Abstract. Convection often initiates in proximity to cold fronts during the warm-season, but how various processes favour convective initiation at different regions relative to the front is still not well-understood. By combining automatic front detection methods and a convective cell tracking and detection dataset, the environments and availability of different lifting mechanisms are analysed. Our results indicate that pre-surface-frontal cells form in the environments with the highest surface dew points and convective available potential instability (CAPE). Behind the surface front, cells form in environments with lower CAPE and surface dew points, though still significantly higher than regions without cells. Mid-level relative humidity discriminates particularly well between post-frontal cell locations and regions without cells. Pre-surface-frontal cells form in environments with the strongest synoptic-scale lifting at 850 hPa and 700 hPa and also with the strongest convective inhibition. We also observe importance of synoptic-scale lifting post-frontal, particularly at 500 hPa. Observational sunshine duration data indicate less sunshine before cell initiation compared to regions without cells at most front relative regions, which highlights that solar heating may not be responsible for the majority of cold-frontal cell initiation. The results in this study are an important step towards a deeper understanding of the drivers of cold-frontal convection at different regions relative to the front.

1 Introduction

What exactly drives convective cells to develop in time and space is not currently well-understood. There has been improvement in recent times of the representation of convective initiation in numerical models, primarily due to convection-permitting models (CPMs) at increased resolution. However, biases regarding the positioning, timing and intensity of convection still remain (e.g. Kain et al., 2008; Kłasa et al., 2018). What is clear is the necessity of three primary ingredients to facilitate deep moist convection: moisture, lift and instability (Doswell et al., 1996). Vertical wind shear is also required to allow convective storm organisation (Markowski and Richardson, 2010). Moisture, instability and wind shear can be directly measured in the storm's environment using vertical profiles. Traditionally, this was done using observational proximity soundings (e.g. Brooks et al., 1994; Púčik et al., 2015; Kolendowicz et al., 2017; Taszarek et al., 2017). However, the advent of ERA5 reanalysis data on a global scale with a spatial and temporal resolution of 0.25 degrees and 1 hour, respectively, has enabled more localised studies where observational soundings are lacking (e.g. Taszarek et al., 2020; Calvo-Sancho et al., 2022; Poręba et al., 2022; León-Cruz et al., 2023). The precursor ERA-Interim also allowed analysis of convective storm environments (e.g. Taszarek

25 et al., 2018), albeit at a coarser spatial and time resolution.

Most previous studies have sought to better understand the environments in which convective storms form by analysing quantities such as mid- and low-level moisture, instability and wind shear. However, few studies have analysed the availability of individual lifting mechanisms. Determining whether air parcels will be lifted to their level of free convection (LFC) is essential for convective initiation and is often difficult to forecast. It is worth mentioning that moist air parcels reaching their LFC is not a guarantee of deep moist convection due to the possibility of entrainment (Morrison et al., 2022). Anticipating the spatiotemporal onset of convective cells is also essential for accurate prediction of convective hazards such as hail, strong winds and tornadoes. This is because if parcels are not lifted to their LFC and thus no CAPE is released then there is no convective cell and no possibility of severe convective storms (SCSs). This is regardless of whether there is a seemingly favourable environment for SCSs (e.g. high CAPE and high vertical wind shear). Indeed, warm season forecast failures for severe convective storms are often related to difficulties anticipating convective initiation (Markowski and Richardson, 2010). Despite this, the environments in which SCSs form have arguably attracted more attention in previous literature compared to convective initiation.

Individual lifting (triggering) mechanisms such as sea-breezes, orography, outflow boundaries and quasi-geostrophic (QG) forcing for ascent cannot be directly sampled in environmental vertical profiles. The latter is thought to be particularly relevant in proximity to cold fronts. QG forcing for ascent or descent (i.e. synoptic-scale lifting or descent) is typically of the order of cm s^{-1} . For this reason, it is unlikely sufficient to allow air parcels to reach their LFC (Trapp, 2013; his chapter 5.2). Nevertheless, mesoscale ascent at frontal boundaries can be an order of magnitude larger (e.g. Sanders, 1955; Koch, 1984) and synoptic-scale ascent can still steepen lapse rates due to adiabatic cooling and thus increase CAPE (Trapp, 2013; his Figure 5.2). Previous literature has alluded to the role of solar heating combined with frontal lift in ultimately determining where and when convection occurs at cold fronts (e.g. Doswell, 2001). Behind the front, where there is generally synoptic-scale descending motion, solar heating seems to carry more importance (e.g. Weusthoff and Hauf, 2008; Pacey et al., 2023). However, when convection occurs the synoptic-scale descent may be weaker than climatology or more localised areas of ascending motion may aid the development of convective cells. Due to the weaker horizontal temperature gradients, synoptic-scale lifting is typically weaker during the warm-season. The literature would benefit from studies quantifying the relevance of synoptic-scale lift at different regions relative to the front, especially during the warm-season. Topography can also influence cell initiation in proximity to cold fronts. Convergence zones due to flow splitting and channelling were observed during the Convective and Orographically-induced Precipitation Study (COPS) in south-western Germany/eastern France (Wulfmeyer et al., 2011). Topographic influences are not addressed in this study as they were already briefly explored in Pacey et al. (2023). The study showed that while overall in Germany cells are most frequent in southern Germany close to higher elevation, post-frontal cells are most frequent in north-west Germany near the coast. Finally, vertical wind shear may positively or negatively affect the transition from shallow to deep convection (Peters et al., 2022). Moist updrafts in sheared environments have been shown in simulations to have lower terminus heights than their non-sheared counterparts (e.g. Peters et al., 2019). On the other hand,

60 updrafts are typically wider in sheared environments so may be less susceptible to entrainment.

In this study, individual lifting mechanisms such as solar heating and quasi-geostrophic forcing for ascent as well as the environments of cold-frontal convective cells are analysed. Here, a special focus is placed on the variation of the environment and lifting mechanisms depending on the region relative to the front. Pacey et al. (2023) already showed large differences in the cell frequency and characteristics depending on the cell location relative to the front in Germany. Namely, cells are between 4-5 times more frequent pre-surface-frontal compared to post-frontal. Furthermore, pre-surface-frontal cells are most likely to be associated with 55 dBZ convective cores and mesocyclones. In this study, we also seek to better understand the differences observed in Pacey et al. (2023)'s climatology by delving into the environments and lifting mechanisms of cold-frontal convective cells. Rather than only focusing on convective cell environments (i.e. ERA5 grid points associated with convective cells), grid points not associated with convective cells are also considered. This allows analysis of how well certain variables can distinguish between grid points where convective cells *did* and *did not* develop. The separation into categories will be explained in Sect. 2.3. The primary research questions addressed in this study are as follows:

- Q1) How do convective cell environments vary across the front?
- 75 Q2) What is the relevance of quasi-geostrophic forcing for ascent (descent) and solar heating at different regions relative to the front?
- Q3) By analysing the environments and lifting mechanisms can we explain the cell frequency at different front relative regions?

This paper is organised as follows:

80

Section 2 introduces the datasets and methods used in this study. Section 3 performs a statistical comparison of the environments and lifting mechanisms of convective cells depending on the region relative to the front. Section 4 puts the results in the context of the cell frequency at different front relative regions (as shown in Pacey et al., 2023).

