major eruptive units. The MVF straddles the boundary between the Colorado Plateau and the  
78 Basin and Range province and covers  $>10,000\text{ km}^2$ , with an estimated total volume of  $12,000\text{ km}^3$  (Rowley et al.,  
79 1998), and hosts three calderas: Three Creeks (~27 Ma), Monroe Peak (23–22 Ma), and Mount Belknap (22–18  
80 Ma). However, most of the eruptive products in the MVF have an unknown source, presumably because many vent  
81 areas are now buried or overprinted by younger calderas. The breakaway regions for each gravity slide are inferred  
82 to be entirely within the MVF, and suggest a genetic connection to local volcanic activity. The breakaway zones of  
83 the SGS and MGS are overprinted by younger calderas (Rowley et al., in press; Biek et al., 2019, 2022), and the  
84 breakaway of the BGS has presumably been eroded over the Mineral Mountains batholith.

85 Initiation of MVF volcanism is associated with Farallon slab rollback and southward migration of  
86 volcanism across western North America. Peak volcanic (23–32 Ma) activity consisted of intermediate calc-alkaline  
87 eruptions (Rowley et al., 1998; 2002; in press) which account for ~90% of the MVF volcanic material contained in  
88 the Bullion Canyon Volcanics and the Mount Dutton Formation (Rowley et al., 1994). The transition to bimodal  
89 basalt and high-silica rhyolite volcanism occurred ca. 22 Ma and is linked to the transition from a subduction-style  
90 regime to Basin and Range extension (Rowley et al., 1997). Basaltic eruptions have continued into the late  
91 Pleistocene (Biek et al., 2015; Marchetti et al., 2020).

92 Recognition of the MGSC began with the early characterization of the Markagunt Megabreccia on the  
93 Markagunt Plateau (Anderson, 1993). Described as isolated allochthonous masses (megabreccia), the Markagunt  
94 Megabreccia consists of monolithic blocks and heterolithic complexes as large as  $2.5\text{ km}^2$  and 50–200 m thick

95 (Sable and Maldonado, 1997). While these large masses were identified as gravity slides, they were interpreted to be  
96 emplaced in several separate events from multiple sources (Anderson, 1993; Sable and Maldonado, 1997). However,  
97 Hacker et al. (2014) and Biek et al. (2014; 2015) reinterpreted the Markagunt Megabreccia as part of a  
98 catastrophically emplaced single slide mass based on new field evidence and mapping, and termed this the  
99 Markagunt gravity slide (MGS). The Sevier gravity slide (SGS) was proposed in 2017 (Biek et al., 2017), and  
100 formally recognized in Biek et al. (2019). Along the western flank of the SGS, Braunagel et al. (2023) characterized  
101 notable structural features that indicate intense deformation, clastic dikes of basal material into overlying rocks,  
102 pseudotachylyte, and cataclastic basal zones. Loffer (2024) identified several pseudotachylyte sites within the SGS,  
103 and proposed an SGS maximum depositional age of 25.5 Ma using detrital zircon extracted from the basal layer of  
104 the slide in two locations.  
105

106  
107 **Figure 1: Sevier gravity slide location (white boundary) shown with Monroe Peak Caldera (MPC) and sampling locations.**  
108 **To the right, a simplified stratigraphic section (not to scale) of the Mount Dutton Formation (light brown) with interspersed**

