23 **Abstract.** Large-eddy simulations (LESs) are conducted for each day of the intensive observation
24 periods (IOPs) of the Green Ocean Amazon (GoAmazon) field campaign to characterize the
25 updrafts and microphysics within deep convective cores while contrasting those properties
26 between Amazon wet and dry seasons. Mean Doppler velocity (V_{dop}) simulated using LESs are
27 compared with 2-year measurements from a Radar Wind Profiler (RWP) as viewed by statistical
28 composites separated according to wet and dry season conditions. In the observed RWP and
29 simulated LES V_{dop} composites, we find more intense low-level updraft velocity, vigorous graupel
30 generation, and intense surface rain during the dry periods than the wet periods. To investigate
31 coupled updraft-microphysical processes further, single-day golden cases are selected from the
32 wet and dry periods to conduct detailed cumulus thermal tracking analysis. Tracking analysis
33 reveals that simulated dry-season environments generate more droplet-loaded low-level thermals
34 than wet-season environments. This tendency correlates with seasonal contrasts in buoyancy and
35 vertical moisture advection profiles in large-scale forcing. Employing a normalized time series of
36 mean thermal microphysics, the simulated cumulus thermals appear to be the primary generator of
37 cloud droplets. ~~When subsequent thermals penetrate the ice crystal layer, droplets within the~~
38 ~~thermals interact with entrained ice crystals, which enhances riming in the thermals.~~ This appears
39 to be a production pathway of graupel/hail particles within simulated deep convective cores. In
40 addition, less-diluted dry-case thermals tend to be elevated higher, and graupel grows further
41 during sedimentation after spilling out from thermals. Therefore, greater concentrations of low-
42 level moist thermals likely result in more graupel/hail production and associated dry-season
43 convective vigor.

Deleted: At the same time, ice crystals tend to be generated in inactive parts of clouds.

Deleted: Time series shows that thermals, however, entrain ice crystals and enhance riming due to large concentrations of droplets in the thermal core

49

50 1. Introduction

51

52 Deep convection is a fundamental process of turbulence that drives the Earth's general circulation
53 and regulates thermodynamic fields (Emanuel et al., 1994). Deep convection undergoes complex
54 dynamical and microphysical processes throughout its life cycle, which appear as towering clouds
55 visible from satellites in different parts of the world (Stephens et al., 2002). As a result, deep
56 convection generates significant amounts of atmospheric latent heat, surface precipitation, and
57 hydrometeors that reflect/absorb solar and infrared radiation, modifying atmospheric circulation
58 and surface energy and mass fluxes (Hartmann, 2016). These complexities in deep convection and
59 feedback processes pose significant challenges in predicting weather and climate using numerical
60 Earth system modeling across different scales (Grabowski and Petch, 2009; Sullivan and Voigt,
61 2021).

62

63 Characteristics of deep convection are unique in different seasons and geographic regimes affected
64 by the local environment. One of the most straightforward yet most robust regime separation
65 concepts is the land-ocean (L-O) contrast (Williams and Stanfill 2002). Solar radiation increases
66 the surface skin temperature over land more readily than over the ocean due to the smaller heat
67 capacity of soils and vegetation than deep water bodies, thus producing stronger surface infrared
68 flux and turbulent heat flux (Matsui and Mocko 2014). This greater surface energy deepens
69 planetary boundary layers that may trigger deeper convective clouds depending on the atmospheric
70 profiles (Pielke 2001). Overall, the continental environment tends to promote deeper convection
71 with stronger, wider convective cores (Lucas et al. 1994, Wang et al. 2019), with suppressed warm
72 rain and enhanced cold precipitation process (Williams et al. 2005), which often leads to unique
73 drop-size distribution characteristics and precipitation partitioning between convective and
74 stratiform process outcomes in different geographic regions (e.g., Tokay and Short 1996;
75 Giangrande et al. 2012; Dolan et al. 2018).

76

77 Satellite observations similarly depict continental convective invigoration as characterized by
78 more frequent lightning flashes and heavily rimed particles aloft over land than ocean (Williams
79 et al. 2004, Zipser et al. 2006, Stolz et al. 2015, Matsui et al. 2016). Takahashi et al. (2017 & 2021)

Deleted: warms

81 show that continental convection generally contains less diluted cores than their oceanic
82 counterparts, following an inverse relationship between convective core width and dilution rate.
83 Similarly, Jeyaratnam et al. (2020) recently suggested that convective updraft and mass flux
84 properties were distinctly different between tropical land and tropical oceanic convection using
85 methods to estimate those properties that blend satellite observations with plume models. Hereafter,
86 we define “convective vigor” by the enhanced cold-precipitation process characterized by larger
87 rimed particles (graupel/hail) and large and copious raindrops in convective cores.

