13 **Abstract**

14 The mixing states and aging time scale of aerosol particles play a vital role in evaluating
15 their climate effects. Here, we identified four different real-time mixing patterns of size-
16 resolved particles using the field measurement by a humidity tandem differential mobility
17 analyzer (H-TDMA) in the urban Beijing. We show that the particles with external, transitional
18 and internal mixing state during the campaign account for 20-48%, 17-24% and 27-56%
19 respectively and the fraction highly depends on particles size. The diurnal variation of the
20 mixing states of particles in all sizes investigated (40, 80, 110, 150 and 200 nm) present an
21 apparent aging process from external to internal mixing state, typically spanning a duration of
22 approximately 5–8 hours from 8:00–10:00 to 15:00–17:00. Additionally, the results illustrate
23 that high ambient temperature during daytime or more humid atmosphere accelerates the aging
24 process of aerosol particles, leading to the particles from external to internal mixing on both

25 clear and cloudy days. Also, with the evolution of particulate pollution, the aerosol particles
26 become more internally-mixed. Our result implies that those fine aerosol particles experience
27 aging through both the photochemical process and aqueous growth in the polluted atmosphere
28 of urban Beijing. Furthermore, through a comprehensive review of the aging timescale of
29 particles adopted in current models and derived from observations, we show the great
30 discrepancy between observations and models, highlighting the importance to parameterize
31 their aging time scale based on more field campaigns.

32

33 **1 Introduction**

34 The mixing state of atmospheric aerosol particles can affect the hygroscopicity and the
35 ability to serve as cloud condensation nuclei (CCN), and thus the air quality and climate (Müller
36 et al., 2017; Xu et al., 2021; Yao et al., 2022; Ge et al., 2024). It has been shown that the aerosol
37 mixing state is closely related to the hygroscopicity (Chen et al., 2022; Fan et al., 2020). Ren
38 et al. (2018) predicted the concentration of CCN using five different mixing state schemes and
39 found that the influence of aerosol mixing state on its activation characteristics ranged from –
40 34% to +16%. Neglecting particle mixing structure can also lead to significant overestimation
41 of the aerosol absorption efficiency (Yao et al., 2022). Therefore, it is important to account for
42 the information of mixing state of ambient particles in climate models so as to reduce the
43 uncertainty in evaluating their environmental and climate effects.

44 The mixing states of ambient particles are complex. Particles in areas affected by primary
45 emissions are mainly with external mixing state (i.e., the chemical components of particles
46 exist independently), while aerosols in relatively clean areas are mainly transported from

47 elsewhere and have a higher degree of internal mixing (Swietlicki et al., 2008; Enroth et al.,
48 2018; Chen et al., 2022). Internal mixing typically includes uniform composition or core-shell
49 structures (Jacobson et al., 2001). The former refers to the same proportion of species in any
50 part of the aerosol component, while the latter is defined as the mixing state formed by certain
51 chemical components coating or condensing on the surface of other components during the
52 aging process. Also, the mixing state of particles is variable. Freshly emitted particles undergo
53 various processes, including photochemical and aqueous-phase processes, as well as physical
54 processes such as coagulation and condensation, leading to an increase in their degree of
55 internal mixing. This gradual transition from external to internal mixing characterizes the aging
56 process of particles. The aging timescale varies greatly between clean and polluted areas (Peng
57 et al., 2016; Chen et al., 2017; Ghosh et al., 2021). However, the timescale of aging process of
58 particles was commonly fixed in many models and did not depend on environmental conditions
59 (Chen et al., 2017; Ghosh et al., 2021), which may introduce great uncertainty in the prediction
60 of regional aerosol concentration and the evaluation of aerosol climate effects (Ghosh et al.,
61 2021). Therefore, capturing the temporal scales of the evolution of the aerosol mixing state
62 based on field campaigns is crucial for accurately parameterizing the aging timescale of aerosol
63 particles in models, thereby enhancing the precision of simulations pertaining to the
64 environmental and climatic impacts of aerosols.

65 At present, some studies have characterized the mixing state and aging process of black
66 carbon (BC) aerosols using different instruments. Transmission electron microscopy (TEM)
67 has been used to determine the mixing state of individual particles in China (Li et al., 2016;
68 Zhang J. et al., 2023). However, based on TEM technique, a large number of aerosol samples