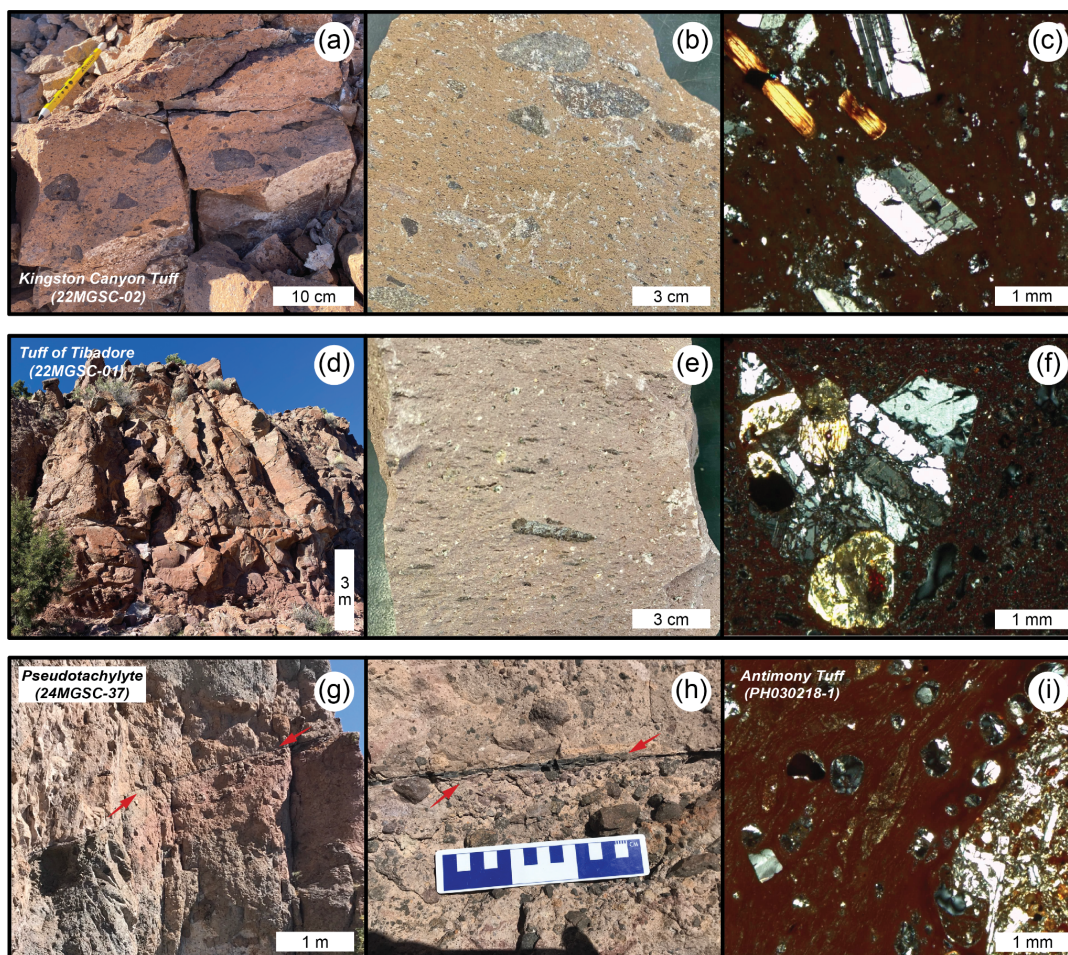

109 ash-flow tuffs and other rocks investigated in this study. The allochthonous block of the SGS includes the within slide  
110 deformed ash-flow tuffs and pseudotachylyte, whereas the overlying undeformed ash-flow tuffs post-date slide  
111 emplacement. Locations labeled with “ZR” indicate samples collected for zircon U/Pb dating. © Google Earth, using 2024  
112 imagery of Airbus, Landsat, Copernicus.

