### Abstract

25 Shallow convection plays an important role in Earth's climate system by regulating the vertical transport of heat, moisture,  
and momentum in the lower troposphere. Aerosols, large-scale meteorology, and low-level convergence influence the  
spatiotemporal variability of shallow convection, and the coastal urban area of Houston, Texas is an ideal laboratory to  
investigate these complex interactions. Here, geostationary satellite and ground-based radar observations from June to  
30 September 2022 during the TRacking Aerosol Convection interactions ExpeRiment (TRACER) and Experiment of Sea Breeze  
Convection, Aerosols, Precipitation, and Environment (ESCAPE) field campaigns are used to characterize the spatial coverage,  
vertical extent and precipitation fraction of shallow convective clouds. The fused operational remote sensing datasets over a  
250x250 km domain are evaluated against profiling observations. The domain-wide diurnal shallow cloud fractions are used  
to identify four distinct modes of shallow convection. In all clusters, the domain-wide cloud fractions are consistently higher  
35 than the domain-wide precipitation fractions, and shallow cloud fractions are higher over water than they are over land while  
the shallow precipitation fractions show the opposite behavior. In the two modes with minimal deep cloud activity, shallow  
cloud frequency is highest over ocean in the early morning, and there is a transition to higher shallow cloud frequency over  
land by the afternoon in one cluster or to high shallow cloud frequencies everywhere by the afternoon in the other. Lastly, we  
find regions with higher shallow cloud top heights and a large region along the coastline where shallow clouds are more likely  
40 to precipitate.

### Short Summary

Convective clouds are a key component of the climate system. Using remote sensing observations during two field experiments  
45 in Houston, Texas, we identify four diurnal patterns of shallow convective clouds. We find areas more frequently experiencing  
shallow convective clouds, and we find areas where the vertical extent of shallow convective clouds is higher and where they  
are more likely to precipitate. This provides insight into the complicated environment that forms these clouds in Houston.

1 Introduction

Atmospheric convection is a fundamental mechanism for the vertical transport of heat, moisture, and momentum in the troposphere, significantly impacting the large-scale atmospheric circulation and local environment. Convection also modulates cloudiness, which further influences large-scale atmospheric circulations (Hartmann et al., 1984; Su et al., 2014; Sherwood et al., 2014). Several factors contribute to the formation, evolution, and dissipation of convective clouds, including aerosols, large-scale meteorology, and boundary layer organization (Rosenfeld et al., 2006; Rosenfeld et al., 2008; Fan et al., 2013; Varble, 2018; Lebo, 2018; Wilson and Schreiber, 1986). A coastal urban area like Houston, Texas is an excellent place to observe all of the complicated interactions between convection, aerosols, large-scale meteorology, and convergence zones (Jensen et al., 2022). In particular, the Houston region is warm and humid in the summer and commonly experiences onshore flow and sea breeze-forced convection (Fridlind et al., 2019), which interacts with a range of aerosol conditions associated with the city’s urban and industrial emissions. This argument was initially put forward by the Aerosols, Clouds, Precipitation, and Climate (ACPC) work group, a joint initiative of the International Geosphere-Biosphere Programme and the World Climate Research Programme (Quaas et al., 2015). This effort led to the organization of two large field experiments in the Houston area during the 2022 summer period. The National Science Foundation (NSF) sponsored the experiment titled “Experiment of Sea Breeze Convection, Aerosols, Precipitation, and Environment” (ESCAPE; Kollias et al., 2024), which took place between 30 May – 30 September 2022. ESCAPE aimed to characterize the lifecycles of convective cloud dynamics in a coastal urban environment with prominent aerosol sources (Jensen et al., 2022). It coincided with the same four-month Intensive Observation Period (IOP) of the United States Department of Energy (DOE) Atmospheric Radiation Measurement (ARM)-funded “TRacking Aerosol Convection interactions ExpeRiment” (TRACER; Jensen et al., 2022) field campaign. TRACER focused on quantifying the impact of aerosols on convective clouds properties such as updraft strength, microphysical properties, and cloud and precipitation coverage.

There is growing body of observational work coming from these field experiments. During TRACER, Wang et al. (2024) identified 46 sea breeze events and the anticyclonic synoptic conditions that favor their development; they found that these events induce updrafts in the boundary layer which likely promote the formation of isolated deep convective precipitating cores that have short lifetimes and mostly exist near the coast. Similarly, Sharma et al. (2024) quantified the impact of airmass heterogeneity across sea- and bay-breeze fronts on 15 IOP days’ worth of shallow and transitioning convective clouds, and they showed that airmass heterogeneity has a more noticeable impact on the bulk microphysical properties of their shallow cloud sample. Finally, Bruning et al. (2024) tracked the radar and lightning characteristics of ~7500 thunderstorms during the period, and they showed that storms with lightning had more pronounced polarimetric signatures, showcasing lightning as a useful tool for understanding mixed-phase precipitation processes in the region.

**Deleted:** Convective clouds are also the source of extreme weather, and several studies have shown that as the climate warms in the future, an increase in the occurrence of extreme precipitation and severe weather associated with convection is anticipated (Trapp et al., 2009; Diffenbaugh et al., 2013; Sillman et al., 2013; Seeley and Roms, 2015).

**Deleted:** ¶  
The goal of these field campaigns was to collect high spatial and temporal resolution observations of convective clouds in the region under a wide array of complicated environmental conditions (i.e., clean and polluted aerosol regimes, sea breeze events, urban dynamics, etc.). In Houston, a combination of urban emissions from a city of 7 million people, coupled with emissions from extensive petroleum refining and chemical manufacturing, creates unique aerosol conditions that could influence cloud properties and lifecycles (Lebo, 2018). Houston also has frequent sea breeze circulations with two bay breeze circulations as well (Kocen, 2013). Another consideration to be made is how the urban environment itself influences clouds, precipitation, and the sea breeze circulation. Simpson et al. (2008) showed that Chennai, India impacted the local sea breeze circulation’s propagation and precipitation totals by increasing the near surface air temperature over the city in the early morning hours. Specifically in Houston, Chen et al. (2011) showed that the land surface could modify the sea and bay breeze circulations as they show soil moisture, sea surface temperature, and the urban landscape modify the stagnation of the circulations. Houston may also affect clouds and precipitation by changing surface fluxes, surface roughness, and production of aerosols (Rozoff et al., 2003; Shepherd, 2005; van den Heever and Cotton, 2007). The change in surface roughness from rural to urban areas may strengthen convective forcing (Changnon et al., 1981; Bornstein and Lin, 2000; Thielen et al., 2000). The urban heat island of a city provides surface heating that will impact convective instability and inhibition while also inducing circulations near the surface that will foster cloud growth (Shepherd et al., 2002; Shepherd and Burian, 2003). Long-term radar observations have been used to show urban impacts on convective initiation, rainfall, lifetime, and other convective properties (Ashley et al., 2012; Ganeshan et al., 2013; Hablerie et al., 2015; Kingfield et al., 2018). Lastly, Ganeshan et al. (2013) showed that the interaction between the urban heat island and sea breeze circulations increased the frequency and intensity of positive rainfall anomalies.