69 are required so as to make the results with the significance of statistics, which means a high
70 cost both on labors and materials. The most important issue is that the mixing state of particles
71 may change during collection and transportation. Recently, aerosol time-of-flight mass
72 spectrometry (ATOFMAS) and soot-particle aerosol mass spectrometry (SP-AMS) have been
73 used to measure the mixing state of BC and coated aerosol species in real time (Liu et al., 2019;
74 Xie et al., 2020). Overall, previous studies focused more on the mixing state of BC of single-
75 particles (Saha et al., 2018; Xie et al., 2020; Chen et al., 2020). While, the mixing state of
76 particles across a population in ambient atmosphere is more complex (Riemer et al., 2019). For
77 example, aerosols containing two or more components may also exhibit external mixing, as
78 evidenced by the bi- or trimodal distributions of the probability density function of hygroscopic
79 growth factor/hygroscopic parameter (κ) (Gf-PDF; κ -PDF) measured using a humidity tandem
80 differential mobility analyzer (H-TDMA) (Fan et al., 2020; Chen et al., 2022; Zhang S. et al.,
81 2023). The mixing state of particles has been retrieved according to the patterns of Gf-PDF/ κ -
82 PDF (Hong et al., 2018; Shi et al., 2022; Spitieri et al., 2023). However, most studies based on
83 the H-TDMA measurements only made qualitative descriptions of the particle mixing state
84 when explaining the variations in the aerosol hygroscopicity (Wang et al., 2019; Chen et al.,
85 2022; Shi et al., 2022).

86 In this study, with the aim of obtaining insights into the mixing state and aging time scale
87 of ambient particles in urban area, we have identified four different types of size-resolved
88 particles mixing states, and characterized their real-time variations using the field measured
89 hygroscopic growth factor by the H-TDMA in urban Beijing. The dependence of mixing state
90 of particles on temperature (T), relative humidity (RH) and the pollution levels was

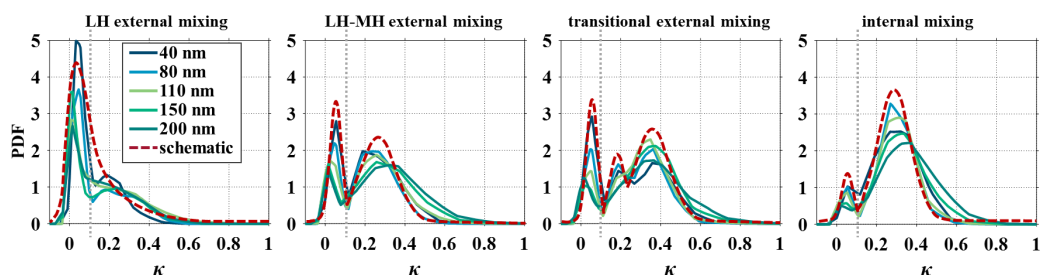

91 investigated. The evolution of mixing state of particles with specific sizes was also explored to
92 imply the timescale of their aging from the diurnal variations during clear and cloudy days.
93 Finally, we compared the aging timescale of aerosol particles with that adopted in current
94 models and other field observations reported in previous literatures.

95 **2 Methods**

96 The campaign was conducted to measure the Gf of particles with different dry sizes (40,
97 80, 110, 150 and 200 nm) using a H-TDMA from 19 May to 18 June 2017 in Beijing. The
98 instrument used in this study has been described previously (Zhang et al., 2017; Wang et al.,
99 2019; Fan et al., 2020; Chen et al., 2022). Here, we mainly describe the interpretation criteria
100 for the mixing state of particles. The Gf-PDF was obtained by TDMA_{inv} algorithm in this study
101 (Gysel et al., 2009). Then, the κ -PDF of size-resolved particles was retrieved according to the
102 κ -Köhler theory (Petters and Kreidenweis, 2007). Subsequently, we accurately defined four
103 mixing states based on the κ -PDF patterns and the number of peaks in κ -PDF (Figure 1, Figure
104 S1). Given that the freshly emitted hydrophobic particles showed an external mixing state (Li
105 et al., 2016), the κ -PDF, that exhibited only one nearly hydrophobic mode or less hygroscopic
106 (LH; the peak of κ -PDF occurs at $\kappa < 0.1$) mode, was defined as LH external mixing state (type
107 1). Mixing type 2 indicates that the maximum peak of κ -PDF occurs at LH mode or more
108 hygroscopic (MH, the peak of κ -PDF occurs at $\kappa \geq 0.1$) mode, and the bimodal distributions of
109 the LH and MH modes are present in κ -PDF. Moreover, the κ -PDF pattern with trimodal
110 distributions called transitional external mixing state in this study (type 3). The κ -PDF of type
111 4 was dominated by MH mode, displaying nearly unimodal patterns, was defined as internal
112 mixing type. In this study, we also calculated the standard deviation of κ -PDF (σ) according to

113 Spitieri et al. (2023), which indicates the degree of dispersion in the data, and is thought to
 114 reflect the mixing degree of particles to a certain extent.