### 113 3 Materials and methods

114 The units investigated here are grouped by their stratigraphic position relative to the SGS. Ash-flow tuffs  
115 ‘within’ the slide material are deformed and were displaced by slide motion as an allochthonous block. Ash-flow  
116 tuffs ‘above’ the slide are all undeformed by and postdate the SGS (Fig. 1). The Kingston Canyon Tuff (samples  
117 21MGSC-02 and KCT; Fig. 2) is a densely welded, red-purple, lithic tuff. Plagioclase is the major mineral phase,  
118 with minor hornblende and biotite. Lithic components consist of mafic igneous rocks. A sample of the alluvial facies  
119 of the Mt. Dutton Formation overlying the KCT sample was collected to examine the detrital zircon record (MVC6-  
120 21-10-16-2; Braunagel et al., in review). The tuff of Tibadore (21MGSC-01, Fig. 2) is a crystal poor, densely  
121 welded lithic ash-flow tuff. Fresh surfaces are purple with black fiamme 1–3 cm long. The Antimony Tuff  
122 (PH030218-1, Fig. 2) is a densely welded, relatively crystal-poor ash-flow tuff, with a red groundmass containing  
123 large plagioclase, minor pyroxene, and lithics. The Langdon Mountain Formation contains a lower lahar facies and  
124 an upper lava flow facies; only the lava flow facies, dated here, clearly postdates the SGS (Rowley et al., 2002). The  
125 lava flow facies is described as a dacitic lava flow containing large phenocrysts of plagioclase, hornblende, and  
126 minor pyroxene (Rowley et al., in press) and considered the last of the minor eruptive sequences prior to the  
127 eruption of the caldera-forming Osiris Tuff (Rowley et al., 1994); eruptive vents of the Langdon Mountain rocks  
128 were likely destroyed by emplacement of the Monroe Peak caldera. The Osiris Tuff (PH030218-2) contains  
129 dominantly large feldspar phenocrysts, conspicuous biotite, and minor pyroxene within a gray groundmass. The  
130 Osiris Tuff is not deformed by the SGS, but was deformed by the later 23 Ma MGS emplacement near the  
131 breakaway zone at Puffer Lake (Biek et al., 2019; Holliday et al., 2022). Pseudotachylyte (24MSGC-37, Fig. 2) is  
132 found on shear planes and in injection veins as much as 200 m above the basal slip surface.  
133

134  
135 **Figure 2:** (a) Outcrop of Kingston Canyon Tuff; (b) Hand sample of Kingston Canyon Tuff showing abundant lithic  
136 fragments; (c) thin section of Kingston Canyon Tuff showing plagioclase and biotite phenocrysts; (d) outcrop of tuff of  
137 Tibadore; (e) tuff of Tibadore hand sample with prominent fiamme; (f) thin section of the tuff of Tibadore showing rare  
138 crystal clot; (g) outcrop of pseudotachylyte vein; (h) outcrop of pseudotachylyte vein; (i) thin section of Antimony Tuff  
139 showing mafic xenolith (right side of image) and fiamme. Thin section photographs were taken in crossed polarized light.

140

### 141 3.1 $^{40}\text{Ar}/^{39}\text{Ar}$ analysis

142 Samples of each ash-flow tuff, lava flow, and pseudotachylyte described above were processed by standard  
143 crushing, magnetic, and density techniques to prepare for  $^{40}\text{Ar}/^{39}\text{Ar}$  analysis. Sanidine was extracted from the Osiris  
144 and Antimony Tuffs, and plagioclase was analyzed from the tuff of Tibadore, Kingston Canyon Tuff, and Langdon  
145 Mountain lava flow. Pseudotachylyte glass was handpicked prior to analysis. Selected materials were co-irradiated  
146 with the 28.201 Ma Fish Canyon Tuff sanidine neutron fluence monitor (Kuiper et al., 2008) at the Cd-lined facility

147 at the Oregon State University TRIGA reactor. Single crystal total fusion analyses were conducted for the ash-flow  
148 tuffs whereas incremental heating experiments were conducted for the lava flow and pseudotachylyte. All analyses  
149 were performed at the WiscAr Geochronology Lab, University of Wisconsin-Madison using either the Noblesse 5  
150 Collector (Jicha et al., 2016) or the Isotopx NGX-600 mass spectrometers (Mixon et al., 2022).