135 A study focusing on a large sample of warm-phase (shallow) convective properties would greatly complement the results of  
these recent studies. Shallow cumulus clouds are the most frequently observed cloud type in the Houston area compared to  
deep convective clouds (Tuftedal et al., 2024). While most of the previous studies focused on deep convection in this area,  
precipitation from shallow convection is non-negligible in terms of the total precipitation in the area (Kumar et al., 2013a;  
Kumar et al., 2013b). Especially in humid environments, even shallow convective clouds can produce heavy precipitation with  
140 comparable radar reflectivities to deep convection (May and Ballinger, 2007; Oue et al., 2010). Furthermore, shallow  
convection can modulate the lower atmosphere by moistening it, which favors the subsequent development of deep convection  
(Sherwood and Wahrlich, 1999; Derbyshire et al. 2004; Mapes et al., 2006; Holloway and Neelin, 2009; Nuijens et al., 2009;  
Powell and Houze, 2013). Aerosol-cloud interactions on shallow convective clouds have been studied since the 1970s. While  
they have established the impact of aerosols on droplet number concentrations and sizes (e.g., Twomey, 1974; Lohmann and  
145 Feichter, 2005), much less has been reported in terms of invigoration (depicted as deepening of the shallow cloud layer) or  
precipitation modulation. Thus, it is not well understood what environments, including meteorological, aerosol, and  
geographical conditions, control the early growth stage of convective clouds.

150 In this paper, operational satellite and weather radar datasets are combined to provide a large statistical sample of clouds and  
precipitation (both shallow and deep) over the Houston area during the four-month ESCAPE and TRACER period. Daily  
statistics are used to infer the different spatiotemporal patterns, and comparisons over land and ocean are used to further  
elucidate the relationships between clouds, precipitation, surface properties and meteorology. The main objective of this paper  
is therefore to characterize the spatiotemporal variability of shallow clouds and their associated precipitation patterns. Four  
main properties of shallow cloudiness will be evaluated: domain fraction, frequency of occurrence, cloud top height, and cloud-  
155 to-precipitation ratio.

## 2 Data

### 2.1 DOE ARM observations

160 During the TRACER field campaign, the DOE ARM program deployed the first ARM Mobile Facility (AMF1) at LaPorte  
Municipal Airport, located 35 km east of the Houston downtown area [29° 40' 12" N, -95° 3' 32.4" E]. The AMF1 operates a  
comprehensive suite of active and passive remote sensors that can provide continuous, high spatiotemporal resolution  
information about aerosols, clouds, precipitation, and radiation in the atmosphere above and around the AMF1 location. For  
165 example, the Parsivel2 laser disdrometer at the AMF1 measures particle size distribution over the range of 0.06 - 24 mm and  
classifies precipitation type (warm and cold season) using the precipitation rate (Bartholomew, 2020). Precipitation type and  
rate are used here (Wang and Shi, 2021). In addition, frequent radiosonde launches were performed at the AMF1. The  
TRACER campaign followed a radiosonde launch schedule of four per day every six hours (approximately 0:00, 6:00, 12:00,

**Deleted:** Here, we focus on the characterization of the spatiotemporal variability of shallow clouds and associated precipitation. The main objective is to characterize the control of meteorology and aerosols on the early growth stage of shallow convective clouds. Three main properties of shallow cloudiness will be evaluated: cloud fraction, cloud top height, and precipitation fraction. Over the four-month IOPs of the ESCAPE and TRACER field campaigns, ...

190 and 18:00 UTC), but this schedule varied slightly on “enhanced sounding days” with forecasted deep convection. On these days, an additional radiosonde was launched at approximately 21:00 UTC to better capture rapid daytime development of the atmospheric thermodynamic structure (Jensen et al., 2019). Vertical profiles of atmospheric state variables like pressure, temperature, relative humidity, wind speed, and wind direction collected by the radiosondes are used here (Burk, 2021).

195 Value-added products (VAPs), which provide post-processed data from the suite of instruments at AMF1, are also available. The Active Remote Sensing of Clouds (ARSCL; Clothiaux et al., 2001; Kollias et al., 2016) VAP combines profiling mm-wavelength radar and lidar observations to estimate a feature mask that includes the moments of the Doppler spectrum and cloud boundary estimates from laser ceilometers and Micropulse Lidars (MPLs). The Ka-band Zenith-pointing Radar (KAZR; Kollias et al., 2020b) is the profiling mm-wavelength radar operating at the AMF1 during TRACER, and it has a vertical resolution of 30m and a temporal resolution of 2 s. The KAZR radar reflectivity and cloud base height estimate from ARSCL are used here (Johnson et al., 2021).

**Deleted:** radar Doppler moments

**Deleted:** Similarly, the INTERPSONDE VAP provides sounding profiles transformed onto a uniform time-height grid with 1-minute time resolution and 332 height levels up to 40 km, which counteracts the relatively lower time resolution schedule of four launches per day. The relative humidity and wind direction as a function of time and height are used here (Jensen et al., 2021).

2.2 KHGX WSR-88D Observations

205 The Next Generation Weather Radar (NEXRAD) network, a joint effort between the United States Departments of Commerce, Defense, and Transportation (Crum and Alberty, 1993), operates about 160 S-band Doppler dual-polarization radars across the country to provide consistent, high-resolution surveillance of weather phenomena for meteorologists and decision makers. These radars have a range resolution of 250 m, an azimuthal resolution of 1°, and, depending on the Volume Coverage Pattern (VCP), a range of temporal resolutions from 4 to 10 minutes (Federal Meteorological Handbook No. 11, Part A, 2011). The Weather Surveillance Radar-1988 Doppler (WSR-88D) system responsible for monitoring the Houston, Texas and Galveston, Texas metropolitan areas is located 35 m above mean sea level in Dickinson, Texas at 29° 28' 18.84" N, 95° 04' 43.82" W, (Federal Meteorological Handbook No. 11, Part A, 2011). It is given the identifier KHGX. KHGX operated in clear air mode, using VCPs 31, 32, and 35, and in precipitation mode, using VCPs 21, 212, and 215, in the four months of interest.

**Deleted:** -

**Deleted:** E

**Deleted:** , and it is located 35 m above mean sea level

215 During the TRACER and ESCAPE IOPs, the KHGX observations were processed in real time to support the operation of the Multisensor Agile Adaptive Sampling (MAAS; Kollias et al., 2020a; Lamer et al., 2023) algorithm implanted in the second-generation C-band scanning ARM precipitation radar (CSAPR2; Kollias et al. 2020b) and the Colorado State University C-band Hydrological Instrument for Volumetric Observation (CHIVO) radar to conduct convective cell tracking (Lamer et al., 2023; Kollias et al., 2024). The three-dimensional KHGX data (two dimensions in azimuth and one dimension in elevation) were first quality-controlled for nonmeteorological echoes and then interpolated onto a horizontal Cartesian grid for comparison with satellite data. These gridded and masked data were then used to construct a 1.5 km above ground level (AGL) constant-altitude plan position indicator (CAPPI; Douglas, 1990) and a map of vertically-integrated liquid (VIL) in the domain. VIL is estimated using the Marshall-Palmer drop size distribution (Marshall and Palmer, 1948) assumptions:

**Deleted:** WSR-88D

**Deleted:** two mechanically scanning radars

**Deleted:** provide

$$VIL = \sum_{i=0}^{top} 3.44 \times 10^{-6} \left[ \frac{Z_i + Z_{i+1}}{2} \right]^{4/7} \Delta h$$

where  $Z$  stands for radar reflectivity (in dBZ) and  $\Delta h$  stands for the depth of the layer between consecutive grid levels (in m). More specific details on these processes can be found in Lamer et al. (2023). For this study, we use the KHGX CAPPI, VIL, and three-dimensional data.