115

116 Figure 1. The mean κ -PDF of five particle sizes and the schematic diagram of κ -PDF for four
 117 mixing types.

118 3 Results and discussion

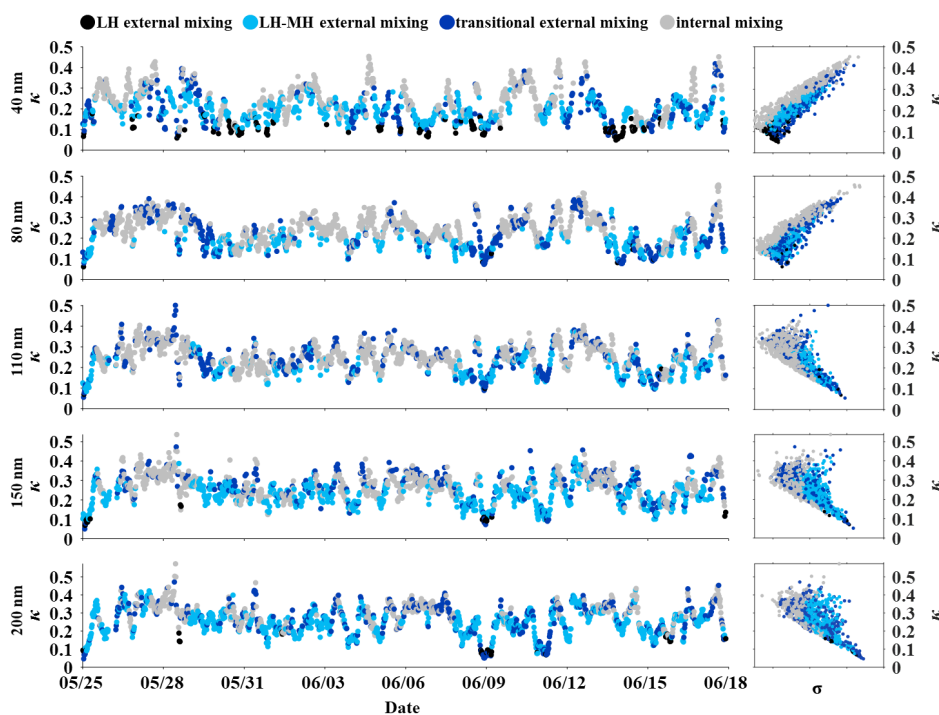

119 3.1 Overview of the mixing state of size-resolved particles

120 Figure 2 shows the time series of size-resolved κ , and κ versus σ . The real-time changes
 121 in the mixing states of particles are represented by different filled colors. The κ shows large
 122 variations in five particle sizes, ranging from 0 to 0.5, accompanied by significant changes in
 123 mixing states. In general, the mixing state of particles gradually transitions from external
 124 mixing to internal mixing along with increases in κ . For example, particles with size of 40 nm
 125 are dominated by LH external mixing and LH-MH external mixing states at $\kappa < 0.2$; and the
 126 transitional external mixing state take up an increasingly proportion often corresponding to κ
 127 values of > 0.2 and the internal mixing state occurs when κ greater than 0.3 (shown by the light
 128 gray dots in Figure 2).

129 However, there exists different correlations between κ and σ for the five sizes. For
 130 particles smaller than 100 nm (i.e., 40 and 80 nm), the σ increases as the κ increases from 0.1
 131 to 0.4, showing a positive correlation. While, the σ for particles larger than 100 nm (i.e., 110,

132 150 and 200 nm) exhibits a negative trend to κ variations, with the internal mixing and strong
 133 particles hygroscopicity but the smaller the value of σ . Our result contrasts with that previously
 134 observed in a vegetated site by Spitieri et al. (2023), which used only σ of Gf-PDF as a single
 135 indicator to characterize the particles mixing state. Our result indicates that the parameter σ
 136 alone cannot characterize the mixing state of particles in megacity of Beijing, where the aerosol
 137 particles are usually severely affected by local anthropogenic emissions.

138

139 Figure 2. Time series of hygroscopic parameter (κ), and plots of κ versus standard deviation of
 140 κ -PDF (σ) for 40, 80, 110, 150 and 200 nm particles (from top to bottom). The colors denote
 141 the different mixing types.

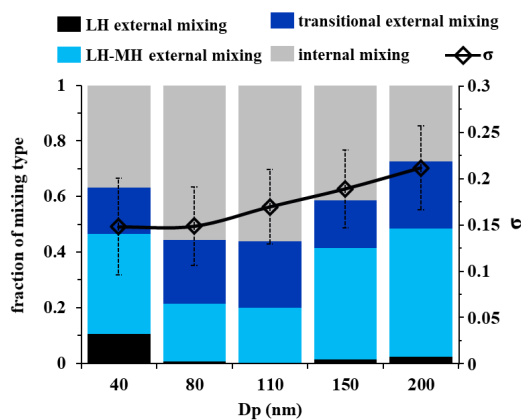

142 The size dependence of mixing type fractions and σ are shown in Figure 3. The external
 143 mixing types, including LH external mixing state and LH-MH external mixing state, dominate