### 151 3.2 Zircon U/Pb analysis

152 Zircon crystals were extracted by traditional methods of crushing and grinding, followed by separation by  
153 panning, heavy liquids, and a Frantz magnetic separator. A large split of grains is incorporated into a 1" epoxy  
154 mount together with fragments or loose grains of Sri Lanka, FC-1, and R33 zircon crystals that are used as primary  
155 standards. The mounts are sanded down to a depth of ~20 microns, polished, imaged, and cleaned prior to isotopic  
156 analysis. Grains of interest are imaged to provide a guide for locating analysis pits in optimal locations, and to aid in  
157 interpreting results. BSE and color CL Images are generated with a Hitachi 3400N SEM and a Gatan CL2 detector  
158 system. U/Pb geochronologic analyses were conducted by laser ablation inductively coupled plasma mass  
159 spectrometry (LA-ICPMS) at the Arizona LaserChron Center ([www.laserchron.org](http://www.laserchron.org)). Methods for U/Pb  
160 geochronology have been described by Gehrels et al. (2006, 2008), Gehrels and Pecha (2014), Pullen et al. (2018),  
161 and Sundell et al. (2021).

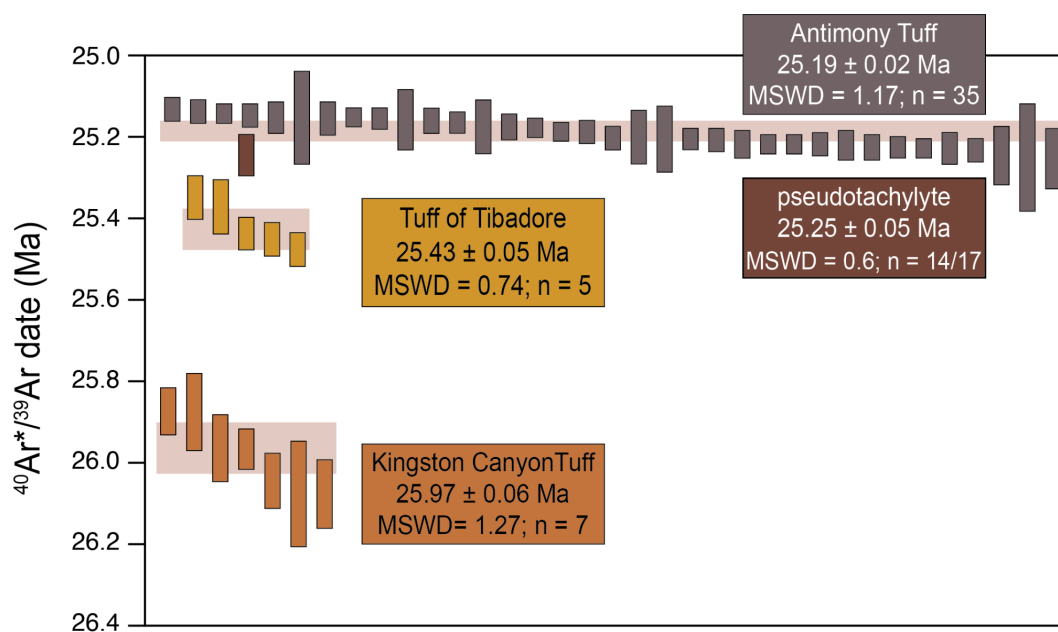

## 162 4 Results

### 163 4.1 $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology

164 Thirty-three plagioclase crystals from the Kingston Canyon Tuff (21MGSC-02) generated a range of  
165 radiogenic yields. As such, only the seven grains with  $>70\%$   $^{40}\text{Ar}^*$  were used to calculate the weighted mean and  
166 associated statistics. The seven grains yield ages from  $25.88 \pm 0.06$  Ma to  $26.08 \pm 0.08$  Ma and produce a weighted  
167 mean of  $25.97 \pm 0.06$  Ma ( $n = 7/33$ ;  $\text{MSWD} = 1.27$ ). All uncertainties reported in this work include errors associated  
168 with the irradiation parameter,  $J$ . Nine single crystal plagioclase fusion analyses from the tuff of Tibadore  
169 (21MGSC-01) yielded dates from  $25.33 \pm 0.01$  Ma to  $25.91 \pm 0.08$  Ma. However, in order to filter the data in a  
170 consistent manner, analyses with  $<70\%$   $^{40}\text{Ar}^*$  were omitted from calculations. Thus a weighted mean for five of the  
171 analyses is  $25.43 \pm 0.05$  Ma ( $\text{MSWD} = 0.74$ ). Incremental heating of pseudotachylyte glass (24MGSC-37) produced  
172 a plateau age of  $25.25 \pm 0.05$  Ma including  $>85\%$  of the cumulative  $^{39}\text{Ar}_K$ . The  $^{40}\text{Ar}/^{36}\text{Ar}$  isochron intercept of  $292.4$   
173  $\pm 8.8$  is within uncertainty of the atmospheric value (Lee et al., 2006). Two locations were sampled for Antimony  
174 Tuff and sanidine from both were analyzed by total fusion. Thirteen grains from sample PH030218-1 produced dates  
175 ranging from  $25.02 \pm 0.07$  Ma to  $25.26 \pm 0.07$  Ma. A weighted mean of these yields an age of  $25.14 \pm 0.06$  Ma  