Deleted: vigorous

88
89 Representation of deep convective cloud land-ocean contrasts is still an ongoing challenge for
90 global atmospheric models at storm-resolving resolution (a few km of horizontal grid spacing),
91 partially owing to the poor representation of cloud dynamics (Matsui et al. 2016). Robinson et al.
92 (2011) configured idealized simulation setups to investigate the “island” effect of convection with
93 finer grid spacing (500 m or 1 km) and successfully simulated convective vigor equivalent to the
94 observed microwave brightness temperature. Matsui et al. (2020) used a nested regional model
95 with 1 km grid spacing to compare mid-latitude continental versus tropical maritime storms and
96 successfully reproduced land-ocean contrasts of hydrometeor identification profiles from
97 polarimetric radars.

98
99 However, statistical evaluation of simulated vertical velocity and association with convective
100 vigor process (i.e., graupel/hail generation) have not yet been examined very well due to a lack of
101 observations and detailed process-oriented model investigation, respectively. For example,
102 mesoscale convective system (MCS) studies performed by Prein et al. (2022) and Ramos-Valle et
103 al. (2023) highlight the challenges when attempting to represent continental convection within the
104 constraints of limited observations while attempting to establish optimal configurations as a
105 function of model grid spacing for typical midlatitude (Oklahoma) and tropical continental
106 (Amazon) conditions.

107
108 The 2-year measurements from the Green Ocean Amazon (GoAmazon) campaign provide
109 unprecedented data on the vertical velocity of deep convection by the Atmospheric Radiation
110 Measurement user facility (ARM, ARM Mobile Facility (AMF), Martin et al. 2017, Giangrande
111 et al. 2017). Recently, Giangrande et al. (2023) contrasted the thermodynamics and lifecycle

113 properties, including the vertical air velocity within isolated convective clouds observed during
114 the Amazon wet and dry seasons, and found that dry-season convection exhibited more intense
115 low-level updrafts and ~~larger reflectivity~~ associated with smaller convective cell areas than wet-
116 season counterparts. Dry-season convection also tended to exhibit a shorter life cycle and often
117 achieved maximum updraft and precipitation intensity at earlier life cycle stages than wet-season
118 storms. Pre-convective thermodynamics profiles from those events revealed that the dry season
119 showed a stronger deficit of dew-point temperature in the middle troposphere and higher values of
120 mean-layer convective available potential energy (MLCAPE) at lower levels.

Deleted: stronger precipitation properties

121
122 In addition to primary thermodynamic transitions between wet and dry season convective regimes
123 (e.g., Giangrande et al. 2020), the Amazon dry seasons may experience larger concentrations of
124 aerosols due to biomass burning that have been recently associated with potential secondary
125 contributions to changes in storm precipitation properties and convective vigor (e.g., Lin et al.
126 2006; Wang et al. 2018; Öktem et al. 2023). Moreover, the Amazon dry (wet) season has long
127 been suggested to promote a continental (maritime) convection contrast for a given
128 thermodynamic profile and background aerosols (Williams et al. 2002). Typical land-ocean
129 contrast is characterized by a “hot” continental surface (Williams and Stanfill 2002) and sea-breeze
130 type of mesoscale dynamics due to the thermal-patch effect (Robinson et al. 2011). Thus, instead
131 of focusing on the complex nature of land-ocean contrast or other active versus break monsoonal
132 contrasts performed globally (e.g., Holland et al. 1986, Keenan and Carbone 1992, Pope et al.
133 2009, Wu et al. 2009), the dry-wet season contrasts over the Amazon basin allows a unique
134 emphasis on the impact of thermodynamic profiles and large-scale dynamics upon the formulation
135 of convective vigor.