144 in 40, 150 and 200 nm particles, accounting for 47%, 41% and 48% respectively of all mixing
145 types. The elevated fraction in particles with external mixing state is intimately associated with
146 the local sources. For instance, previous study revealed the particle size distribution of aerosols
147 from different sources in urban Beijing, suggesting that the particles with 40 nm predominantly
148 originated from primary emissions, and particles with 150 and 200 nm displayed a strong
149 correlation with transportation sources and biomass burning sources (Ren et al., 2023).
150 Furthermore, for 40 nm particles, besides the impact from primary sources, the relative higher
151 fraction of particles with internal mixing state (37%) is likely due to that the growth and aging
152 process of newly generated particles that are with high hygroscopicity (Wu et al., 2016; Liu et
153 al., 2021a). This is similar to the result observed in Athens, Greece, in which the particles with
154 30 nm were more internally-mixed (Spitieri et al., 2023). While, for particles with sizes of 80
155 and 110 nm, the transitional and internal mixing states totally account for 50-80% of all mixing
156 types, corresponding to a significant decrease from about 10% to less than 1% of the fraction
157 of the LH external mixing type. Note that the proportion of transitional external mixing state
158 remains relative constant, with a mean value of 21% across all sizes in this study, implying a
159 continuous influence of atmospheric aging process on the particles mixing state. On average,
160 the result reveals that the externally and internally mixed particles accounted for $56\pm 12\%$
161 and $44\pm 12\%$ respectively. The mixing state of particles derived in this study differs from that
162 reported by Zhang et al., (2017), in which they conducted the measurements at a suburban site
163 of Xinzhou where the aerosols is much less affected by sources nearby, and the aerosols are
164 mainly transported from elsewhere and are thus more aged and well mixed. The result implies
165 that the influence of mixing state on hygroscopicity should be explored at specific particle sizes

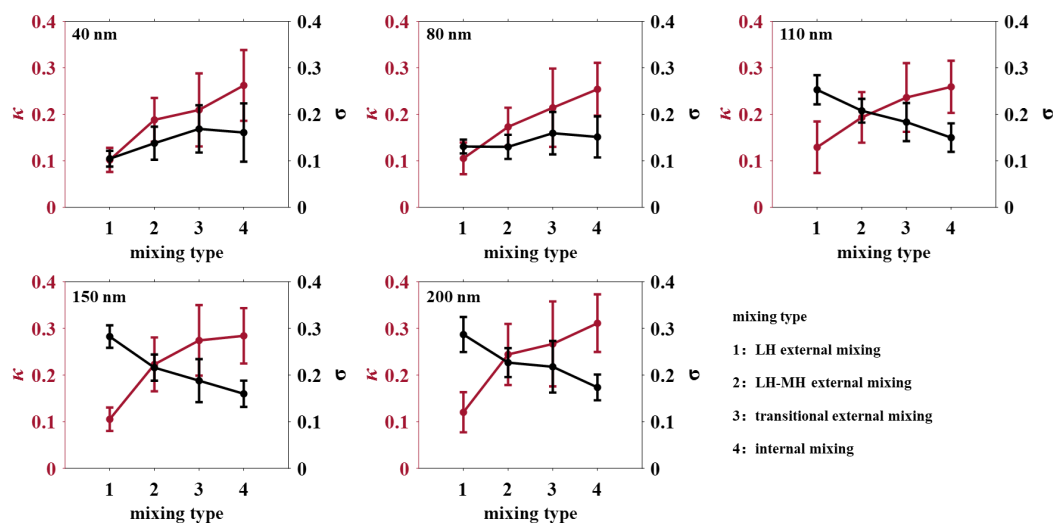

166 due to the heterogeneity of chemical compositions with particle size (Fan et al., 2020, Figure
 167 S2).

168

169 Figure 3. The size dependence of fraction of particles mixing types and σ .

170 Further, we compared the dependence of κ and σ on the variations of mixing states for five
 171 particle sizes (Figure 4). At 40 and 80 nm sizes, it shows that both κ and σ increases markedly
 172 when the particles change from external to internal mixing state. While, for particles with sizes
 173 of 110, 150 and 200 nm, the σ reduced but the κ increased when the particles change from
 174 external to internal mixing state. In other words, the σ of the particles larger than 80 nm shifts
 175 to lower values as the particles become more internally mixed. Our results indicate that the
 176 standard deviation of κ -PDF alone is insufficient to characterize mixing degree in polluted area.