176 ( $\text{MSWD} = 1.33$ ). Twenty-seven sanidine grains from sample (MP071020-2) produced dates ranging from  $25.14 \pm$   
177  $0.03$  Ma to  $25.23 \pm 0.03$  Ma, and a weighted mean of these produce an age of  $25.19 \pm 0.02$  Ma ( $\text{MSWD} = 1.45$ ).  
178 Combining the two datasets and applying normalized Median Absolute Deviation (nMAD) filter of 1.5 (e.g., Kuiper  
179 et al., 2008), 35 of the 40 total grains produce a weighted mean age of  $25.19 \pm 0.02$  Ma ( $\text{MSWD} = 1.17$ ). Bulk

180 plagioclase from the Langdon Mountain lava flow was incrementally heated and produced a plateau age of  $24.68 \pm$   
181  $0.32$  Ma with 100% of the cumulative  $^{39}\text{Ar}_k$ . The  $^{40}\text{Ar}/^{36}\text{Ar}$  isochron intercept of  $299.3 \pm 10.3$  is within uncertainty  
182 of the atmospheric value (Lee et al., 2006). Holliday et al. (2022) report total fusion dates of thirteen sanidine grains  
183 from the Osiris Tuff, which produced dates ranging from  $23.16 \pm 0.08$  Ma to  $23.37 \pm 0.04$  Ma and a weighted mean  
184 age of  $23.27 \pm 0.05$  Ma (MSWD = 1.60).  
185

189 **date and  $2\sigma$  uncertainty of a single experiment. The height of the shaded region behind Kingston Canyon Tuff, tuff of**  
190 **Tibadore, and Antimony Tuff represents the weighted mean with  $2\sigma$  uncertainty of the shown analyses.  $n$  = number of**  
191 **single crystal analyses used to calculate the weighted mean, except for the pseudotachylyte, in which  $n$  refers to the number**  
192 **of incremental heating steps used to calculate a plateau age.**

193

#### 194 4.2 Zircon U/Pb geochronology

195 Zircon  $^{206}\text{Pb}^*/^{238}\text{U}$  dates from the Kingston Canyon Tuff (sample KCT) range from  $25.11 \pm 0.37$  Ma to  
196  $1871 \pm 12$  Ma ( $n = 122$ ; supplementary materials). Precambrian grains ( $n = 5$ ) and the single young zircon ( $n = 1$ )  
197 that is outside statistical uncertainty of the  $^{40}\text{Ar}/^{39}\text{Ar}$  eruption age were excluded from calculations. The  $^{206}\text{Pb}^*/^{238}\text{U}$   
198 dates produce a bimodal distribution (Fig. 4), with mixture model deconvolution peaks at  $26.41 \pm 0.06$  Ma (29%)  
199 and  $33.96 \pm 0.05$  Ma (54%) (Sambridge 1994; Ludwig, 2012). Zircon from the Mount Dutton Formation produced  
200  $^{206}\text{Pb}^*/^{238}\text{U}$  dates ranging from  $25.13 \pm 0.50$  Ma to  $1823 \pm 15$  Ma ( $n = 156$ ). Grains older than 50 Ma were excluded

201 from calculations ( $n = 17$ ). The  $^{206}\text{Pb}^*/^{238}\text{U}$  dates of the Mount Dutton Formation produce a fairly unimodal  
202 distribution, with a tail to slightly older ( $>30$  Ma) dates. Mixture modeling deconvolution suggests the dominant  
203 population is  $26.56 \pm 0.04$  Ma (78%). However, this value is skewed slightly older than the age of the peak (Fig. 4).