2 Data and Methodology

85 A convective cell detection and tracking dataset (KONRAD; Wapler and James, 2015) and ERA5 data (Hersbach et al., 2018a, 2020) are combined between 2007–2016 for the months April–September in the German radar domain. An automatic front detection algorithm is applied to ERA5 (Sect. 2.1) to build a time series of cold fronts. Cell environments and lifting mechanisms are analysed mostly using ERA5 data but also using sunshine duration station data (Sect. 2.4.3). To understand the differences in the environment and lifting mechanisms at different regions relative to the front, the distance in kilometres between the front and ERA5 grid points is derived. Grid points on the warm and cold side of the front are assigned a positive and negative distance, respectively.

90

2.1 Front Detection

Since the same methodology is used to detect fronts as described in Pacey et al. (2023) (their Sect. 2.1), the methods are only briefly reintroduced here. The front detection method is based on the Thermal Front Parameter (TFP) equation.

$$95 \quad \text{TFP} = -\nabla|\nabla\tau| \cdot \frac{\nabla\tau}{|\nabla\tau|} \quad (1)$$

The TFP denotes the rate of change of a thermodynamic variable (τ ; e.g., potential temperature or equivalent potential temperature) projected in the thermal gradient's direction.

A projection of the horizontal wind (\mathbf{v}) onto the frontal line is enabled using Equation 2 (Hewson, 1998).

$$100 \quad v_f = \mathbf{v} \cdot \frac{\nabla(\text{TFP})}{|\nabla(\text{TFP})|} \quad (2)$$

The term v_f is the horizontal wind (v) projected in the direction of the TFP gradient. The criteria used to detect cold fronts in this study are summarised below:

$$|\nabla\theta_e| > 6 \text{ K}(100 \text{ km})^{-1} \quad (1A)$$

$$v_f > 1 \text{ ms}^{-1} \quad (1B)$$

$$105 \quad L > 1000 \text{ km} \quad (1C)$$

The equivalent potential temperature is denoted by θ_e and the along front length by L . The overlap of the θ_e gradient threshold (condition 1A) and velocity threshold (condition 1B) is the front contour. As in Pacey et al. (2023), only synoptic fronts (~ 1000 km) are of interest. Therefore, fronts with an along front length (L) less than 1000 km are not included in the analysis (condition 1C). The frontal line is identified at the maximum of the equivalent potential temperature gradient by
110 applying the following condition:

$$\text{TFP} = 0 \quad (1D)$$

The latitude and longitude of where $\text{TFP}=0$ is determined using interpolation. The distance between each adjacent point is calculated and summed across the whole line to give the front length (L). The four aforementioned criteria are applied to smoothed θ_e and horizontal wind fields at 700 hPa in ERA5. A smoothing function is applied to the fields whereby the nearest
115 four neighbours of a grid point are averaged. The process is repeated 30 times to remove any local-scale features. There is no universal approach to select the degree of smoothing since it is dataset dependent. Here, it was chosen subjectively by varying the degree of smoothing for different case studies and ensuring only synoptic-scale air mass boundaries remained. The fronts are detected on the 700 hPa pressure level to avoid interaction with orography, which is a common issue in central Europe (Jenkner et al., 2010; their Sect. 4.4). Furthermore, the 700 hPa level is further above the turbulent boundary layer.

120 The thresholds (conditions 1A, 1B and 1C) are stricter than some previous studies. For example, Schemm et al. (2016) tested
 300 km and 500 km front length criteria. Looser thresholds may increase the number of erroneously detected fronts. On the
 other hand, higher thresholds generally reduce the number of fronts in the dataset but limit the dataset to synoptic-scale cold
 fronts. Overall, a dataset with a lower front count and higher percentage of correctly detected fronts is prioritised. Cold fronts
 are detected in a subsection of the European domain ([40N–70N, 20W–20E]). Examples of the detected cold frontal lines in
 125 Germany are shown in Figure 1. A total of 4 timesteps are shown across different days and years.

2.1.1 Surface front relative to the 700 hPa front

Due to the rearward slope of cold fronts with height, using a single pressure level to detect fronts (700 hPa in this case) requires
 some special consideration. The 700 hPa level is approximately 3 km above the surface and cold fronts have a mean slope of
 $\sim 1:100$ (Bott, 2023). This means that the surface front would be on average 300 km horizontally displaced ahead of the 700 hPa
 130 front. By taking an average of convergence over ERA5 grid points at different distances relative to the front, the maximum at
 the surface is indeed 300 km ahead of the 700 hPa front (Pacey et al., 2023; their Figure 3). This supports the aforementioned
 geometry-based assumption. While the slope of the front and corresponding surface front location relative to the 700 hPa front
 are likely to vary per case study, we proceed assuming the climatological location of the surface front (hereafter surface front)
 is 300 km ahead of the 700 hPa front and use it as a reference point for this study. A full list of terminologies is shown in Table
 135 1.

2.2 KONRAD Convective Cell Detection and Tracking Algorithm

KONRAD (KONvektionsentwicklung in RADarprodukten, convection evolution in radar products) is a convective cell de-
 tection and tracking algorithm originally applied to 2D radar data in the German radar domain (Wapler and James, 2015).
 KONRAD is run operationally by the German Weather Service (DWD) with a spatial and time resolution of 1 km and 5 min-
 140 utes respectively. A convective cell is defined as an area with 15 pixels (condition 2A) or more exceeding 46 dBZ (condition
 2B). As the spatial resolution of KONRAD is 1 km, 1 pixel $\sim 1 \text{ km}^2$. The cell centre as well as the maximum north, south, west
 and east extent of the cell are provided. Further details are available in Pacey et al. (2023) (their Sect. 2.2). Unlike Pacey et al.
 (2023), additional definitions such as the number of pixels exceeding 55 dBZ, lightning strike count and mesocyclone intensity
 are not used in this study. Here, the convective cell definition is solely based on the criteria below:

145

$$\text{Reflectivity} \geq 46 \text{ dBZ}$$

$$\text{Cell Area} \geq 15 \text{ km}^2$$

$$\text{Reflectivity} \geq 46 \text{ dBZ} \quad (2A)$$

2.3 Defining non-cell regions, cell regions and cell grid points

Rather than solely focusing on where cells occurred (cell grid points), the surrounding regions are also assessed (cell regions), as well as regions where no cells occurred (non-cell regions). This comprehensive approach allows us to understand how well certain variables can distinguish between grid points where convective cells *did* and *did not* develop. First, cell grid points must be defined. The KONRAD dataset (Sect. 2.2) has a spatial and temporal resolution of 1 km and 5 minutes, respectively. ERA5 has a 0.25 degree spatial resolution and a 1 hourly temporal resolution, respectively. Spatially, ERA5 grid points within the maximum north, south, west and eastern extent of the cell area are labelled as convective cell grid points. To take the different spatial resolutions of the datasets into account and the fact that some cells are smaller than the ERA5 grid box size, the cell boundaries are extended by 0.125 degrees in each direction. Applying this approach ensures that the area where the convection is occurring is labelled as a convective cell grid point. Temporally, cells are associated to the timestep before the first cell detection time. For example, a cell first detected between 14:00–14:59 UTC is assigned to the 14 UTC timestep. This is to avoid sampling the post-convective environment, which is particularly important for thermodynamic variables such as convective available potential energy (CAPE).