### 2.3 GOES-R ABI Observations

The Geostationary Operational Environmental Satellite - R Series (GOES-R) is the National Oceanic and Atmospheric Administration's (NOAA) latest generation of satellites, providing users with continuous, high-resolution data to assist with weather forecasting, storm tracking, and atmospheric research (Geostationary Operational Environmental Satellite-R Series, 2019). The Advanced Baseline Imager (ABI) is one of the key instruments on GOES-R and provides radiance data in 16 spectral bands/channels ranging from the visible part of the electromagnetic spectrum to the near-infrared and the infrared. Of interest here, Channel 2 sits in the wavelength range of 0.59-0.69  $\mu\text{m}$ , has an instantaneous field of view (IFOV) of 0.5 km, and has a temporal resolution of 5 minutes (Schmit et al., 2005; Schmit et al., 2018), which is useful for studying fog, anvils, cumulus clouds, and ice/snow cover amongst phenomena. Channel 13 sits in the wavelength range of 10.1-10.6  $\mu\text{m}$ , has an IFOV of 2 km, and has a temporal resolution of 5 minutes (Schmit et al., 2005; Schmit et al., 2018), and it is useful for studying atmospheric moisture, performing cloud identification and classification, estimating cloud top temperature and particle size, and characterizing surface properties (Lindsey et al., 2012). Specifically, this study uses the reflectance data from Channel 2 to identify cloud presence and the brightness temperature data from Channel 13 to identify cloud phase.

The ABI Cloud Mask (hereafter ACM) product combines nine of the 16 bands to provide a binary classification of "cloudy" or "clear" for each pixel using spectral, spatial, and temporal signatures and has a horizontal resolution of 2 km and a temporal resolution of 5 minutes (Heidinger and Straka III, 2013). We make use of the four-level version of the mask which provides a classification of "cloudy", "probably cloudy", "probably clear", or "clear" for each pixel.

### 2.4 HRRR data

The High-Resolution Rapid Refresh (HRRR; James and Benjamin, 2017; Dowell et al., 2022; James et al., 2022) is run by NOAA/National Centers for Environmental Prediction (NCEP), and it is the convection-allowing implementation of the Advanced Research version of the Weather Research and Forecasting (WRF-ARW; Skamarock et al., 2019) Model. HRRR has 3 km spatial resolution and 51 vertical levels, hourly data assimilation, and hourly forecasts for the continental United States. Boundary conditions are provided by the Rapid Refresh system. We acquired the hourly HRRR files using the Herbie

285 **3 Methodology**

**3.1 Observational domain**

290 The analysis domain size is 250 km x 250 km, centered at KHGX. In terms of spatial extent, the southwestern-most point of the domain is 28° 20' 35.8794" N, 96° 21' 16.56" W, and the northeastern-most point of the domain is 30° 35' 17.16" N, 93° 46' 31.08" W. Figure 1a shows the domain, with the KHGX site located southeast of the city of Houston and the AMF1 located northeast of the radar location and southeast of the city. The KHGX and GOES-R data are gridded onto a horizontal Cartesian grid using a KD-Tree interpolation algorithm at a 500-m grid spacing (Bentley, 1975).

295 An important methodology step is to consider limitations of the operational GOES-R and KHGX observations that will affect the cloud and precipitation analysis. A preliminary perusal of the GOES-R ABI Cloud Mask (ACM) indicated a noticeable suppression of cloud detections in the grid points around the coastline of Houston compared to the surrounding areas. The surface properties (reflectance and emissivity) play a key role in the ACM performance, and this affects the ACM statistics in the areas where there is surface type transition (i.e. water to land) near the coastlines and water bodies over land. As a result,

300 the grid points that correspond to these areas (white areas in Figure 1a) are ignored in further analysis of the GOES-R observations. Overall, 135,994 (87.5%) of the land grid points and 81,202 (85.9%) of the water grid points are used here. The coverage, resolution and sensitivity of the KHGX observations depend on distance from the radar (Kollias et al., 2022). As a result, the 1.5 km CAPPIs show artifacts generated by the fact that only one elevation angle (the lowest) provided coverage at this height AGL. Thus, we have limited the KHGX analysis to the region within the 225 km diameter range ring (Fig. 1b).

305 Overall, 102,490 (65.9%) of the land grid points and 56,311 (59.6%) of the water grid points are used here.

**3.2 Comparison of KHGX WSR-88D, GOES-R ABI, and DOE ARM observations**

The study of the cloud and precipitation spatiotemporal patterns presented in this study is based on the KHGX and GOES-R sensor fusion. The AMF1 provides a unique opportunity to evaluate the ability of the GOES-R ACM to detect clouds and the ability of the KHGX to detect light precipitation. Previous studies have assessed the cloud mask's skill using other satellite measurements (Jimenez, 2020; McHardy et al., 2022), but, to our knowledge, a verification using ground-based measurements has never been conducted. An example of collocated KHGX, GOES-R and ARM observations is shown in Figure 2. Figure 2 shows a time-height plot of KHGX observations over the AMF1 location using KHGX radar reflectivity data collected at different elevation angles. The ARSCL cloud layer boundaries and the KAZR radar reflectivity are shown in Figure 2b. Finally,

the corresponding GOES-R ABI reflectance data from Channel 2 and the brightness temperature data from Channel 13 are shown in Figure 2c.

Between 0 and 6 LT on 23 July 2022, the GOES-R ACM accurately reports the presence of thin cirrus clouds identified in the ARSCL data (Fig. 2b). The cirrus clouds' low radar reflectivity and high altitude make them impossible to be detected with the KHGX WSR-88D due to the radar's limited sensitivity and the limit in the maximum height of the radar observations (dashed line in Fig. 2a) imposed by the maximum elevation angle of the radar and its distance from the AMF1 site. Overall, there is good correspondence, in terms of cloud presence and duration, between the ACM and the cloud/precipitation and clear conditions as captured by KHGX and ARSCL observations. The 'cloudy' periods show increases in radar reflectivity in both radars, increases in reflectance, and decreases in brightness temperature (Fig. 2). The comparison between KAZR and KHGX also shows the value a WSR-88D can provide in representing a cumulus cloud's morphology (width, cloud top height, etc.) despite its usage for operational surveillance. A more comprehensive assessment of the ACM is provided in Appendix A.

A notable feature in Figure 2a is the radar reflectivity echoes present in the lowest 3 km during 0 – 3 LT and 21-23 LT; these are nonmeteorological echoes associated most likely with biological activity. It is important to consider that WSR-88Ds are sensitive not only to hydrometeors (precipitation) but also Bragg scattering and insects (Melnikov et al., 2011). There is also a consistent presence of radar reflectivity echoes in the lowest 1 km throughout the day due to ground clutter. Although not a perfect one-for-one comparison, the ARSCL data do not show these features and certainly do not have any strong precipitation echoes at the times noted (Fig. 2b), so despite the vigorous quality control done in Lamer et al. (2023), some nonmeteorological echoes made it into the dataset. To ensure we are examining hydrometeors only, we use a VIL threshold of 0.1 kg m<sup>-2</sup> throughout the study, as used in Lamer et al. (2023).

We then use the AMF1 measurements to determine the lowest KHGX radar reflectivity value applicable across the domain to detect the presence of precipitation in cumulus clouds. The AMF1 surface disdrometer observations over the four-month IOP are used to characterize the precipitation types and their frequency of occurrence at the observatory. Measured surface precipitation, which includes all weather codes associated with drizzle and rain, is observed 2.26% of the time (not shown). To compare, the KHGX 1.5 km CAPPI radar reflectivity values over the AMF1 site are used to estimate the frequencies of individual radar reflectivity values, and we find that the most frequently occurring radar reflectivity values over the site are between 10 and 30 dBZ (Fig. 3a). We also calculate the cumulative frequency of occurrence of radar reflectivity thresholds between -10 dBZ and 60 dBZ, meaning we calculate the frequency with which values greater than a threshold on the x-axis occur during the period (Fig. 3b). We find that a KHGX 1.5 CAPPI radar reflectivity threshold of 7.5 dBZ matches the frequency of occurrence of measured surface precipitation by the disdrometer at AMF1. The 7.5 dBZ radar reflectivity threshold is subsequently used to derive the diurnal variability of precipitation over the AMF1 site, and it is compared to the

380 diurnal variability of precipitation by the AMF1 disdrometer (Fig. 3c). They show strong agreement and both measure the maximum occurrences between 12 and 18 LT and the secondary maxima in late evening and early morning hours (Fig. 3c).