204 The maximum depositional age (MDA) was estimated using maximum likelihood age algorithms (MLA;  
205 Galbraith and Laslett, 1993; Vermeesch, 2021). The MLA age for the Kingston Canyon Tuff of  $26.13 \pm 0.20$  Ma  
206 (Fig. 5) is in agreement with the  $^{40}\text{Ar}/^{39}\text{Ar}$  eruption age, but is significantly younger than the mixture modeling  
207 deconvolution age discussed above. The MLA for the alluvium of the Mount Dutton Formation is  $25.24 \pm 0.17$  Ma  
208 (Fig. 5), again significantly younger than the deconvolution age.  
209

210  
211 **Figure 4: Probability distribution functions for U/Pb zircon dates from the Kingston Canyon Tuff (sample KCT) and**  
212 **overlying alluvium of the Mount Dutton Formation. Mixture modeling deconvolution ages and fraction of total grains are**  
213 **displayed for each mode. The dashed lines mark those deconvolution ages relative to the probability distribution functions.**

219

## 220 **5 Discussion**

221 Emplacement of the SGS was previously constrained to between 23.0 and 25.4 Ma based on a K-Ar age  
222  $25.4 \pm 0.9$  Ma for the tuff of Tibadore, which is the youngest deformed volcanic unit in the SGS, and the 23.0 Ma  
223 age of the overlying, undeformed Osiris Tuff (Biek et al., 2019). This age was updated to between 26.2 and 25.1 Ma  
224 based on an age of 25.1 Ma for the Antimony Tuff, which post-dates emplacement, and an age of 26.2 Ma for the  
225 Buckskin Breccia, the youngest rocks underlying the SGS (Rowley et al., 1994; in press). The breccia itself had not  
226 been dated, but included clasts of the Spry and Showalter quartz monzonite intrusions which have similar intrusion  
227 dates (Biek et al., 2022). Loffer (2024) estimated an emplacement age of 25.5 Ma based on detrital zircon U/Pb  
228 dates from the basal layer of the SGS at two locations. The discovery of pseudotachylyte within the SGS offered an  
229 additional opportunity to refine the emplacement age; this work presents an  $^{40}\text{Ar}/^{39}\text{Ar}$  age of  $25.25 \pm 0.05$  Ma for  
230 SGS emplacement, consistent with previous estimates but with higher precision. The significant improvement in the  
231 plateau age uncertainty for the SGS experiment relative to the pseudotachylyte analysis of Holliday et al. (2022) is  
232 because the analyses were performed using the NGX-600 mass spectrometer, which has stable ATONA®-backed  
233 Faraday collectors (Mixon et al. 2022) and an incredibly low noise floor (Cox et al., 2020). As such a Bayesian  
234 statistical optimization age is not needed. Emplacement occurred approximately 170 kyr after the eruption of the tuff  
235 of Tibadore and immediately preceding the eruption of the Antimony Tuff. The slide may have occurred up to 130

236 kyr prior to the eruption of the Antimony Tuff, or may have occurred near simultaneously, given that the ages and  
237 uncertainties for the pseudotachylyte and Antimony Tuff are statistically indistinguishable. Importantly, because the  
238 pseudotachylyte had been found within the upper plate associated with subsidiary faults, it has been impossible,  
239 until now, to conclusively demonstrate it was formed during slide emplacement. The pseudotachylyte age reported  
240 here thus provides tight constraints on the timing of SGS emplacement, and confirms the catastrophic nature of  
241 emplacement, consistent with prior interpretations (e.g., Biek et al., 2019; Braunagel et al., 2023).