To define the regions, bins are first created at different front relative distances. Following the approach from Pacey et al. (2023), we only consider grid points within 750 km of the 700 hPa front. Using 100 km intervals there are a total of 15 bins. Each ERA5 grid point within 750 km of a 700 hPa front detected between 2007–2016 and April–September is associated to one of these bins. If a convective cell grid point is present within one of the 100 km bins at the current timestep but *not* at the given grid point then this grid point is labelled as a *cell region*. If no convective cell grid point is present within the 100 km bin at the current timestep then this grid point is labelled *non-cell region*. The number of grid points associated to each category at different distances from the front is shown in Figure 2. The total number of grid points in each bin varies since pre-frontal regions occur more often than post-frontal in Germany. This can be explained by cold fronts reaching southern parts of Germany less frequently, which then allows a larger number of post-frontal grid points to be sampled. Grid points in each category are visualised in Figure 1 for 4 independent timesteps. In the first example (Figure 1a) most grid points are labelled non-cell regions (green). Cells were only detected in the bins 300–400 km and 400–500 km, therefore most grid points in this region are labelled cell regions (purple). Grid points where convective cells occurred (cell grid points) are in yellow. Only timesteps with cells occurring in proximity to the front are shown in Figure 1, however timesteps with no cells are also included in the analysis. In this case, all grid points would be assigned the non-cell region category (green).

2.4 Variables

The variables analysed in this study broadly follow the ingredients based methodology proposed by Doswell et al. (1996); moisture, lift and instability. Wind shear is also considered as it may also both positively or negatively affect convective initiation (e.g. Peters et al., 2022) and is related to the organisation of convective cells (e.g. Markowski and Richardson, 2010).

Large-scale and convective precipitation are analysed to see how ERA5 represents precipitation amounts across the front. A full list of the variables analysed in this study is shown in Table 2.

2.4.1 Convective Inhibition Dataset

185 The Convective Inhibition (CIN) parameter available from the Climate Data Store assigns a missing value if CIN exceeds 1000 J kg⁻¹ or if there is no cloud-base present (Hersbach et al., 2018b). To ensure that a CIN value is present for all grid points, CIN is obtained from an alternative data source (thundeR; Taszarek et al., 2023). CIN is derived in thundeR using ERA5 model level data. Three model parcel departure levels are considered: most unstable CIN (MUCIN), mixed-layer CIN (MLCIN) and surface-based CIN (SBCIN). The CIN parameters are calculated by integrating negative parcel buoyancy between the
190 parcel initialisation height and the LFC. The most unstable parcel refers to the parcel with the highest equivalent potential temperature between the surface and 3 km above ground level (AGL). The mixed-layer parcel is calculated by averaging the potential temperature and mixing ratio between the surface and 500 metres AGL and initialising from surface. The surface based parcel is the nearest parcel to the surface.

2.4.2 Q-vectors

195 The quasi-geostrophic forcing for ascending and descending motion can be expressed using the Q-vector convergence derived from the quasi-geostrophic omega equation (Hoskins et al., 1978). Q-vectors are derived using the Python package MetPy (May et al., 2022), which derives Q-vectors in the following way (Equation 3).

$$\begin{aligned} Q_i &= -\frac{R}{\sigma p} \left[\frac{\partial u_g}{\partial x} \frac{\partial T}{\partial x} + \frac{\partial v_g}{\partial x} \frac{\partial T}{\partial y} \right] \\ Q_j &= -\frac{R}{\sigma p} \left[\frac{\partial u_g}{\partial y} \frac{\partial T}{\partial x} + \frac{\partial v_g}{\partial y} \frac{\partial T}{\partial y} \right] \end{aligned} \quad (3)$$

Where:

200 Q_i : x component of the Q-vector

Q_j : y component of the Q-vector

R : Gas constant for dry air

σ : Static stability parameter

p : Pressure

205 u_g : u component of geostrophic wind

v_g : v component of geostrophic wind

T : air temperature

The u and v components of the geostrophic wind are derived from the geopotential height field. The geopotential height fields are first smoothed using a simple smoothing function whereby the nearest four neighbours of a grid point are averaged. The process is repeated 50 times. The air temperature field (T) is also smoothed 50 times. The smoothing is required to filter out local scale features to be left with the large-scale circulation. Smoothing values between 10 and 100 were tested and 50 was selected as it showed a realistic and smooth frontal circulation with Q-vector convergence ahead of the front and divergence behind the front. As the smoothing of fields in Sect. 2.1, the choice is ultimately subjective and there is no universal approach to select the degree of smoothing.

The Q-vector convergence is analysed at three pressure levels. The 850 hPa level is the typical height of the boundary layer during the daytime and the location of the strongest capping inversion. Rising air parcels must overcome this inversion to reach the LFC. The 700 hPa and 500 hPa levels are also analysed to understand the importance of mid-level quasi-geostrophic forcing for ascent. As discussed in the introduction, mid-level synoptic-scale lifting can increase lapse rates and increase CAPE.

2.4.3 DWD Sunshine Hours Station Data

In Sect. 3.6 solar heating is analysed using total incoming solar radiation from ERA5. Observational sunshine duration data from the German Weather Service (DWD) is also analysed to see if the two datasets are in agreement. The data was downloaded from the Open Data Server (Kaspar et al., 2019). The 10-minute station observations of sunshine duration (Deutscher Wetterdienst, 2024) are used for the years 2010–2016 between 09-18 UTC. Only ERA5 grid points within 15 km of a DWD station are considered as solar radiation can vary on small spatial scales.

3 Results

The environments and lifting mechanisms of cold-frontal cells are analysed at different regions relative to the front. A comparison is also made to cell regions and non-cell regions (see definitions in Sect. 2.3). The mean and median of each variable are taken across each 100 km front relative bin for each category (i.e. cell grid points, cell regions and non-cell regions; Figure 2). Plots with additional markers for the 25th and 75th quartiles of the distributions are shown in the supplementary material.

3.1 Moisture

Surface dewpoints (2-metres above ground level in this case) are a measure of moisture availability at the surface. While sufficient moisture directly at the surface is not essential for convective initiation since convection can be elevated (e.g. Corfidi et al., 2008), surface dewpoints are a commonly used tool by forecasters. Lower dewpoint air generally requires more lifting to reach the lifting condensation level (LCL). Figure 3 shows that pre-700-frontal cells develop in environments with a surface dewpoint of around 15–16 °C on average. Cells 650–750 km ahead of the 700 hPa front, which is the furthest distance from the front considered, have the highest mean dewpoints. Post-700-frontal cells formed in environments with lower surface dewpoints ranging between 12–14 °C. Dewpoints at cell grid points are around 1 °C higher than at cell region grid points on average. The difference in the mean between cell grid points and non-cell region grid points is significant at all distances

relative to the front. The difference between the cell grid point mean and non-cell regions mean ranges between 3–4 °C. A similar result is found for the surface air temperature (Figure A1).

Mid-level moisture is also relevant for the initiation of deep moist convection since entrainment of dry environmental air can lead to updraft dilution, hence influencing updraft buoyancy. Recent work has shown that how susceptible the updraft is to dry environmental air is dependant on the updraft width below the LFC (Morrison et al., 2022). However, the updraft, which occurs on the storm-scale, will not be looked at in this study. The relative humidity (RH) is analysed at 700 hPa (hereafter RH700) as parcels have typically already passed the LFC at this level, so entrainment is important in determining whether updrafts can reach upper levels of the atmosphere.