One final consideration is that KHGX's sensitivity is inversely proportional to the square of the radar range. Before using the 7.5 dBZ radar reflectivity threshold, we confirm that it is above KHGX's minimum detectable signal at far ranges (as depicted in the 1.5 km AGL CAPPI data) and that it is above any Bragg scattering returns. At the furthest range considered in this study (~176 km from KHGX), the minimum detectable signal is -5 dBZ, so our threshold is applicable. This means, using the conversion of the KHGX radar reflectivity to rainfall rate (R) in this climatological regime provided by the National Weather Service ( $R = 300Z^{1.4}$ ; Battan, 1973), we detect rainfall rates as low as  $0.058 \text{ mm hr}^{-1}$  in our domain. So, for the rest of our analysis, the pixels in our KHGX dataset must exceed a 1.5 km CAPPI radar reflectivity of 7.5 dBZ and a VIL of  $0.1 \text{ kg m}^{-2}$  to be classified as precipitation.

### 3.3 Shallow and deep cloud/precipitation classification

An example of the cloud and precipitation classification during an ESCAPE aircraft IOP on 2 June 2022 at 11:22:36 LT is shown in Figure 4. The GOES-R ACM data are used to define clear and cloudy conditions (Fig. 4b). The GOES-R Channel 13 brightness temperature data ( $T_{B13}$ ) in Fig. 4a show widespread shallow cloudiness across the domain, except a small region south and east of Galveston Bay where colder  $T_{B13}$  are observed. The  $T_{B13}$  are used to further classify the clouds identified in the GOES-R ACM data as warm phase only if  $T_{B13} > -5^\circ\text{C}$ , in which it is reasonable to assume there is no ice present, and as mixed-phase only if  $T_{B13} < -5^\circ\text{C}$ . The cloud top height and temperature are strongly related; thus, the warm phase only clouds are hereafter called shallow convection and the mixed-phase clouds are called deep convection (Figs. 4c-d). In addition, the gridded KHGX CAPPI data are used to classify the detected clouds as precipitating or not (Fig. 4f-h). We use the radar reflectivity and VIL thresholds described above, and we classify each pixel as shallow or deep by comparing the highest KHGX echo top height at that pixel to the median height of the  $-5^\circ\text{C}$  level (5.79 km; not shown) derived from the AMF1 soundings, where a radar echo top height less than 5.79 km is shallow and greater than 5.79 km is deep. At this instance in time, the shallow clouds over the Gulf (Fig. 4c) are not precipitating (Fig. 4g) from the radar's perspective, while more of the shallow clouds along the coastline and over land are in fact precipitating. There is a prominent cold top feature east of Galveston Bay (Fig. 4d) with some deep precipitation associated with it (Fig. 4h). Otherwise, this instance in time is defined by more shallow cloud and precipitation features, with abundant activity along the coastline.

410 An important consideration for this approach is that the satellite will report the brightness temperature of the coldest (highest) feature at that pixel. This means that a deep cloud pixel could be a cirrus cloud, an anvil, or a deep convective cumulus cloud, and we do not any sort of classification. These features may also obscure shallow clouds beneath them, leading to an underrepresentation of shallow clouds in environments with deep cloud activity. In the subsequent analysis, we report all

Deleted: The KHGX 1.5 km CAPPI radar reflectivity values over the AMF1 site are used to estimate the cumulative distribution of KHGX radar reflectivity values between -10 dBZ and 60 dBZ (Fig. 3a). Using the cumulative distribution of KHGX values over the AMF1 site, a radar reflectivity threshold of 17 dBZ, where the frequency of occurrence of KHGX radar reflectivity values and the frequency of occurrence of precipitation at the AMF1 (2.2%) as depicted by the disdrometer match, is identified (Fig. 3a). The 17 dBZ radar reflectivity threshold is subsequently used to derive the diurnal variability of precipitation over the AMF1 site, and it is compared to the diurnal variability of precipitation by the AMF1 disdrometer (Fig. 3b). Both have similar timing for the local maxima overnight and early in the morning and the absolute maximum in the late afternoon, and the magnitudes are similar, although the WSR-88D has more frequent precipitation at 21 Local Time (LT) and the disdrometer has more frequent precipitation at 13 LT and 15 LT.¶

Deleted: ¶

The 17 dBZ KHGX radar reflectivity threshold is suitable for matching the performance of a surface disdrometer to characterize precipitation across the entire analysis domain. Furthermore, the 17 dBZ is well-above the minimum detectable signal of the KHGX radar across the analysis domain. However, the disdrometer only accounts for precipitation that reaches the surface and is above its detection limit ( $\sim 0.1 \text{ mmhr}^{-1}$ ; Angulo-Martinez, 2018). To account for lighter precipitation that does not reach the surface (i.e., virga) or is below the rainfall rate detection limit of the disdrometer, th ... [1]

shallow and deep cloud activity, but we will eventually focus on periods with minimal deep cloud activity to avoid underrepresenting the shallow clouds we are scientifically interested in.

#### 4 Results

##### 4.1 Domain-averaged diurnal cycle of clouds and precipitation

The gridded KHGX radar and GOES-R data products are used to estimate the fraction of the analysis domain covered by warm (shallow) and cold (deep) cloud tops. We calculate the number of shallow cloud, deep cloud, shallow precipitation, and deep precipitation pixels and divide by the total number of pixels in the domain used for each instrument. The domain-average fractions are estimated approximately every five minutes, and their median value within an hour is used to derive the diurnal variability of shallow and deep clouds throughout the four-month TRACER and ESCAPE IOP period (Fig. 5). The maximum hourly median shallow cloud fraction in the dataset is 84.2% at 9 LT on 8 June; meanwhile, the maximum hourly median deep cloud fraction in the dataset is 100% at 15 LT on 4 September. Of the 121 days that are not missing data, 37 have their maximum hourly median shallow cloud fraction occur between 0-5 LT, 13 have their maximum occur between 6-11 LT, 31 have their maximum occur between 12-17 LT, and 40 have their maximum occur between 18-23 LT. Similarly, of the 112 days that are not missing data and that have hourly median deep cloud fractions above 0% all day, 19 have their maximum hourly median shallow cloud fraction occur between 0-5 LT, 12 have their maximum occur between 6-11 LT, 44 have their maximum occur between 12-17 LT, and 37 have their maximum occur between 18-23 LT. Indicated by these statistics, the morning hours of 6-11 LT experience the maximum hourly median shallow and deep cloud fractions least frequently, and the maximum hourly median shallow cloud fraction occurs most frequently in the evening while the maximum hourly median deep cloud fraction occurs most frequently in the afternoon. Overall, the domain-averaged fractional coverage of shallow clouds indicates that they are more frequently observed than deep clouds in the domain throughout the period. The domain-averaged shallow cloud fraction is always above 0% while nine days have no observable deep clouds in the domain. Likewise, the maximum hourly median shallow cloud fraction is below 5% only in four days, including one day in July and three days in September (Fig. 5a), whereas there are 28 days when the maximum hourly median deep cloud fraction is below 5%, including six in June, seven in July, and 16 in September (Fig. 5b). August has the most widespread shallow and deep cloud activity, with 22 days and 17 days, respectively, having maximum hourly median cloud fractions exceeding 50%. July has the fewest days where the maximum hourly median deep cloud fraction exceeds 50% (4 days) while September has the fewest days where the maximum daily median shallow cloud fraction exceeds 50% (5 days).