177

178 Figure 4. The mixing type dependence of hygroscopicity and σ for five particle sizes.

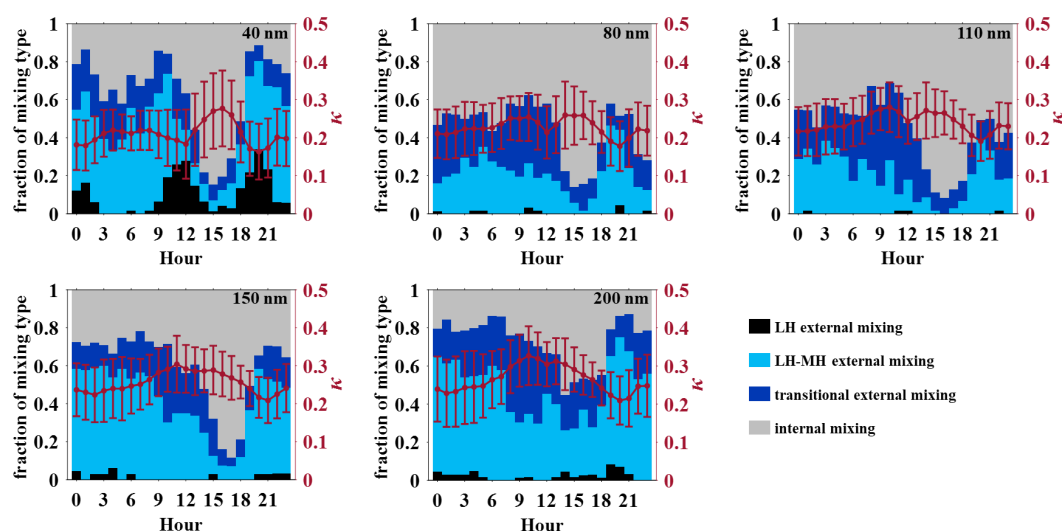

179 3.2 Evolution of mixing state of the particles

180 3.2.1 Diurnal variations

181 The average diurnal variations of the mixing state and κ of different particle sizes are
 182 shown in Figure 5. For 40 nm particles, the fraction of LH external mixing state presents three
 183 peaks at morning (9:00–12:00 local time; LT), evening rush hours (18:00–20:00 LT) and
 184 nighttime (0:00–03:00 LT). This is accompanied with the impacts from those primary cooking
 185 and traffic emissions (Xu et al., 2021; Liu et al., 2021b). Unlike the 40 nm particles, there is no
 186 apparent increase of external mixing state for the particles with sizes of 80, 110, 150, 200 nm
 187 in the rush hours or cooking times. The results indicate that the particles emitted from local
 188 primary sources are small mainly with sizes around 40 nm during the campaign.
 189 Correspondingly, the proportion of the particles with internal mixing state was smallest in the
 190 morning and nighttime, but exhibiting a rapid increase from about 9:00 until the evening rush
 191 hours (about 16:00–18:00). The particles with LH-MH external mixing and transitional

192 external mixing state represent the intermediate state of the aging process in which particles
 193 transition from external mixing to internal mixing, and both showed a decrease to around 10%
 194 during the corresponding period of the day as the proportion of particles with internal mixing
 195 state increased up to 80%. The diurnal variations imply an apparent aging process that leads
 196 the particles changed from external mixing in the early morning to internal mixing in the
 197 afternoon. The aging process also changes particles physiochemical properties. As a result, an
 198 obvious enhancement in particles hygroscopicity was observed during the daytime, indicating
 199 the impact of particles mixing and aging on their hygroscopicity (Hersey et al., 2013; Müller
 200 et al., 2017).

201

202 Figure 5. Diurnal variations of the mixing state fraction and κ for five particle sizes.

203 3.2.2 Dependence of the mixing state on T, RH and PM₁

204 To elucidate the effect of meteorological condition and particulate pollution level on
 205 mixing state of particles, the dependences of particles mixing types on ambient T, RH and PM₁
 206 mass concentrations are further examined (Figure 6). It shows that there is a clear dependence