136
137 The main objective of this paper is to investigate dry-wet seasonal contrast and potential changes
138 in the evolution of deep convection cloud processes using an LES model and forward simulations
139 of Doppler radar observations. This attempts to reveal dynamical and microphysical processes that
140 explain the observed dry-wet contrasts, focusing on the bulk controls imposed by the background
141 thermodynamic profiles and large-scale forcing. The motivation for these efforts is the argument
142 that an improved understanding of these dry-wet contrasts should facilitate untangling the more
143 complex processes of land-ocean contrasts in deep convection. For this study, we employ a series

145 of daily large-eddy simulations (LESs) with bulk single-moment microphysics throughout the
146 GoAmazon campaign dry and wet season intensive observation periods (IOPs) to characterize dry-
147 wet season contrast in convection. These simulations are validated against the cumulative statistics
148 of ground-based Doppler velocity measurements during those periods. A thermal tracking analysis
149 is conducted to select golden cases from these dry- and wet-season LES runs to investigate the
150 physical process of convective vigor further. This effort focuses on thermodynamic impacts and
151 cloud dynamical roles in this manuscript, while the aerosol effects will be investigated in another
152 study.

153

154 Section 2 describes the general methodology and tools, including radar profilers, LES,
155 instrumental simulators, large-scale meteorological forcing, and thermal-tracking algorithms for
156 this study. Section 3 shows the results of the dry-wet contrast of meteorological forcing, statistical
157 composites of Doppler velocity, and thermal tracking analysis. Section 4 summarizes a thermal-
158 driven process of dry-season convective vigor, its uncertainties, and future directions.

159

160

161 2. Methods

162

163 2.1 GoAmazon: RWP Observations

164

165 The primary datasets for this study are those collected by the 1290 MHz ARM Radar Wind Profiler
166 (RWP) operated during the U.S. Department of Energy’s ARM facility deployment during
167 its “Observations and Modeling of the Green Ocean Amazon 2014–2015” (GoAmazon) campaign
168 near Manaus, Brazil, from March 2014 through December 2015 (e.g., Martin et al., 2017). The
169 RWP was configured for precipitation sampling that included frequent vertical pointing to collect
170 conventional radar reflectivity factor Z and mean V_{dop} profiles through deep convective cells to
171 approximately 17 km in altitude (e.g., Giangrande et al. 2013, Giangrande et al. 2016, Wang et al.
172 2019, Williams et al. 2023). For measurements collected at these ultra-high frequencies and
173 without expectations for larger hail in Amazon deep convective storms (Liu and Zipser 2015, Bang
174 and Cecil 2019), all radar estimates are assumed as within Rayleigh scattering regimes, and
175 measurements are unattenuated in rain. The RWP deployed during GoAmazon had a beam width

Deleted: collected by

Formatted: Font: (Default) Times New Roman, 12 pt

Formatted: Font: (Default) Times New Roman

177 of approximately 10 degrees thus horizontal measurement resolution is typically less than 1 km,
178 with a 200 m vertical (bin, gate) resolution and 10-s intervals between consecutive radar profiles.
179 All radar measurements were calibrated against a reference laser disdrometer collocated at the
180 main AMF site during the campaign (e.g., Wang et al. 2018), [and a detailed method is discussed](#)
181 [in Williams et al. \(2023\)](#).

Formatted: Font: (Default) Times New Roman, 12 pt

182
183 For observation and simulation comparisons, the deep convective core is defined by using
184 thresholds applied to the observed and simulated RWP profiles: 1) column-maximum reflectivity
185 is greater than 35 dBZ, and 2) column-maximum V_{dop} is greater than 5 m/s. The choice for these
186 criteria is admittedly flexible, as model-vs-observed Z thresholds, in particular, are not necessarily
187 well-posed for convective-stratiform segregation such as removing all stratiform cells (e.g., Steiner
188 et al. 1995). Still, the additional velocity constraint afforded by the vertically-pointing RWP and
189 statistical representation of convective and stratiform composites seems to be reasonable (not
190 shown here), noting what is important is an attempt to apply thresholds for both observations and
191 simulations. A slightly different threshold does not alter the conclusions. Note that events on
192 3/19/14, 3/20/14, and 3/23/14, as well as the 10/4/14 cases from the dry season IOP, are clear
193 examples of Amazon mesoscale convective systems (MCSs, e.g., Wang et al. 2019). Thus, these
194 cases have also been removed from our statistical analysis to focus on isolated convective days.

195
196

197 **2.2 GoAmazon LES, Forcing, and Simulator**

198

199 GoAmazon LES runs utilize the Goddard Cumulus Ensemble (GCE), a cloud-process model
200 developed and improved at NASA GSFC over several decades (Tao *et al.* 2014). The GCE is
201 driven by large-scale forcing (LSF) with cyclic boundary conditions to generate cloud dynamics
202 and microphysics processes in Cartesian grid coordinates. No additional heat, moisture, or
203 momentum enters the domain apart from that imposed by the LSF or solar/infrared radiative
204 processes. In addition, GCE's anelastic dynamic core option allows faster integration of finer-
205 resolution runs (up to 1.5~2 times) than its compressible dynamic core option.