The diurnal variability of the domain-averaged shallow and deep precipitation is estimated as well (Fig. 6). The maximum hourly median shallow precipitation fraction in the dataset is 9.3% at 15 LT on 15 July; meanwhile, the maximum hourly median deep precipitation fraction in the dataset is 63.7% at 17 LT on 3 September. Of the 110 days that are not missing data

and that have hourly median shallow precipitation fractions above 0% all day, 19 have their maximum hourly median shallow precipitation fraction occur between 0-5 LT, 36 have their maximum occur between 6-11 LT, 42 have their maximum occur between 12-17 LT, and 13 have their maximum occur between 18-23 LT. Similarly, of the 95 days that are not missing data and that have hourly median deep precipitation fractions above 0% all day, 9 have their maximum hourly median shallow precipitation fraction occur between 0-5 LT, 16 have their maximum occur between 6-11 LT, 54 have their maximum occur between 12-17 LT, and 16 have their maximum occur between 18-23 LT. Of the four variables thus far, the maximum hourly median deep precipitation fraction shows the strongest preference for a period of the day (12-17 LT), and the maximum hourly median shallow precipitation fraction occurs most frequently then, too. Overall, the precipitation activity is less widespread than the cloud activity. For 68 days (more than half of the total days), the maximum hourly median shallow precipitation fraction never exceeds 5%, which includes 27 days in June, 26 days in July, 11 days in August, and four days in September. Similarly, for 81 days (two-thirds of the total days), the maximum hourly median deep precipitation fraction never exceeds 5%, which includes 24 days in June, 23 days in July, 12 days in August, and 22 days in September. Finally, the deep precipitation in general is far more widespread than the shallow precipitation, as only 7 days have maximum hourly median shallow precipitation fractions greater than 5% while 23 days and 10 days have maximum hourly median deep precipitation fractions greater than 10% and 25%, respectively.

4.2 Shallow cloud fraction variability

Due to the high variability seen in figure 5a, a k-means clustering approach (Lloyd, 1982) is applied to the our satellite-based shallow cloud data to identify the dominant diurnal modes of shallow cloudiness across the analysis domain. A principal component analysis (Pearson, 1901) of the same data indicated that the first four principal components (or modes) account for over 90% of the variability in the data. As a result, k is set to four in the k-means algorithm (Thronkike, 1953), and we use the 121 median diurnal patterns of shallow cloud fraction as the input. Each day (September 13<sup>th</sup> is not classified because of missing data) is assigned to one of four clusters. Finally, for each cluster, we identify the applicable days and calculate the median shallow cloud fraction and the shallow cloud fraction interquartile range every hour to create composite behaviors.

The diurnal variability of the four dominant modes of median shallow cloudiness and their interquartile ranges every hour for each of the four clusters is shown in Figure 7. The four modes have distinct characteristics in terms of magnitude, shape, and timing of maxima and minima. Cluster 1 (C1) is the largest with 48 days grouped in this mode. C1 represents days with the lowest amount of shallow cloudiness, with the median shallow cloud fraction never exceeding 10% (Fig. 7a). The median fraction is at its minimum at 23 LT; it then begins to grow at 4 LT and reach its maximum by 15 LT in the afternoon. The 21 days belonging to Cluster 2 (C2) have higher shallow cloud fractions and exhibit the opposite diurnal cycle compared to C1 (Fig. 7b). In C2, the median shallow cloud fraction is at its highest value at 22 LT while reaching its absolute minimum at 16 LT. In the 22 days comprising Cluster 3 (C3), the diurnal absolute maximum occurs at 2 LT, and the median shallow cloud

fraction decreases steadily for the rest of the day (Fig. 7c). Finally, the 30 days in Cluster 4 (C4) are similar to C1 in that they both experience growth starting in the morning and continuing into the afternoon, but the growth rate is much steeper in C4. The shallow cloud fraction then becomes steady from the late afternoon and on, which does not occur in C1. The median shallow cloud fraction reaches its maximum at 13 LT and then persists around that value for the rest of the day. Monthly calendars corresponding to the four months of the period and the cluster each day belongs to are shown in Appendix B.

### 4.3 Cloud and precipitation fraction variability

The diurnal variability of shallow cloudiness and associated precipitation is affected by deep convective clouds, their mesoscale organization, and their impact on boundary layer organization. Using C1-4, the diurnal analysis is expanded to include the shallow precipitation fraction and the deep cloud and precipitation fractions. Their median hourly values, as well as the interquartile ranges, for C1-4 are shown in Figure 8. C2 and C3 have significantly more fractional coverage of clouds with cold tops, and the median deep cloud fraction is above 0% all day (Figs. 8b-c). Furthermore, deep cloud fraction is higher than shallow cloud fraction between 14-19 LT in C2 and between 15-18 LT in C3. In all clusters (Figs. 8a-d), the hourly median deep cloud fraction consistently reaches its diurnal maximum in the late afternoon. The timing of the shallow and deep cloud maxima differs, however: the maximum hourly median shallow cloud fraction occurs six hours after the maximum hourly median deep cloud fraction in C2, while the maximum hourly median shallow cloud fraction occurs 14 hours earlier than the maximum hourly median deep cloud fraction in C3 (Figs. 8b-c). Meanwhile, the shallow cloud fraction in C1 and C4 begins to increase in the late morning and then the deep cloud fraction begins to increase 2-3 hours later (Figs. 8a and 8d).

The domain is covered by far less precipitation as noted before; the median shallow and deep precipitation fractions never exceed 5% regardless of the cluster (Figs. 8e-h). Comparing the cloud and precipitation data, the median deep precipitation fractions in C1, C2, and C4, like the median deep cloud fractions, attain their diurnal maxima in the late afternoon. Meanwhile, in C3, the median deep precipitation fraction reaches its maximum earlier in the day than the median deep cloud fraction does. The median shallow cloud and precipitation fractions in all four clusters do not behave similarly and therefore have different maxima timing. Lastly, like the deep cloud fractions, C2 and C3 have periods when the median deep precipitation fraction exceeds the median shallow precipitation fraction (Figs. 8f-g). C4 also has this feature in the precipitation data (Fig. 8h).

### 4.4 Land versus Ocean

About 40% and 60% of the analysis domain is covered by ocean and land, respectively. Due to the prominent sea and land breeze circulations in Houston (Kocen, 2013) and the differences in convective properties over ocean and land, we repeat the analysis for the land and ocean portions of the analysis domain (Figs. 9 and 10). There are some noticeable differences in the timing and magnitude of the median shallow cloud fraction over land and over water. C1 shows a larger maximum median

690 shallow cloud fraction occurring over water five hours earlier than the one occurring over land (Figs. 9a and 9e), and, while both profiles see their largest values in the latter half of the day, the median shallow cloud fraction over land in C4 reaches its maximum before the median shallow cloud fraction over water does (Figs. 9d and 9h). Although the timing of the maxima in the shallow cloud fractions over land and over ocean is relatively similar in C2 and C3 (Figs. 9b-c and 9f-g), the magnitudes over water are greater, meaning, across all four clusters, the median shallow cloud fraction over water is consistently greater than it is over land. On the other hand, we see that the maxima of the median deep cloud fractions over land and over water are similar in timing (a one-hour difference in C2, a two-hour difference in C3, and no difference in C4), but the magnitudes over land are higher than they are over water across all four clusters (Fig. 9). Breaking down the two surface types also allows us to see that the periods where the deep cloud fractions exceed the shallow cloud fractions in C2 and C3 from Figure 8 persist regardless of land or ocean (Figs. 9b-c and 9f-g).