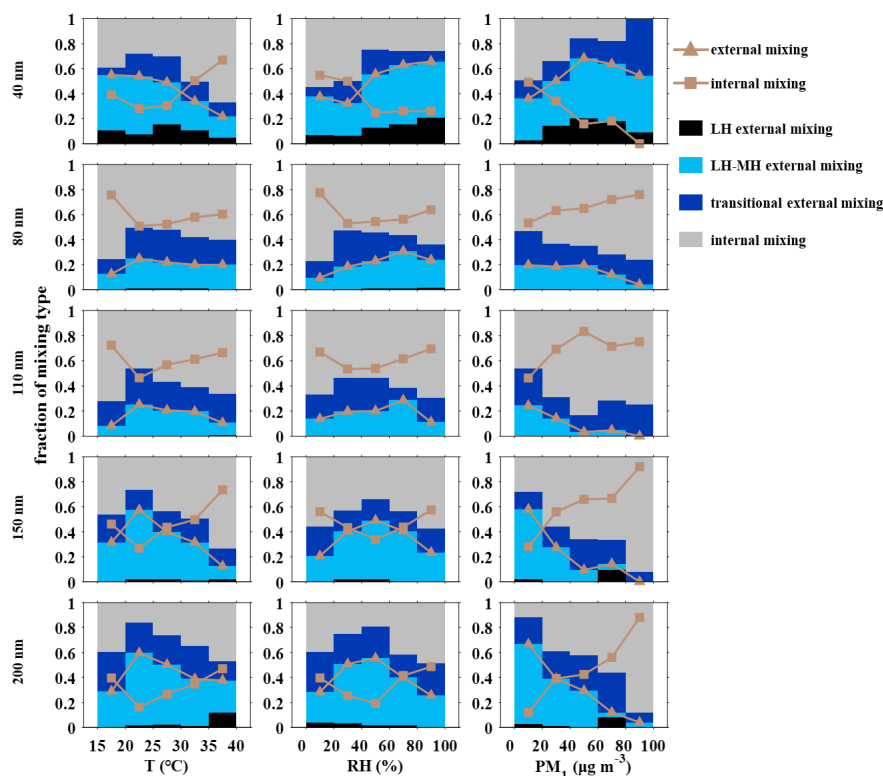

207 of mixing state of the particles across all observed sizes on T, for example, for the 40 nm
208 particles, the fraction with external mixing state reduces from 60% to 20%, while that of the
209 internal mixing state increases from 30% to 70% with the increase of T from $<20^{\circ}\text{C}$ to $>35^{\circ}\text{C}$.
210 This can be easily explained that the higher ambient T (usually corresponding to the periods in
211 daytime) will generally promote the photochemical aging and mixing of the particles (Riemer
212 et al., 2004; Zhang et al., 2015). But note that, the fraction of particles with internal mixing
213 state decreases evidently when the T increases from 15°C to about 25°C . With the increase of
214 RH from 20% to 80%, the fraction of particles with internal mixing state at 40 nm reduces from
215 60% to 20%. However, the fraction of the internal mixing state for particles larger than 80 nm
216 is reduced with the increase of RH when its value $<60\%$, while it increases with the RH increase
217 as it larger than 60%, indicating that the very humid atmosphere with high RH is more
218 favorable for particle aging that was reported promoted by the aerosols aqueous process (Zhang
219 et al., 2021).

220 With the evolution of PM_{10} pollution, the fraction of internal mixing state for 40 nm
221 particles significantly decreases to less than 10% due to accumulation of small particles from
222 local primary emissions under heavy pollution conditions, which thus leads to enhanced
223 heterogeneity of particles chemical composition and externally-mixed degree (Fan et al., 2020).
224 While for particles with sizes of 80, 110, 150 and 200 nm, the proportion of internally-mixed
225 state increase to nearly 90% under heavy PM_{10} pollution, which is consistent with previous
226 observations in winter of urban Beijing (Chen et al., 2020) and in Xi'an (Wang et al., 2014).
227 Our result implies that those fine aerosol particles experience aging through both the
228 photochemical processes and aqueous growth in the polluted atmosphere of urban Beijing,

229 thereby affecting their mixing state.

230

231 Figure 6. Mixing type fraction as a function of T, RH and PM₁ for five particle sizes. Solid
 232 triangles and solid squares represent the fraction of internal and external (LH external mixing
 233 + LH-MH external mixing state) mixing states, respectively.

234 3.3 Particles aging timescale: on clear and cloudy days

235 Figure 7 shows the average diurnal variations of the fraction of particles with internal
 236 mixing state and the mean fractions of all the four mixing types on clear and cloudy days. On
 237 clear days, the fraction of internal mixing state increases significantly from ~10-40% before
 238 9:00 to nearly 100% during 12:00–15:00, especially when particle size smaller than 150 nm.
 239 While, there is no such notable enhancement on cloudy days. The difference in the proportion

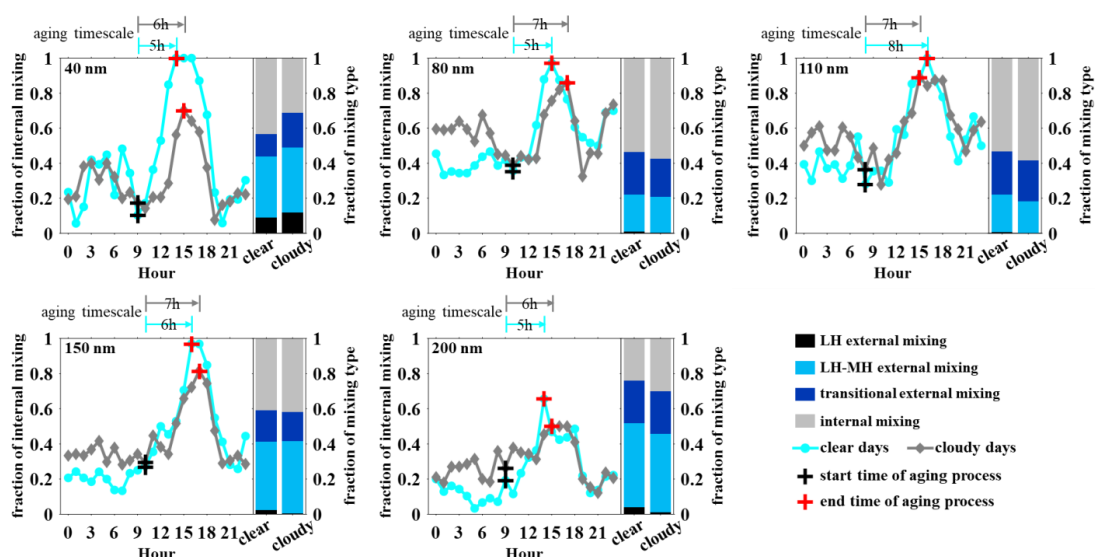

240 of particles with internal mixing state between the period before 9:00 and during 12:00–17:00
241 usually does not exceed 50% on cloudy days, and the maximum fractions of particles with
242 internal mixing state on cloudy days were about 50%-90%. Compared with the cloudy days,
243 the fraction of particles with internal mixing for 40 nm is noticeably higher on clear days, which
244 accounts for about 40% of all mixing states, indicating that the 40 nm particles are likely from
245 nucleation processes. On clear days, the particles undergo a gradual shift from external to
246 internal mixing states during 8:00–16:00 accompanied by a growth in particle size from 20 nm
247 to about 100 nm (Figure S3), which is generally 1–2 hours shorter than that observed on cloudy
248 days.