Cells form in environments with a mean RH700 of between 60–70% post-700-frontal and 70–85% pre-700-frontal (Figure 4). Cells have the largest RH between 50–250 km ahead of the 700 hPa front, which is also the case for cell regions and non-cell regions. The RH700 at cell grid points is significantly higher than non-cell regions at all distances from the front except in the region 50–150 km ahead of the 700 hPa front. A larger difference exists between cell grid points and non-cell region grid points post-700-frontal (up to 30% difference) compared to pre-700-frontal (up to 10% difference). This indicates that a larger enhancement of RH700 humidity is required to facilitate post-700-frontal cell development. On the other hand, the warm-sector typically already has high mid-level moisture content. Excluding the region 50–250 km, cell regions have slightly lower RH than cell grid points but are above non-cell region grid points. These results are consistent with environment studies of lightning in Europe which found that lightning is less favourable when mid-level relative humidity is low (Westermayer et al., 2017) and that 75% of lightning cases in Poland had RH700 of 65% or higher (Poręba et al., 2022; their Figure 11). The average RH between 850–500 hPa (Figure 4) shows a very similar result as RH700.

3.2 Instability

CAPE is a measure of atmospheric instability; a prerequisite for deep moist convection (Doswell et al., 1996). It is also a very commonly used parameter in severe convective storm forecasting. Since there are numerous ways to derive CAPE, e.g. using different departures levels and (not) applying the virtual temperature correction (Doswell and Rasmussen, 1994), we do not compare our CAPE values with other studies. Rather we look at CAPE differences across the cold front using the same consistent definition of CAPE (MUCAPE; see Table 2 caption). Figure 5 shows that pre-surface-frontal cells have the highest mean CAPE, up to around 650 J kg⁻¹ 700–750 km ahead of the 700 hPa front. In comparison, post-700-frontal cells occur in environments of lower CAPE; between 150–250 J kg⁻¹ on average. The mean CAPE at convective cell grid points is between 5–8 times higher than non-cell regions depending on the front relative region and is significant at the 95% confidence level. The difference between cell grid points and non-cell regions is particularly large pre-surface-frontal. In the 650–750 km bin, the 25th percentile of cell grid points is around 130 J kg⁻¹ higher than the 75th percentile of non-cell regions (Figure S3) indicating a large separation between the two distributions. Like the moisture variables the cell region means are between the non-cell region and cell grid point means.

3.3 Convective Inhibition

Environments with high convective inhibition (CIN) require stronger lifting so that parcels can reach their LFC. CIN is considered using parcels with different departure levels: most unstable parcel (MUCIN), mixed-layer parcel (MLCIN) and surface based parcel (SBCIN). Only CIN at convective cell grid points is available for analysis, the reader is referred to Sect. 2.4.1 for further details. Pre-surface-frontal cells form in environments with the strongest CIN with around -35 J kg^{-1} of MUCIN on average (Figure 6). Post-700-frontal cell environments had weaker CIN in comparison. The same result applies for MLCIN and SBCIN, albeit with stronger CIN overall (Figure A2). Therefore, more CIN needed to be overcome to initiate convective cells pre-surface-frontal compared to post-700-frontal. However, the stronger pre-surface-frontal CIN may be advantageous for large CAPE build up (see Figure 5) since convection will not be initiated prematurely (Ludlam, 1980). MUCIN is weaker than MLCIN and SBCIN for pre-700-frontal cells which could be explained by surface inversions (mostly at night and early morning) leading to stronger CIN for parcels departing closer to the surface. MUCIN, MLCIN and SBCIN are shown again using daytime cells only (09–18 UTC) (Figure A3) showing that daytime post-700-frontal and pre-surface-frontal cells formed in environments with a mean of -8 J kg^{-1} and -28 J kg^{-1} of SBCIN, respectively. A similar result was found for MLCIN and MUCIN. While overall cells formed in environments with weaker CIN during the daytime, pre-surface-frontal cell environments still have stronger CIN than post-700-frontal during the daytime.

3.4 Quasi-geostrophic forcing for ascent

Q-vector convergence is a commonly used diagnostic by forecasters to highlight areas of geostrophic forcing for ascent or descent. Q-vectors are derived from the quasi-geostrophic equations (Hoskins et al., 1978). The reader is referred to Sect. 2.4.2 for further details on how Q-vectors are calculated and the choice of pressure levels. Figure 7 shows that cells marginally ahead of the surface front have the strongest convergence of the Q-vector at 850 hPa (hereafter QVEC850). The strongest QVEC850 convergence of non-cell region grid points is at the mean surface front location. The strongest QVEC850 divergence, which is linked to descending motion, is near-700-frontal for all categories. However, near-700-frontal the QVEC850 divergence is weaker at cell grid points compared to cell region grid points and non-cell regions. From 750 km behind the 700 hPa front up to near the surface front there is no significant difference between the QVEC850 for non-cell regions and cell regions indicating the importance of QVEC850 specifically where the convective cells are detected. QVEC700 convergence shows a similar result to QVEC850 with slightly weaker mean convergence and divergence. The regions of strongest ascent and descent shift towards the left (cold-side) of the plots with increasing height going from 850 hPa to 500 hPa due to the rearward slope of cold fronts with height.

Q-vector convergence at 500 hPa (hereafter QVEC500 convergence) is strongest near-700-frontal across all three categories (Figure 7). Pre-700-frontal cells formed in environments with weaker QVEC500 than non-cell regions and cell regions, which is in contrast to QVEC700 and QVEC850. QVEC500 convergence at cell grid points near-700-frontal (-50 to 50 km) is over 3 times stronger compared to non-cell regions and around 5 times stronger compared to the maximum cell grid point means at 700 hPa and 850 hPa. Non-cell regions post-700-frontal have mean QVEC500 divergence but cell regions and cell grid points

have convergence of QVEC500. This result highlights the importance of upper-level forcing on the development of convective cells near-700-frontal and also post-700-frontal. The forcing for ascent could be linked to a post-frontal trough or may also act to destabilise upper-layers and hence increase CAPE.

3.5 Vertical Velocity

310 The vertical velocity at 850, 700 and 500 hPa is shown from left to right in Figure 8. Like Q-vector convergence, the variable can be used to highlight areas of ascending and descending motion. However, the vertical velocity is not solely linked to vertical motion due to quasi-geostrophic forcing for ascent or descent. Additional sources of ascending motion such as areas of convection may also show a signal in the vertical velocity variable in ERA5. At all levels the cell region and non-cell region grid point means are similar to the Q-vector in terms of where ascending and descending motion are present (Figure 7). However, 315 there is a difference at cell grid points as there is mean ascending motion at all locations relative to the front at all three vertical levels. The strong anomaly near-700-frontal which was seen for QVEC500 convergence is not seen in the vertical velocity at 500 hPa. Ahead of the 700 hPa front, vertical motion is maximised at 500 hPa, which is consistent with observations of quasi-geostrophic vertical motion being maximised around 500 hPa (Holton and Hakim, 2013). The highest vertical velocity is at 500 hPa at cell grid points near the surface front (around $0.06\text{--}0.07\text{ m s}^{-1}$). This ascent rate is around two orders of 320 magnitude lower than what has been seen in observations and numerical models of convective cell updrafts (e.g. Weisman and Klemp, 1982). While the mean vertical velocity ascent rates are not representative of convective updrafts, it is possible that the parameterized convection could interact with the vertical velocity field. Once the convection parameterization scheme is triggered, the convection may feedback on the vertical velocity field due to cloud formation and latent heat release (and hence further ascent). It is not trivial to disentangle the contribution of the background synoptic-scale lifting and contributions from 325 convection on the vertical velocity. We will revisit this topic in section 3.8.

At non-cell region grid points, the convective parameterization scheme is less likely to be triggered so this should primarily be vertical motion of the background flow. The non-cell region means suggest that the lifting from the front at 850 hPa, 700 hPa and 500 hPa is typically maximised between the surface front and the 700 hPa front.