700 Precipitation fractions behave differently according to surface types. The median deep precipitation fraction over water reaches its diurnal maximum before the median deep precipitation fraction over land does in C2 and C4 (Fig. 10), and the same goes for the shallow precipitation fractions in C1, C2, and C4. On the other hand, C3 indicates that the median deep and shallow precipitation fractions over land peak before they do over water (Figs. 10c and 10g). However, regardless of cluster, the maximum median deep and shallow precipitation fractions over land are higher than those over water. Also, the shallow and deep precipitation over land has a shift in timing depending on the clusters: the median shallow precipitation fraction peaks two hours before the median deep precipitation fraction in C2 (Fig. 10b), at the same time in C3 (Fig. 10c), and at the same time in C4 (Fig. 10d). Comparing the cloud and precipitation data over land and over water, there is a larger discrepancy in the timing of the maximum deep precipitation and cloud fractions over land in C3 (Fig. 9c and Fig. 10c) than there is in C2 and C4. Lastly, C1's median deep precipitation fraction over land never exceeds 0%.

715 We also calculate the diurnal cycle of the percentage of clouds and precipitation that are classified as shallow over land and over water in Clusters 1 and 4 in figure 11. Over land in C1, between 40% and 65% of clouds are shallow, with the minimum occurring at 8 LT and the maximum occurring at 13 LT, and between 20% and 55% of precipitation is shallow, with the minimum occurring at 19 LT and the maximum occurring at 6 LT (Fig. 11a). Over water in C1, the percentage of clouds that are shallow is similarly between 40% and 65%, but the minimum's and maximum's timings are reversed at 18 LT and 9 LT, respectively (Fig. 11c). The percentage of precipitation that is shallow shows far more variability over water than it does over land. Over land in C4, the percentage of clouds that are shallow is consistently higher than it is in C1, as 20 different hours feature a percentage greater than 60% in C4 compared to five different hours in C1 (Figs. 11a-b). The cloud and precipitation percentages in C4 over land also a similar diurnal pattern: a maximum attained in the morning hours between 8-11 LT followed by a steady decrease until the absolute minimum is reached after 16 LT (Fig. 11b). The precipitation percentage is also more variable over water than it is over land in C4 (Fig. 11d). Finally, a striking difference between land and water in C4 appears. The percentage of clouds that are shallow over water is steadily between 70% and 85%, and as noted already, the percentage

of clouds that are shallow over land features a large decrease between morning and late afternoon. More exactly, the percentage for clouds over land starts at 84.4% at 11 LT and reaches 50% by 18 LT; meanwhile, in that same time frame, the percentage over water starts at 77.4% and ends at 76.7%▼

#### 4.5 Meteorological variability in the clusters

▼  
Due to its high spatial resolution, we use HRRR model output to provide meteorological context for the cloud and precipitation patterns we have outlined thus far. We calculate composites of forecast hour zero 850 hPa temperature, relative humidity, and wind speed and direction at 9 LT, 13 LT, and 17 LT for each of the four clusters in Figure 12. There is a clear correlation between 850 hPa moisture and the deep cloud coverage in the cluster, as C1 and C4 feature the driest conditions at this level. The relative humidity minimum also shifts in C1 and C4 as the day progresses, starting in the northwestern part of the domain over land at 9 LT (Figs. 12a and 12d) and ending in the southwestern part of the domain over ocean at 17 LT (Figs. 12i and 12l). The opposite is true for the relative humidity maximum, which starts over the ocean in the morning and progresses over land by the late afternoon, located to the west of Houston-Galveston Bay (HGB) across all four clusters (Figs. 12i-l). The composite wind behavior across all four clusters is persistently weak (5-10 knots) onshore flow from the southeast in C1, C2 and C4 and the south/southwest in C3. The temperature gradient is oriented parallel to the coast all day in C1 and C4 which, combined with the winds and moisture, favors sea breeze conditions. Despite a perpendicular temperature gradient orientation at 9 LT in C2 and C3 (Figs. 12b and 12c), the gradient attains a parallel orientation to the coast although not as pronounced as in C1 and C4. Finally, C1 and C4 feature the highest temperatures which shows a correlation between higher (lower) 850 hPa temperatures and more shallow (mix of shallow and deep) cloud activity.▼

#### 4.6 Spatial variability in clusters 1 and 4

C1 and C4 are the most frequently occurring modes and represent atmospheric conditions with minimal to no deep clouds and precipitation. This provides an opportunity to examine the shallow clouds and precipitation present in these modes and to avoid potentially severe shallow cloud underestimation noted in the methodology, and so we will focus on these two clusters for the remainder of the study. The domain-averaged diurnal variability has indicated that influence of the land-ocean contrast is important in determining the diurnal cycle. Here, the spatial variability in these two clusters during daytime (09:00 – 19:00 LT) is investigated. At every pixel, we calculate the number of shallow cloud occurrences and divide by the number of total data points. The spatiotemporal variability of shallow cloud frequency every 2 hours from 9:00 to 19:00 LT for C1 and C4 is shown in Figure 13. In the morning at 9 LT, shallow clouds in C1 are more frequently occurring over water, and a sharp gradient in shallow cloud frequency is observed across the coastline (Fig. 13a). The maximum in shallow cloud frequency (15-20%) over the ocean during early morning hours is consistent with the diurnal variability of the oceanic shallow cloud fraction (Fig. 10e) that maximizes in early morning hours and with the location of the 850 hPa relative humidity composite maximum

**Deleted:** Some forcing mechanism over land is causing more shallow clouds to transition into deep clouds that does not exist over water. It is likely we do not see this pattern in C1 because deep cloud and precipitation activity is minimal already.

**Deleted:** f

**Deleted:** The INTERSONDE VAP, which provides 1-minute resolution profiling data of temperature, relative humidity, and wind speed and direction, is used to describe the meteorological conditions in these clusters. The median time-height cross sections of relative humidity and wind direction variables for the four clusters are shown in figure 12. All clusters show a similar diurnal cycle below 1 km: relative humidity values greater than 80% between 0-6 LT and then a steady drop until the minimum is reached in the early afternoon (Figs. 12a-d). For example, C1 has the lowest relative humidity during these afternoon hours, with a value of 54.9% at 8 m at 13 LT (Fig. 12a). At the same height, C2 reaches 67% between 11-13 LT, C3 reaches 63.5% at 11 LT, and C4 reaches 60.1% at 13 LT (Figs. 12b-d). All four clusters feature a humidity inversion between 12-18 LT, and the region of higher relative humidity (compared to the surface) exists between 1-2 km. The most noticeable difference across the clusters is the depth of the moisture layer. C1 is noticeably drier (RH < 20%) above 6 km compared to the other three clusters (Fig. 12a), and this, combined with the driest surface conditions in the afternoon, may help explain the lack of deep cloud and precipitation presence on these days. This region above 6 km is also drier in C4 compared to C2-3. Overall, C2 and C3 feature deeper moisture profiles, and there is a clear correlation between this and the larger cloud and precipitation fractions seen on these days. f

**Deleted:** f

The four clusters show a similarity near the surface in the wind direction data, too. The first nine to ten hours of the day feature a wind direction coming from the south or southwest. This persists after 11-12 LT between 1-2 km while the wind direction shifts and is coming from the southeast below 1 km (Figs. 12e-h). This veering wind profile is indicative of warm air advection, and, given the location of the AMFI (Fig. 1), a southeast wind would mix marine air from Houston – Galveston Bay (HGB) with continental air from the southwest wind above it. Like the relative humidity profiles, the upper atmosphere is where the glaring differences in the clusters appear. There are north-westerly winds above 10 km in C2-3 (Figs. 12f-g) while most of the wind directions above 4 km in C4 are coming from the east or northeast (Fig. 12h). f

**Deleted:** f

840 (Fig. 12a). Later in the day, as a convective boundary layer forms over land, shallow cloud frequency begins to increase over land. The maximum of the C1 shallow cloud fraction is observed initially near the coast and gradually shifts further inland, following the 850 hPa relative humidity composite maximum. Aided by the onshore flow we showed in Figure 12, we hypothesize that the suppression of shallow frequency near the coastline at this point of the day is due to penetration of stable marine boundary layer air. In the meantime, shallow cloud frequency over the ocean gradually decreases and reaches a minimum after 17 LT (< 5%; Figs. 13e-f).