206

207 GoAmazon LES runs use 200-m horizontal grid spacing with 512 x 64 x 128 grids (x-y-z cartesian
208 coordinates) with a 2-second model time step. Vertical grid spacings stretch from near surface
209 level (starting from 44 m) and reach 200m around 4 km level, not to exceed horizontal resolution.
210 Thus, the domain covers a 102 km x 12.8 km area; this “narrow channel” domain setup intends to
211 resolve three-dimensional large eddies (i.e., thermals) while minimizing computational cost in
212 order to run LES for the entire IOPs. In terms of model physics, the 1.5-order turbulent kinetic
213 energy (TKE) scheme is used for subgrid turbulent mixing, and the Goddard radiation scheme is
214 used for computing radiative flux and heating (Chou and Suarez 1999 & 2001, Matsui et al. 2018).
215 The Goddard bulk one-moment 6-class scheme (4ICE hereafter) has four ice classes and uses
216 preset size and density mapping for snow, graupel, and hail (Lang et al. 2014; Tao et al. 2016).
217 4ICE successfully generated a realistic L-O contrast of convective-core hydrometeor distributions
218 compared to polarimetric radar retrievals in the previous study (Matsui et al. 2020). Also, note that
219 the one-moment scheme is unaffected by the background aerosol concentrations to focus on the
220 impact of thermodynamic and large-scale forcing on convective vigor in this study.

221
222 The LSF is derived from the VARIational ANALysis (VARANAL) approach, which is a broadly
223 accepted method for generating large-scale forcing wherein data are collected and adjusted based
224 on the vertical integration of the atmospheric mass, moisture, dry static energy, and momentum
225 budgets (Zhang and Lin 1997, Zhang et al. 2001, Xie et al. 2004). The VARANAL approach is
226 applied to the GoAmazon field campaign using ERA-Interim reanalysis (Dee et al., 2011) and
227 constrained by radar-based surface precipitation rate (Tang et al. 2016). The horizontal/vertical
228 advective forcings, mean wind profiles, and surface heat fluxes from the GoAmazon LSF are used
229 to drive the LES. These fields are interpolated and imposed as tendency terms at every model time
230 step. Our previous research demonstrated that GCE reproduced the observed precipitation quite
231 well when forced by the GoAmazon LSF (Tao et al. 2022). GoAmazon LESs are run from
232 September 2014 to 10 October 2014, defined as the dry-season IOP, and also run from 14 February
233 2014 to 26 March 2014, defined as wet-season IOP, as suggested by thermodynamic behaviors
234 characteristic of larger dry and wet-season expectations, respectively (Giangrande et al. 2017,
235 2020). Each daily LES is initialized at 12 AM local time from the LSF and integrated just for 30
236 hours rather than continuously integrated during the entire IOPs because the convection life cycle
237 typically follows a strong diurnal cycle due to the solar heating cycle, excepting propagating

Formatted: Font: (Default) Times New Roman, 12 pt

Formatted: Font: (Default) Times New Roman, 12 pt

238 organized convection (Tang et al. 2016, Giangrande et al. 2017, 2020). As a default setting, hourly
239 LES outputs are used to analyze the mean seasonal behavior of LESs.

240

241 Hourly LES outputs include an additional Doppler velocity field, corresponding to an expected
242 RWP observation through a multi-instrumental simulator, Goddard Satellite Data Simulator Unit
243 (G-SDSU, Matsui et al. 2014a; Matsui et al. 2014b). In this study, a ground-based Doppler radar
244 simulator is implemented in the model to replicate RWP observable signals. Radar backscatter is
245 estimated from nonRayleigh calculations with a Maxwell-Garnett assumption of air-water-ice
246 mixtures at 1290 MHz frequency, though for the RWP frequency, vertical pointing, and media
247 type/size expectations therein, the forward modeling is more straightforward than most weather
248 radar wavelength applications and appropriate for Rayleigh scattering assumptions. Doppler
249 velocity is estimated using pressure-adjusted hydrometeor terminal velocities weighted by radar
250 backscatter spectrum for each particle size distribution (PSDs). All these single scattering
251 calculations follow the 4ICE microphysics calculation/assumptions of particle size, density, and
252 phase for each hydrometeor species for physics consistency (Matsui et al. 2014b). Finally,
253 simulated signals are averaged consistent with the RWP beamwidth (10 degrees). This beamwidth
254 implies different averaging at different heights, for example, corresponding to six horizontal grids
255 of the LESs being averaged for a representative output at the 15 km height. Overall, this beamwidth
256 averaging smear LES-scale Doppler velocity signal statistics closer to the anticipated observed
257 instrumental signals (Matsui et al. 2014b). However, it should be noted that the exact sampling
258 methods are different between observations and simulations. For example, the RWP observations
259 are vertical pointing measurements that collect profiles at 6-second (“instantaneous”) intervals. In
260 contrast, the modeled RWP signals are drawn from a domain-wide sampling of hourly LES outputs.