3.6 Solar heating

330 Solar heating (insolation) is linked to increased surface temperatures, which contributes towards atmospheric instability (Markowski and Richardson, 2010; their Figure 7.9c). Solar heating also gives parcels positive buoyancy near the surface, which can help parcels to be lifted to their LFC. The total incoming solar radiation (hereafter solar radiation) is shown in Figure 9. Only timesteps between 09–18 UTC are used since solar radiation is weaker during the early hours of the morning, the late evening and not possible during the night. The variable refers to the radiation accumulated during the hour prior to the ERA5 335 timestep, thus before convective cell detection. Post-700-frontal cells develop with the largest solar incoming radiation (around 250 W m^{-2}). The lowest solar radiation is ahead of the 700 hPa front but behind the surface front (50 to 150 km region), consistent with where the total cloud cover is highest (Figure A4) and vertical velocity at non-cell regions is highest (Figure 8). Solar radiation at cell grid points between -250 to 50 km and pre-surface-frontal is lower than at non-cell regions. The result

may seem counterintuitive as solar radiation is thought to be a driver of convective initiation so higher solar radiation would be expected before cell initiation. The result could indicate that ERA5 struggles with the timing of convective initiation thus produces convective clouds before the actual convective initiation. Nevertheless, on consultation of observational station data from the DWD (see Sect. 2.4.3), the same negative anomaly was observed for sunshine minutes (Figure A5). The negative anomaly is particularly strong pre-surface-frontal. One explanation for the negative anomaly in solar radiation (ERA5) and sunshine duration (observational data) could be attributed to cloud cover from pre-existing convective cells. The importance of cold pools (outflow boundaries) on convective initiation has been already highlighted in previous literature. For example, Hirt et al. (2020) showed using high-resolution model simulations for case studies that up to 50% of convective initiation is at the edge of cold pools. At the edge of cold pools it is likely to be cloudy and convection may not be directly triggered by solar heating. This is especially true in the case of a mesoscale convective system (MCS), where several new cells could initiate inside the pre-existing cloud system due to cell recycling.

350

3.7 Vertical Wind Shear

Vertical wind shear is related to storm organisation (e.g. Markowski and Richardson, 2010) and can potentially both positively or negatively affect convective initiation (Peters et al., 2022). The bulk wind shear between the surface and 500 hPa is highest for convective cell grid points near-700-frontal with around 13 m s^{-1} on average (Figure 10). The wind shear near-700-frontal is also higher than non-cell region grid points by around 1 m s^{-1} . There is less difference between cell regions and cell grid points near-700-frontal. The wind shear decreases at increasing distance away from the 700 hPa front. At a certain distance behind the 700 hPa front wind shear is lower at cell regions and cell grid points compared to non-cell region grid points. While there is some asymmetry around the maximum, post-700-frontal cells generally form in environments with comparable wind shear compared to pre-surface-frontal cells.

360 Calculating the bulk wind shear between the surface and 500 hPa (as Figure 10) will lead to a lower vertical distance being sampled for grid points at higher elevation. For this reason, the bulk wind shear between the surface and 6 km above ground level (AGL) is sometimes used instead of the surface-500 hPa wind shear. To check that this does not have a major effect on our results, the surface to 6 km AGL wind shear is analysed at cell grid points using ERA5 model level data (Taszarek et al., 2023). Even though there are differences in the magnitude of the wind shear between the bulk wind shear surface–500 hPa (Figure 10) and 0–6 km AGL (Figure 11), the regions of maximum and minimum wind shear around the front are very comparable. Cells near the 700 hPa front have a particularly high 0–6 km AGL mean wind shear of around 23 m s^{-1} . Supercells have been shown in several studies to form in environments with around 20 m s^{-1} of 0–6 km AGL of shear (e.g. Doswell and Evans, 2003). However, Pacey et al. (2023) showed that 2.5% of near-700-frontal cells were associated with mesocyclones compared to around 5% of pre-surface-frontal cells (their Figure 11f). They showed also that post-700-frontal cells have an even lower fraction with mesocyclones where the mean wind shear also remains high. Therefore, thermodynamics likely explain why a higher fraction of pre-surface-frontal cells are associated with mesocyclones compared to near-700-frontal and post-700-frontal cells owing to the more frequent overlap of high shear and high CAPE environments in the pre-surface-frontal zone.

370

3.8 Precipitation

To see how precipitation is represented in ERA5 across the front, large-scale and convective precipitation are shown in Figure 12. In Sect. 3.5, we previously mentioned that convection might interact with the vertical velocity field, which if true should show a similar signal in the precipitation fields. We do not seek to validate ERA5 rainfall amounts for which a comparison with a combined radar and rain gauge product would be more suitable.

The large-scale precipitation is highest for all three categories between the 700 hPa and surface front. This is in agreement with the classical conceptual model of an Ana cold front where the primary precipitation region associated to a cold front is behind the surface front (Browning, 1990; EUMeTrain, 2012). In this case, the primary precipitation region refers to mostly stratiform precipitation that results from cloud formation in the ascending warm conveyor belt (Browning, 1986). Figure 9 also shows that the lowest solar radiation is at this location relative to the front. Total cloud cover, high cloud cover and vertical velocity for non-cell regions are also highest at this location (Figures A4 and 8). This suggests that convective cells between the 700 hPa front and surface front are mostly embedded in stratiform precipitation regions (e.g. Oertel et al., 2020). At most regions relative to the front the large-scale precipitation is higher at cell grid points compared to non-cell regions.

Convective precipitation is maximum 150–250 km ahead of the 700 hPa front for all three categories. This maximum is around 150 km behind the convective cell maximum found in Pacey et al. (2023) (see Figure 13). The differences could relate to weaker precipitation than the 46 dBZ threshold being more frequent closer to the front or ERA5 struggling to resolve the location of convection relative to the front. The minimum convective precipitation is 50–150 km behind the 700 hPa front (again for all three categories) before increasing slightly further behind the front. The increase behind the 700 hPa front is consistent with the slight increase seen in the convective cell climatology (Figure 13). Convective precipitation at cell grid points is significantly higher compared to non-cell region grid points and shows a similar trend to the vertical velocity fields (Figure 8). This corroborates the hypothesis that the vertical velocity signal in Figure 8 comes from the convective parameterization scheme being triggered in the correct time and place in some cases. Indeed, 51.5% of all convective cell grid points have convective precipitation greater than 0.1 mm hr^{-1} .

4 Relating the results to cold-frontal cell climatology

A statistical comparison between cell grid points, cell regions and non-cell regions (Sect. 2.3) depending on the region relative to the front has been made in Sect. 3. The purpose of this section is to relate the results to the cell climatology shown in Pacey et al. (2023) and address our third research (Q3). Figure 5a from Pacey et al. (2023) is shown here again as Figure 13. In this discussion, three front relative regions are focused on: pre-surface-frontal cells (300–750 km ahead of the 700 hPa front), near-700-frontal (-50 to 50 km from the 700 hPa front) and post-700-frontal cells (-750 to -50 km from the 700 hPa front).

4.1 Pre-surface-frontal cells

Cells are between 4–5 times more frequent pre-surface-frontal than post-700-frontal and near-700-frontal (Figure 13). A key
405 result from this study is that while the environment quickly becomes unfavourable for cells behind the surface front, this is not
the case in the other direction ahead of the front. For example, 750 km ahead of the 700 hPa front (around 450 km ahead of
the surface front), Q-vectors remain convergent at 850 hPa and 700 hPa even when cells are not occurring (non-cell regions;
Figure 7). On the other hand, 300 km behind the surface front (near-700-frontal), Q-vectors at 850 and 700 hPa are divergent
at non-cell regions and cell regions. Similar results are found for CAPE, surface dew points and solar radiation with the mean
410 values remaining higher ahead of the surface front compared to the same distance behind the surface front. These results can
explain why cell frequency remains high ahead of the front but sharply decreases towards the 700 hPa front. This is despite
the fact that CIN is also higher for pre-surface-frontal cells (Figure 6). The presence of pre-surface-frontal convergence lines
(Dahl and Fischer, 2016) is one possible source of lift that may aid parcels in overcoming this CIN.