249 Overall, the aging process is confirmed by the transition of particle from external to
250 internal mixing states, the growth of particle size, and the increase of secondary organic aerosol
251 (Figure S3), which typically spans a duration of approximately 5 to 8 hours, as is similar to the
252 aging timescale of aerosol particles in the polluted Indo-Gangetic Plain (< 10 hours) (Ghosh et
253 al., 2021). Actually, the aerosol particles aging would be largely affected by local atmospheric
254 conditions, and thus would vary both spatially and temporally (Pöschl et al., 2001; Huang et
255 al., 2013). For example, using an environmental chamber approach, Peng et al. (2016) revealed
256 that the timescale of BC aerosols aging is 2.3 and 4.6 hours, 9 and 18 hours over two cities—
257 Beijing and Houston respectively. Note that the faster aging time in Beijing derived in the
258 chamber experiment is probably due to the different levels in the concentration of gaseous
259 precursors. In addition, there is only photochemical aging occurred in the chamber experiment,
260 however, in the atmosphere, the particles aging is also through coagulation process which
261 usually occurs slower than the photochemical reaction and condensation processes (Chen et al.,

262 2017). This can also explain our observed faster aging time on clear days when the
 263 photochemical process is more significant considering that the difference of the pollutant
 264 concentrations in daytime between clear and cloudy days is not obvious (i.e., SO₂, NO₂, O₃,
 265 PM₁; Figure S4).

266
 267 Figure 7. Diurnal variations of internal mixing proportion and statistical results of the fraction
 268 of mixing state for five particle sizes on clear and cloudy days. The line segments and time
 269 above the graph represent the aging timescale of particles. The start time and end time of
 270 particle aging process was selected when the proportion of particles with internal mixing state
 271 is closest after sunrise, and when the fraction of internally-mixed particles reaches its maximum,
 272 represented by black and red cross respectively.

273 3.4 Implications to parameterization of the current models

274 The aging timescale of aerosol significantly impacts their physiochemical properties,
 275 which in turn affects their atmospheric lifetime, transport characteristics (Zhang J. et al., 2023)
 276 and the direct radiative forcing of aerosol particles (Moffet and Prather, 2009; Wang et al.,

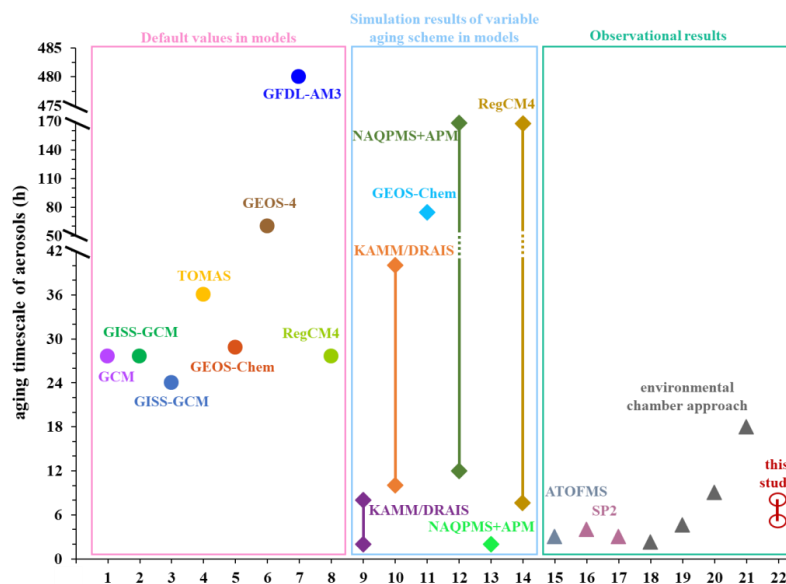

277 2018). We further compared our results with the results derived from five field sites and the
278 values adopted in current models (Table S1). As shown in Figure 8, the aging timescale of
279 particles in Beijing achieved in this study is 5–8 hours, which is comparable with the
280 observations of that reported in other urban areas like Mexico City (3 hours; Moffet and Prather,
281 2009) and Los Angeles (3 hours; Krasowsky et al., 2016). The result is also close to the aging
282 timescale of particles in source area of biomass burning in California (4 hours; Akagi et al.,
283 2012). However, the aging time of particles displays large spatial variations at different sites.
284 For example, the aging timescale of particles observed in Beijing (4.6 hours) was four times
285 faster than that in Houston (18 hours) where the precursors concentrations are extremely low
286 (Peng et al., 2016). Overall, the aging time of particles obtained in ambient atmosphere is much
287 shorter than the default values adopted in most models, which is commonly with a duration of
288 1.15–2.5 days. In addition, the values among different models range greatly from 1 to 20 days
289 (Figure 8). For example, a timescale of 20 days was used to represent a slow aging process (i.e.,
290 coagulation) by Liu et al. (2011), as may be not properly applied in regions with high particle
291 number concentration where the particles coagulation is also efficient (Chen et al., 2017).