Deleted: a

Deleted: while the

Deleted: the

Deleted: suppresses shallow cloud frequency near the coastline

850 C4 is associated with much higher shallow cloud frequency (Figs. 13g-l). In the morning at 9 LT, higher shallow cloud frequency is observed over water than over land as in C1 (Fig. 13g), which corresponds to the 850 hPa relative humidity composite maximum as in C1, too (Fig. 12d). In the transition from late morning to early afternoon (Figs. 13h-i), the contrast in shallow cloud frequency between the ocean and land disappears, and shallow cumulus fields are observed across the domain with 25-35% frequency. In C4, some noticeable spatial patterns are observed at 15 and 17 LT (Figs. 13j-k), and these patterns are not associated with the coastline and the surface type transition. Higher shallow cloud frequencies (25-40%) are observed east of HGB while, west of the HGB area, lower shallow cloud frequencies (10-25%) are observed (Figs. 13j-k). At 15 LT, the maximum shallow cloudiness is observed over land west of HGB, and, in the later afternoon and evening hours, the maximum shallow cloudiness frequency is observed over water unlike in C1 (>40%; Figs. 13k-l).

Overall, the spatiotemporal variability of the shallow clouds fractional coverage is significant. C1 represents more suppressed atmospheric conditions, and we hypothesize the land-ocean contrast and boundary layer stability likely explain most of the observed variability. C4 represents conditions that can support higher shallow cloud frequency. More complex processes and surface/atmospheric properties are responsible for the observed spatiotemporal patterns. The area east of the HGB is home to shipping lanes and most of the refineries and industrial complexes while the area west of HGB has less polluted air (Kollias et al., 2024). No comprehensive aerosol data are available that can match the spatiotemporal sampling of the operational sensors used in this study; thus, no attempt is made to correlate the shallow convective clouds properties with aerosol conditions.

Deleted: surface properties (land versus ocean)

865 The corresponding spatiotemporal variability of shallow cloud top heights every 2 hours from 9:00 to 19:00 LT for C1 and C4 is shown in Figure 14. Using the soundings launched from the AMF1 site, we convert the  $T_{B13}$  of the cloudy pixels to cloud top height, and we calculate the median cloud top height in 10 km x 10 km boxes (to enhance interpretability) every hour for each cluster. During early morning (9 LT), C1 shallow clouds have higher cloud tops (>2 km) over land (Fig. 14a). During 11 and 13 LT, the cloud top heights over land are lower than they are over ocean (Figs. 14b-c). One noticeable feature is that higher cloud top heights are observed in the area east of HGB compared to the area west of HGB. This trend persists and amplifies as we progress through the day (Figs. 14d-e). On the other hand, C1 shallow cumulus over ocean have low cloud tops (<1 km) and maintain these low cloud tops throughout the day. The higher cloud top heights east of HGB are also present in C4 (Figs. 14h-k). While shallow clouds get deeper west of the HGB in early and later afternoon (15-17 LT), the

Deleted: f

corresponding cloud top heights east of the HGB are higher (Figs. 14j-k). By 19 LT, the contrast between the sides of HGB muddies, and this is consistent in both clusters (Figs. 14f and 14l). The presence of shallow clouds with higher cloud top heights east of the HGB area is persistent and coherent in time and space while also detectable in both C1 and C4. It suggests that, in this area, shallow clouds have stronger updrafts possibly driven by surface and aerosol properties.

Finally, the combined KHGX and GOES-R cloud and precipitation data are used to estimate the spatiotemporal variability of the shallow cloud-to-precipitation ratio for C1 and C4 in Figure 15. For each 10 km x 10 km box, we divide the total number of shallow cloud occurrences (precipitating and non-precipitating) by the total number of shallow precipitation occurrences every hour for each cluster. At 9 LT in C1, shallow clouds over ocean are more likely to precipitate than their counterparts over land, but, overall, the cloud-to-rain ratios are very low (Fig. 15a). A prominent band of very low cloud-to-precipitation ratios is observed at 15 LT on both sides of HGB (Fig. 15d), and the band of low cloud-to-precipitation ratios coincides with the area of high shallow cloud frequency in Figure 13d. At 17 LT, a band with very high cloud-to-precipitation ratios is observed along the coastline while a less pronounced band of low cloud-to-precipitation ratios is observed further inland (Figs. 15e). At 19 LT, little precipitation is observed in the domain (Fig. 15f). This signal is not observed in C4, as none of the six time periods examined have a pronounced area of low cloud-to-precipitation ratio.

## 5 Summary and Discussion

In this study, we characterize the spatiotemporal variability of clouds and precipitation properties in the Houston area during the ESCAPE and TRACER field campaigns. Operational satellite and radar datasets are used to provide large samples in time and space for statistics on cloud fraction, cloud top heights, and cloud-to-precipitation ratios over a 250 km x 250 km domain. A novel aspect of the proposed methodology is that we utilize the state-of-the-art instrumentation at the TRACER AMF1 to validate and constrain the operational datasets. We evaluate the performance of the GOES-R ACM and estimate a radar reflectivity threshold for KHGX that is applicable in the entire domain and can detect the presence of light rainfall rate ( $< 0.1 \text{ mmhr}^{-1}$ ).

Throughout the four-month period, we identify shallow clouds and associated precipitation and deep clouds and associated precipitation, and we establish the four main diurnal patterns of shallow cloud fraction in the domain. We quantify the timing and magnitude of the cloud and precipitation occurrences while also noting the differences between land and water. Mainly, we find the cloud coverage is larger than the precipitation coverage, and we show that the deep clouds' coverage maximizes in the afternoon in all four modes while three modes have deep cloud and precipitation coverages maximizing at the same time. Shallow cloud coverage is higher over water than it is over land while the shallow precipitation coverage shows the opposite, and deep cloud and precipitation coverage is higher over land across all four modes.

Deleted: Higher occurrences of clouds with higher cloud tops are the key feature of C4.

Deleted: experiments

Deleted: . The Houston area is a natural laboratory for the study of convective clouds. However, there are several factors that could influence the spatiotemporal variability of shallow clouds specifically such as sea breeze circulations, varying aerosol conditions, surface heterogeneities, and cold pools from deep convection. These factors can operate in isolation or at the same time to influence the mesoscale organization of shallow cumulus clouds, their depth, and propensity to precipitate. Any observational effort that aims to disentangle these effects should be based on a large data sample. Here, o

Deleted: occurrence

Deleted: large

Deleted: all

One of the reasons for identifying the different modes of diurnal shallow cloud fraction variability is to identify time periods that have limited deep cloud activity. Clusters 1 and 4 fit this description and, at the same time, are the most populous clusters; thus, we have a robust sample size to study shallow clouds' spatiotemporal variability. Using this approach, we isolate regions and times of the day with interesting signals in shallow cloud frequency, shallow cloud top heights, and shallow precipitation fraction that warrant further consideration. For example, the presence of shallow clouds with higher cloud top heights east of the HGB is persistent and coherent in time and space. It suggests that, in this area, shallow clouds have stronger updrafts. We hypothesize that this could be due to aerosol properties given the large gradients shown in Kollias et al. (2024), in which we would need data on aerosol number concentration, composition, and supersaturation provided at different heights and high temporal resolutions to confirm a potential warm-phase invigoration signal. Given the onshore flow we showed, the clouds may be part of a synoptic-scale system over the Gulf of Mexico that is advected over land. The terrain itself may be higher in this region, which would cause stronger updrafts, too.