4.2 Near-700-frontal cells

415 Convection is least frequent surrounding the 700 hPa frontal line location (Figure 13). At 850 hPa, divergence of the Q-vector
is typically found at this region relative to the front (Figure 7). This is also supported by the minimum vertical velocity at
850 hPa (Figure 8). Furthermore, the mean solar radiation is also lower and CAPE is lower than other regions relative to the
front. The high wind shear (Figures 10 and 11) may also contribute towards the low cell frequency since deep moist convection
may struggle to initiate when initial updraft width is low and shear is high (Morrison et al., 2022 and Peters et al., 2022).

420 4.3 Post-700-frontal cells

Post-700-frontal cells are associated with lower cell frequency than pre-700-frontal cells (Figure 13) and almost always occur
during the daytime (Pacey et al., 2023; their Figure 6). Generally Q-vectors are divergent at 850, 700 and 500 hPa which would
act to hinder the development of convective cells. Figure 4 shows that mid-level post-700-frontal relative humidity is generally
low (50% or lower). Owing to the lower CIN (Figure 6) less lifting would generally be required to allow post-700-frontal cell
425 initiation. However, parcels may be more susceptible to entrainment (Morrison et al., 2022) due to the combined effects of a
dry mid-troposphere and wind shear thus not be able to reach the threshold of a convective cell (46 dBZ in this study). These
results can explain the overall low cell frequency post-700-frontal. The higher cell frequency compared to near-700-frontal
cells can be explained by solar radiation possibly acting as a source of lift and increasing instability (Figures 9 and A5).

5 Conclusions

430 In this study, the environments and lifting mechanisms associated with warm-season cold-frontal convective cells were analysed
by combining automatic front detection and cell detection methods. Previous studies had primarily focused on the storm's
environment looking at parameters such as mid- and low-level moisture, instability and wind shear with less consideration of

different lifting (triggering) mechanisms. Furthermore, variation in the environment and lifting mechanisms at different front relative regions had not been considered in any detail. Here, a comprehensive set of variables relevant for convective initiation were considered, including synoptic-scale lifting, solar heating, CIN, CAPE, relative humidity and dew points. A strong focus was placed on differences in the convective cell environments and lifting mechanisms depending on the region relative to the front. How well each variable discriminates between regions where cells occurred and did not occur was also assessed. The primary findings of this study are highlighted below and a shorter overview is visualised in Figure 14.

- Pre-surface-frontal cells form in the environments with the highest dew points and CAPE, around 16 °C (Figure 3) and 600–700 J kg⁻¹ (Figure 5) on average. These cells are associated with the strongest CIN (Figure 6) and also strongest Q-vector convergence (synoptic-scale lift) at 850 hPa and 700 hPa (Figure 7). However, synoptic-scale lift at 500 hPa is less relevant for pre-surface-frontal cells.
 - Between the surface and 700 hPa front, cells form in environments with the highest mid-tropospheric relative humidity (Figure 4), which is linked to the frontal cloud band (Figures 9 and A4).
 - Near the 700 hPa frontal line, strong synoptic-scale lifting at 500 hPa is key for cell initiation (Figure 7). The lifting may not be (only) relevant for maintaining positive buoyancy of updrafts, rather (also) steepening lapse rates and increasing CAPE through adiabatic cooling.
 - Post-700-frontal non-cell regions have mean divergence of the Q-vector at 850, 700 and 500 hPa, whereas weaker divergence or even convergence of the Q-vectors is found at cell locations (Figure 7). Post-700-frontal cells have relative humidity at 700 hPa around 20–30% higher than non-cell regions (Figure 4), highlighting the importance of higher relative humidity than usual to allow cell development and reduce the likelihood of entrainment.
 - At all front relative regions, there is a positive anomaly for ascending motion in the vertical velocity which is not present for Q-vector convergence at all pressure levels (Figures 8 and 7). Furthermore, solar radiation (ERA5) and sunshine duration (observational data) before cell initiation are generally lower at cell locations compared to non-cell regions.
- While solar heating may be relevant for the first cell initiation, we speculate other factors (e.g. outflow boundaries) are more relevant for the majority of cold-frontal cell initiation.

These results advance understanding of the environments in which cold-frontal convective cells form and the importance of different lifting mechanisms on cell development depending on the region relative to the front, addressing our first and second research questions (Q1 and Q2). In section 4, explanations for the differences in cell frequency at different front relative regions are provided, addressing our third research question (Q3). The results from this study have a direct forecasting application since a forecaster can better understand in which environments to expect convective cell initiation depending on the region relative to the front.

Furthermore, the results leave several interesting open questions for future work. For example, is the lifting at 500 hPa generally more important for increasing instability through adiabatic cooling or also relevant for maintaining positive buoyancy

465 of updrafts? The positive vertical velocity anomaly at cell grid points which is not present in the Q-vector fields at all pressure levels raises questions on how well ERA5 represents convection. The positive anomaly in the vertical velocity may come from the convective parameterization scheme being triggered in the right place and time in some cases and the convection then feeding back on the vertical velocity field.

Finally, we remark that each variable was considered individually in this study but when forecasting convection, moisture, 470 lifting mechanisms and instability must be considered in tandem. While we show significant differences between the cell grid points and non-cell regions means for most variables, there is some overlap of the distributions for most variables (see supplementary material). Future studies seeking to better understand the importance of different lifting mechanisms may benefit from only considering grid points where there is sufficient moisture and instability.

Code and data availability. ERA5 data can be downloaded from the Copernicus servers (Hersbach et al., 2020). KONRAD is available 475 for research purposes on request (contact kundenservice@dwd.de). Front detection and plotting code are available on request from the corresponding author.

Author contributions. GP carried out the data analysis and wrote all sections of the manuscript. SP and LS provided comments and support during the data analysis and manuscript process. SP and LS wrote the original research proposal.

Competing interests. At least one of the (co-)authors is a member of the editorial board of Weather and Climate Dynamics.

480 *Acknowledgements.* This research has been funded by Deutsche Forschungsgemeinschaft (DFG) through grant CRC 1114 'Scaling Cascades in Complex Systems, Project Number 235221301', Project C06 "Multi-scale structure of atmospheric vortices". We thank the German Weather Service (DWD) for providing the KONRAD cell detection and tracking dataset. The Open Data Server from the DWD also allowed sunshine duration data to be downloaded. We thank Johannes Dahl for useful discussions and insights as well as Mateusz Taszarek for providing convective parameter data which were used in sections 3.3 and 3.7. Finally, we would like to thank two anonymous reviewers 485 whose comments helped to improve the quality of the manuscript.