292 Although using dynamic parameterization scheme of particles aging in models could
293 achieve the application of different particles aging time to different regions, the simulated
294 values show large variations and uncertainties among different models. For example, in
295 RegCM4 model, the conversion time from fresh to aged BC range from about 5 hours to 7 days
296 (Ghosh et al., 2021). The range in KAMM/DRAIS, however, is only 2 hours to about 1.6 days
297 (Riemer et al., 2004). The aging timescales has been reported ranging from 12 hours to 7 days
298 over central-eastern China based on a regional chemical transport model by Chen et al. (2017),

299 which is much longer than that derived in urban Beijing by this study.

300 The large uncertainties in the aging timescale can significantly affect the accuracy of
301 simulation and assessment for atmospheric lifetime, loading and radiation forcing of aerosols.
302 For example, to better simulate the intercontinental transport of aerosols, Huang et al. (2013)
303 implemented a variable aging scheme in the GEOS-Chem model, which showed that the total
304 atmospheric burdens and global average lifetimes of BC (OC, organic carbon) were increase
305 by 8% (2%) compared to the default value (1.15 days). Similarly, due to the implementation of
306 the dynamic aging scheme in models, the column burden and surface mass concentration of
307 carbonaceous aerosols increased during the dry season in the polluted Indo-Gangetic Plain, and
308 the atmospheric heating increased by at least 1.2 W m^{-2} (Ghosh et al., 2021). Therefore, given
309 the large spatiotemporal variations in aging timescale of particles, the study emphasizes the
310 urgency of conducting investigations at more field sites. In addition, the other factors such as
311 the meteorology, aerosol mass loading and particle sizes that affect the aerosols aging should
312 be accounted for so as to improve the dynamic aging schemes in climate models.

313

314 Figure 8. The aging timescale of particles reported in literatures (1. Cooke et al., 2002; 2. Chung
 315 and Seinfeld, 2002; 3. Koch and Hansen, 2005; 4. Pierce et al., 2007; 5. Yu and Luo, 2009; 6.
 316 Colarco et al., 2010; 7. Liu et al., 2011; 8, 14. Ghosh et al., 2021; 9, 10. Riemer et al., 2004; 11.
 317 Huang et al., 2013; 12, 13. Chen et al., 2017; 15. Moffet and Prather, 2009; 16. Akagi et al.,
 318 2012; 17. Krasowsky et al., 2016; 18-21. Peng et al., 2016). The solid circle, diamond and the
 319 triangle denote the default aging time of particles used in models and stimulation results of
 320 variable aging scheme in models, as well as the observational results, respectively.

321 4 Conclusions

322 The real-time mixing state of ambient aerosol particles with dry particle sizes of 40, 80,
 323 110, 150 and 200 nm was investigated in urban Beijing, according to PDF of hygroscopic
 324 growth factor measured using the H-TDMA system. Four mixing states of ambient size-
 325 resolved particles were captured in this study. In general, particles with LH external, LH-MH
 326 external, transitional external and internal mixing state account for 0-10%, 20-46%, 17-24%

327 and 27-56% respectively, which depends on particles size greatly. The diurnal variation of
328 mixing state of particles in all sizes considered present a visible aging process, showing that
329 the fraction of particles with internal mixing state increases significantly from ~10-40% before
330 9:00 to about 100% during 12:00–15:00 on clear days, accompanied by a growth in particle
331 size from 20 nm to 100 nm, which is more notable than that on cloudy days. Specifically, the
332 aging process of particles within approximately 5–8 hours. In addition, the mixing state of
333 particles was observed to be dependent both on T and RH, showing that the particles with
334 internal mixing state elevates obviously when T or RH exceeds 25°C or 60% respectively.
335 Moreover, with the intensification of particulate pollution, the particles become more
336 internally-mixed. The results indicate that both high ambient temperature and very humid
337 atmosphere are more favorable for particle aging in polluted atmosphere. The large difference
338 of aging timescale of particles between values in models and the timescale achieved by
339 observations, emphasizing the vital role of exploring the aging timescale through more field
340 measurements to improve the accuracy of aging schemes in climate models. The results
341 revealed in our study highlight the considerable impact of atmospheric aging on mixing state
342 of fine aerosol particles in polluted megacities.

343

344 **Data availability**

345 All data used in the study are available from the corresponding author upon request
346 (zhangfang2021@hit.edu.cn).

347 **Author contributions**

348 FZ and JL conceived the conceptual development of the paper. FZ directed and
349 performed of the experiments with JR, LC and JL. JL conducted the data analysis and wrote
350 the draft. All authors edited and commented on the various sections of the paper.

351 **Competing interests**

352 The authors declare that they have no conflict of interest.

353 **Acknowledgments**