We also showed a prominent band of very low cloud-to-precipitation ratios in C1 in the early afternoon, and this band coincides with the area of maximum shallow cloud frequency. Later in the day, very high cloud-to-precipitation ratios are observed along the coastline while lower cloud-to-rain ratios are observed further inland. Given the location and time of day of these signals, we hypothesize that the prominent sea breeze circulation in Houston (Kocen, 2013) is inducing shallow clouds to precipitate. The meteorological set-up we showed in the HRRR composite maps suggests sea breeze conditions, though to confirm sea breeze conditions, low-level thermodynamics would be needed. Other independent analyses show consistency with our findings, too. Most notably, Wang et al. (2024) used reanalysis to quantify the synoptic variability during the period and identified sea breeze circulations using surface meteorological data and operational datasets. Of the 46 sea breeze events they identified, 38 corresponded to days belonging in C1 and C4 (28 in C1 and 10 in C4). Over 70% of their events fell into the anticyclonic regime defined in Wang et al. (2022), which corresponds to weak onshore flow and moisture advection that we also showed in our analysis.

Finally, this analysis will be useful and informative to the modeling studies in progress for ESCAPE and TRACER days, as their simulations can be benchmarked against our results. The correlations between the cloud/precipitation fields and the 850 hPa thermodynamics we show could also inspire modeling studies that modulate the moisture and temperature gradients at different levels of the atmosphere and measure the cloud/precipitation response.

6.1 Appendix A

To provide a more comprehensive assessment of the cloud mask's skill, we use the following skill metrics:

Deleted: healthy

Deleted: their

Deleted: The rationale of the proposed approach is that, by focusing on C1 and C4, we could potentially isolate the role of the sea breeze circulation on shallow cloud properties and at the same time investigate any other spatial patterns that can affect shallow cloud properties. For example, C1 contains days with negligible amounts of precipitation and low shallow cloud fraction, and C4 contains days with relatively higher shallow cloud fraction.

Deleted: ¶  
Because of our large sample sizes, we can identify robust signals in the domain like these that warrant future investigation. We hypothesize that the low cloud-to-precipitation ratios in the afternoon in C1 is related to the sea breeze, but without a comprehensive thermodynamic analysis of variables like virtual potential temperature, we cannot say that with certainty. Combine that analysis with a radar and satellite-derived boundary identification, and we could empirically identify the presence of sea breeze conditions for each day and clarify how much of an impact sea breezes have on the signals in C1. It appears sea breeze conditions play more of a role in determining shallow cloud properties in C1, but the forcing mechanism over land that causes more shallow clouds to become deep clouds in C4 could be the sea breeze, too. We do not expect every day in C1 and C4 to have (... [4]

$$\text{Accuracy} = \frac{\text{True Positives (\#)} + \text{True Negatives (\#)}}{\text{True Positives (\#)} + \text{False Positives (\#)} + \text{False Negatives (\#)} + \text{True Negatives (\#)}}$$

$$\text{Precision} = \frac{\text{True Positives (\#)}}{\text{True Positives (\#)} + \text{False Positives (\#)}}$$

For our purposes, we use the ARSCL data as the truth and the cloud mask data at the grid point over AMF1 as the prediction. We then consider a true positive to be an instance when both datasets report cloudy conditions, a false positive to be an instance when the cloud mask reports cloudy conditions and ARSCL reports clear conditions, a false negative to be an instance when the cloud mask reports clear conditions and ARSCL reports cloudy conditions, and a true negative to be an instance when both products report clear conditions.

One final consideration to make is the different temporal resolutions of the ARSCL and cloud mask datasets; the cloud mask provides data every five minutes and the ARSCL product provides data every few seconds. Initially, in the five minutes leading up to the cloud mask data point, if ARSCL has at least one cloud base height measurement, we designate the truth as cloudy and compare it to the prediction. The accuracy and precision of the cloud mask across the four-month period are 75% and 98%, respectively, or the leftmost data points in Figure A1a. The exceptional precision means the cloud mask is not false reporting cloudy conditions as clear conditions, but the accuracy leaves much to be desired. To improve the accuracy, we use stricter criteria: a greater fraction of the five minutes leading up to the cloud mask measurement must have cloud base height measurements in the ARSCL data. We incrementally increase this fraction until we reach 1 (or 100%), meaning there must be cloud base height measurements for the entire five-minute period in the ARSCL data for the truth to be designated as cloudy. Figure A1a displays the accuracy and precision as a function of this percentage. At a value of 100%, the precision drops to about 90%, which is still satisfactorily high. The accuracy shows marked improvement, reaching 86%. We use a percentage of 100 for the rest of the analysis.

We calculate the accuracy and precision as a function of time in Figure A1b during the four months. The accuracy stays between 81.9% and 91% throughout the day with an absolute maximum at 8 LT and a local maximum at 15 LT, and the precision is above 95% between 0-3 LT (local maximum of 97.6% at 3 LT) and 20-23 LT (absolute maximum of 98.6% at 20 LT) while experiencing an absolute minimum of 71.7% at 12 LT (Fig. A1b). Heidinger and Straka III (2013), using CALIPSO measurements to validate the cloud mask, found a similar diurnal discrepancy, as they showed the cloud mask had a probability of detection (accuracy) of 93.9% and a false cloud detection of 4.6% over land during the day and a probability of detection (accuracy) of 89.5% and false cloud percentage of 2.2% over land at night. Jimenez (2020) compared the cloud mask to CALIPSO measurements over the contiguous United States and also found lower performance during the daytime in summer due to misdetections of clear sky conditions. Both studies showed lower performance with low cloud as well, so lastly, we

Deleted: highest

1095 examine the accuracy as a function of cloud base height. We calculate the median cloud base height of each five-minute period  
and test the cloud mask’s accuracy as a function of height. Figure A1c indicates the accuracy is greater than 80% for median  
cloud bases less than 8 km; the accuracy decreases rapidly with median cloud base heights greater than this. These encouraging  
results suggests the cloud mask dataset is a feasible one for cloud research, and the improved performance for clouds closer to  
the surface in our analysis may be due to using ground-based measurements for validation instead of satellite-based  
1100 measurements used in previous studies.

**6.2 Appendix B**

1105 Monthly calendars corresponding to the four months of the ESCAPE and TRACER campaigns and the cluster each day belongs  
are shown in Figure B1. June has a representative mix of the four clusters, with 12 C1 days, five C2 days, six C3 days, and  
seven C4 days (Fig. B1), and July is similar, with 14 C1 days, two C2 days, five C3 days, and 10 C4 days. August and  
September shift the pattern, as August has the least C1 days (two of 31 total days) of the four months while C1 days dominate  
September (20 of 30 total days). To see the transition from consistent domain-wide shallow cloudiness in August to far less in  
September leads us to believe we are observing the seasonal transition from summer to fall, which also marks the end of the  
1110 convective season in Houston (Fridlind et al., 2019).