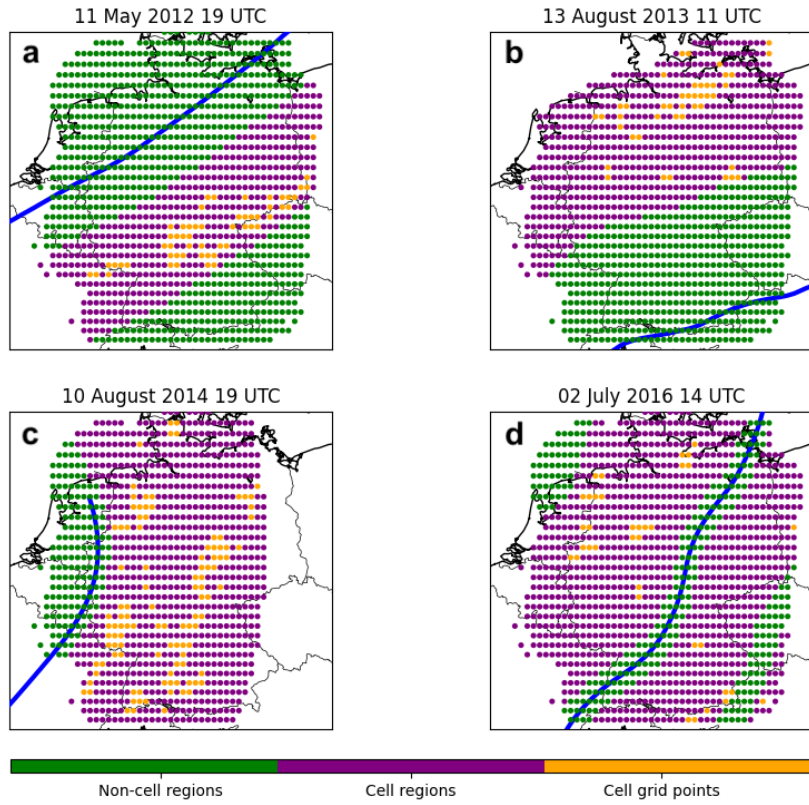

Figure 1. Visualisation of how cell grid points (yellow), cell regions (purple) and non-cell regions (green) are defined for four timesteps on different days. The 700 hPa frontal line is shown by the blue line and was detected using the methods defined in Sect. 2.1.

Figure 2. Number of grid points in each category (non-cell regions, cell regions and cell grid points) depending on the distance from the 700 hPa front. Note the log y-axis.

Figure 3. 2-metre dewpoint temperature (Celsius) depending on distance from the 700 hPa front (km) for cell grid points (orange), cell region grid points (purple) and non-cell region grid points (green). Stars indicate that the convective cell grid point mean is significantly different from the non-cell region grid point mean at the 95% confidence level based on a Welch's t-test, which does not assume equal population variance. The triangle represents the median of each distribution. The dashed vertical line and solid vertical line represent the 700 hPa front and mean surface front location (see Sect. 2.1.1), respectively.

Figure 4. As Figure 3 but for relative humidity at 700 hPa (%) and mean relative humidity between 850–500 hPa.

Figure 5. As Figure 3 but for CAPE. The ERA5 CAPE variable uses the parcel with the highest CAPE considering different departure levels below 350 hPa.

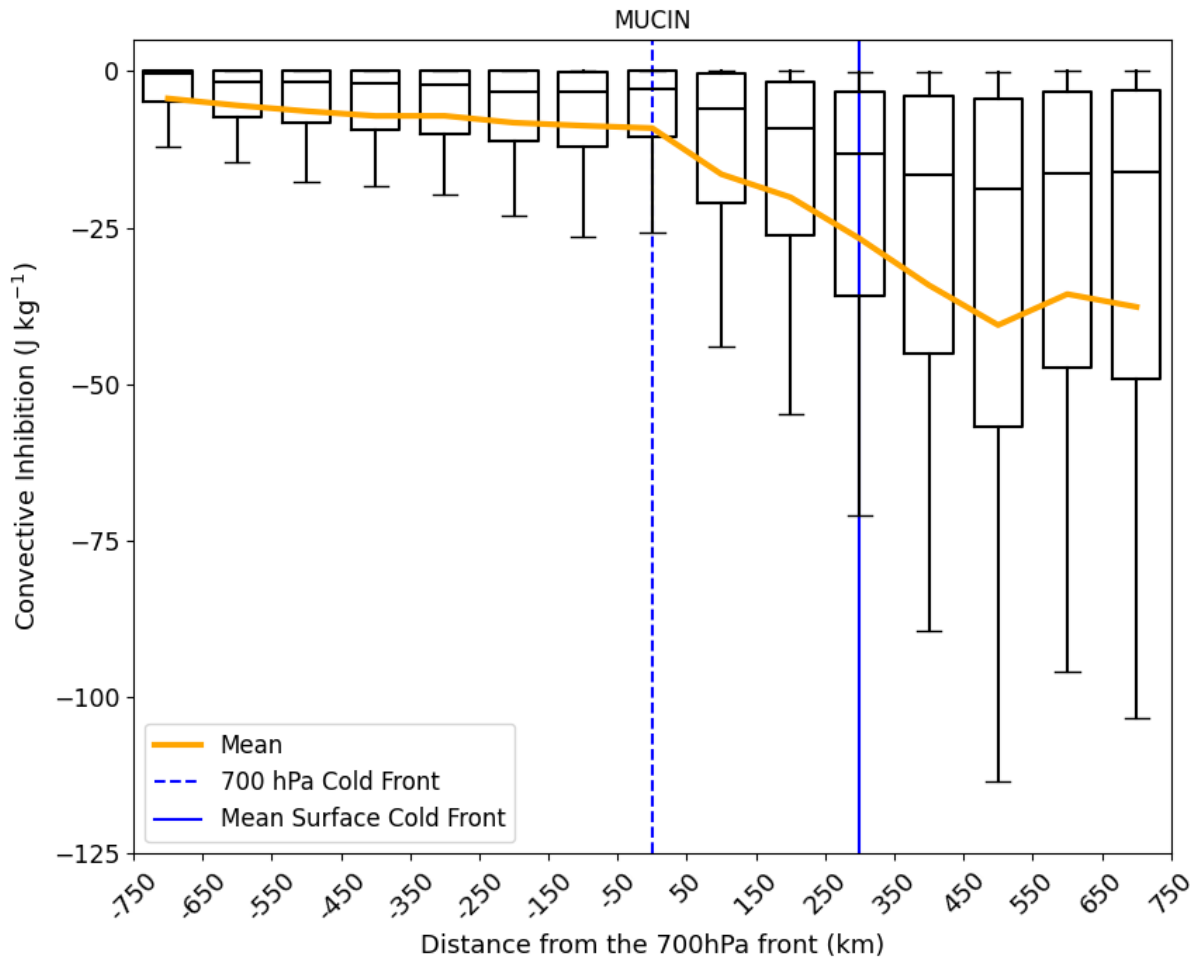

Figure 6. Most unstable CIN (MUCIN) for convective cell grid points only. The whiskers represent the 10th and 90th percentiles, the median is represented by the horizontal black line and the mean by the orange line.

Figure 7. As Figure 3 but for Q-vector convergence at 850 hPa, 700 hPa and 500 hPa (left to right). Positive and negative values indicate convergence (ascending motion) and divergence (descending motion) of the Q-vector, respectively. Q-vectors are derived using the methodology described in Sect. 2.4.

Figure 8. As Figure 3 but for vertical velocity at 850, 700 and 500 hPa. Positive and negative values indicate ascending and descending motion respectively.

Figure 9. As Figure 3 but for total incoming solar radiation (W m^{-2}) only using timesteps between 09–18 UTC.

Figure 10. As Figure 3 but for wind shear between the surface and 500 hPa.

Figure 11. As Figure 6, but for bulk wind shear between the surface and 6 km AGL. Only convective cell grid points are shown.