242 The bimodal zircon U/Pb distribution of the Kingston Canyon Tuff suggests a significant zircon  
243 contribution from a previously crystallized subsurface magma. Xenocrystic inheritance is not observed in the  
244  $^{40}\text{Ar}/^{39}\text{Ar}$  data, possibly due to the small number of grains analyzed. Interestingly, the U/Pb zircon record of the  
245 alluvium atop the Kingston Canyon Tuff does not contain a strong 34 Ma signal. This, along with the overall  
246 younger MLA of the Mount Dutton alluvium, suggests that the dominant sediment input was derived from a  
247 different source. The MLA of the alluvium at the basal layer of the slide is also identical to that of the  
248 pseudotachylyte, suggesting that the former land surface was 25.25 Ma when the pseudotachylyte formed.

249 The Eocene Heart Mountain gravity slide in Wyoming is a comparable feature that is associated with  
250 igneous activity of the Absaroka volcanic field. Initiation of the gravity slide has been debated, ranging from  
251 incremental movement spanning millions of years (Malone et al. 2014), or catastrophic emplacement spanning  
252 several minutes to hours (Craddock et al. 2009). Recently, a lamprophyre suite (breccia, dike, diatrema) was  
253 identified at the base of allochthonous rocks. High-precision zircon U/Pb dating of the lamprophyre yielded dates  
254 that were identical to those obtained from other basalt cataclases, leading to the interpretation that the eruption of  
255 the diatrema triggered the gravity slide (Malone et al., 2017).

256 In both the MGSC and Heart Mountain, trigger mechanisms for gravity slides have been poorly  
257 understood; however, timing of igneous events relative to the sliding are essential for unraveling the relationship  
258 between the two types of events. In the Eocene Heart Mountain gravity slide, igneous activity apparently led to  
259 sliding, whereas in the Oligocene SGS, decompression associated with the gravity slide may have initiated the  
260 eruption of the Antimony Tuff. However, the timing of the intrusion of the magma body which became the  
261 Antimony Tuff is still unknown. Additional insights into the processes associated with Antimony Tuff's pre-  
262 eruption magma injection into the upper crust could be unraveled using detailed mineral analyses.

## 263 **6 Conclusion**

264 New high-precision  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of key units involved in the SGS suggest an emplacement age of 25.25  
265 Ma  $\pm$  0.05 Ma. This is approximately two million years prior to the Markagunt gravity slide (Holliday et al., 2022).  
266 The emplacement model proposed here is that the slide was initiated from injection of magma, which led to slope  
267 failure. This prompted decompression and ultimately the eruption of the 25.19  $\pm$  0.02 Ma Antimony Tuff. The  
268 association of magmatic intrusions and gravity slides was also proposed at Heart Mountain, Wyoming, suggesting  
269 that large-volume volcanic plateaus may generate these types of catastrophic events more frequently than previously

270 identified. Further, we begin to resolve the questions about causes for gravity slides (Hacker., 2014) and assess the  
271 relationship between igneous activity and mass movements.

272

273 **Data availability.** All data used in this work are provided in the supplementary materials.

274

275 **Supplementary materials.** The supplement is available online.

276

277 **Author contributions.** TR and MH designed the study and performed field collection with BJ, DHM, MJB, RFB,  
278 and WAG. BJ and BHM performed  $^{40}\text{Ar}/^{39}\text{Ar}$  and U/Pb data collection, respectively. TR, MH, and VABF  
279 performed data analysis. TR prepared the figures and the manuscript, and all authors contributed to the interpretation  
280 of results and improvement of the manuscript.

281

282 **Competing interests.** The authors declare no competing interests.

283

284 **Acknowledgements.** We thank the Arizona LaserChron Lab for assistance in analyzing samples for U/Pb data.  
285 Samples for this work were obtained from the homelands of the Ute, Southern Paiute and Goshute people.

286

287 **Financial Support.** Funding for this research was provided by the National Science Foundation (EAR-2412838;  
288 EAR-2113158, EAR-2113157, EAR-2113155, EAR-2050246).