Figure 12. As Figure 3 but for large-scale precipitation and convective precipitation.

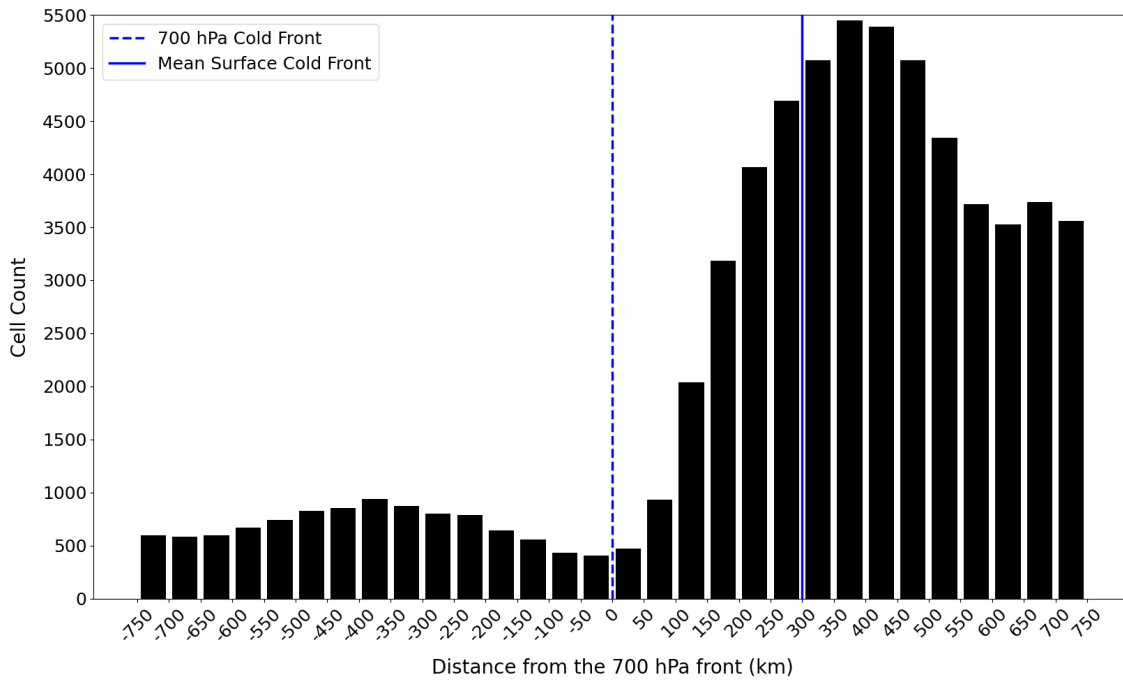

Figure 13. Convective cell frequency depending on the distance from the 700 hPa front (adapted Figure 5a from Pacey et al., 2023).

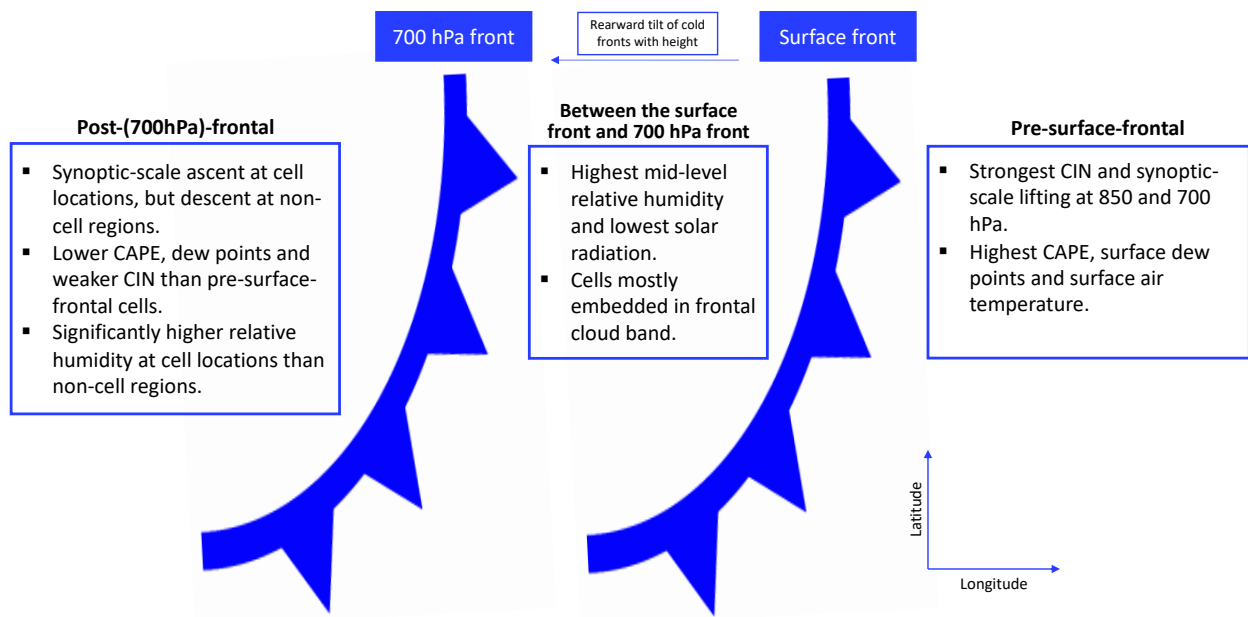

Figure 14. Overview of convective cell environments and lifting mechanisms at three front relative regions: post-700-frontal, between the 700 hPa and surface front, and pre-surface-frontal.

Table 1. Definitions of front relative regions.

Terminology	Definition
Post-700-frontal	behind (on the cold-side of) the 700 hPa front
Near-700-frontal	within 50 km of the 700 hPa frontal line
Pre-700-frontal	ahead (on the warm-side) of the 700 hPa front (includes pre-surface-frontal region)
Pre-surface-frontal	300 km or more ahead of the 700 hPa front (ahead of the surface front)

Table 2. A list of variables analysed in this study and the associated level and dataset.

Variable	Level	Dataset	Units
Dewpoint temperature	2-metres above ground level	ERA5	°C
Air temperature	2-metres above ground level	ERA5	°C
Relative Humidity	700 hPa, 850–500 hPa average	ERA5	%
CAPE ¹	single level	ERA5	J kg ⁻¹
Convective Inhibition (CIN)	different departure levels	ERA5 ²	J kg ⁻¹
Q-vector convergence	850 hPa, 700 hPa, 500 hPa	ERA5	m ² kg ⁻¹ s ⁻¹
Vertical Velocity	850 hPa, 700 hPa, 500 hPa	ERA5	m s ⁻¹
Total incoming solar radiation	surface	ERA5	W m ⁻²
Sunshine duration	surface	DWD Station Data	minutes
Vertical Wind Shear	surface-500 hPa, 0–3 km, 0–6 km AGL ³	ERA5	m s ⁻¹
Large-scale precipitation	surface	ERA5	mm hr ⁻¹
Convective precipitation	surface	ERA5	mm hr ⁻¹
Total and high cloud cover	single level	ERA5	%

¹The ERA5 CAPE parameter downloaded from the Copernicus Climate Data Store (Hersbach et al., 2018b) is used. CAPE is derived considering parcels departing from different model levels below the 350 hPa level and the departure level with the highest CAPE is retained. In essence, the ERA5 CAPE parameter is the Most Unstable CAPE (MUCAPE).

²The data source and methods to calculate CIN are shown in Sect. 2.4.1.

³Above ground level (AGL).