261

262

263 **2.3 Thermal Tracking Algorithm**

264

265 The thermal tracking method used here is described in detail by Hernandez-Deckers and Sherwood
266 (2016), who improved the initial version used by Sherwood et al. (2013). It is an offline algorithm
267 that uses high temporal resolution output (~1 min) from LES to identify and track coherent rising
268 volumes of cloudy air, i.e., thermals. The algorithm first identifies all peak vertical velocities larger

269 than 0.8 m/s that have water condensate content of at least 0.01 g/kg at every available snapshot
270 of the simulation and matches peaks from successive snapshots to identify the available points of
271 the trajectories of rising cloudy air parcels. A third-order polynomial is fitted to these points to
272 reconstruct smooth trajectories and to allow a precise estimate of the ascent rate of the rising air
273 volume at each snapshot. Notice that this ascent rate differs from the actual vertical velocity at a
274 particular grid point since thermals develop internal toroidal circulations such that the peak vertical
275 velocity at their centers is higher than the actual ascent rate of the air volume (e.g., Blyth et al.
276 2005; Sherwood et al. 2013).

277
278 The extent of each rising air volume (the size of each thermal) is estimated assuming a spherical
279 shape centered at its smoothed trajectory, ensuring that the average vertical velocity of the enclosed
280 volume matches that obtained from the derivative of the trajectory. Tracked thermals must fulfill
281 certain requirements; for example, they must be tracked for at least three time steps, their radius
282 must be larger than twice the horizontal grid spacing, their time-average ascent rate must be at
283 least 1 m/s, their change in size in between successive snapshots must be less than 80% of the
284 smallest radius, and most importantly, their trajectories must be consistent with their vertical
285 momentum budget. The momentum budget of a tracked thermal is computed from its buoyancy
286 (obtained from the density field), the pressure gradient force (obtained by integrating the pressure
287 field over the entire thermal's surface), a "resolved mixing term" (obtained from the convergence
288 of vertical momentum flux across the thermal's surface), and an entrainment or detrainment
289 contribution due to the change in size between snapshots. This allows us to compute the expected
290 final position of each thermal based only on its initial ascent rate, which is compared with the
291 thermal's last tracked position. The distance between the actual and expected final positions must
292 be smaller than the average thermal diameter and smaller than 20 % of the vertical distance
293 traveled; otherwise, the thermal is discarded.

294
295 Once thermals are tracked with this algorithm, many properties can be studied based on all
296 available model variables of interest. For example, average values for each thermal, such as ascent
297 rate, size, altitude, entrainment rate, etc., are easily computed. Also, composites of different
298 quantities can be obtained for different "stages" of a thermal's lifecycle. Typically, thermals exhibit
299 one maximum ascent rate throughout their lifetime, which indicates their most vigorous phase.

300 This time step is used as a time reference common ($t=0$) to all thermals to create composites of
301 various properties at different stages of thermal lifetimes. [Note that our tracking algorithm cannot](#)
302 [analyze merging or splitting thermals, regardless of their occurrence. This limitation requires](#)
303 [further study.](#)

Formatted: Font: (Default) Times New Roman, 12 pt

Formatted: Font: (Default) Times New Roman, 12 pt

Formatted: Font: (Asian) Arial, 11 pt

304
305 This thermal tracking algorithm was first used to study the main properties of cumulus thermals in
306 simulations of transient-growing convection (Sherwood et al., 2013; Hernandez-Deckers and
307 Sherwood, 2016) and provided strong evidence that thermals are typically small, short-lived (4-5
308 minutes on average), and mix vigorously with their environment. Also, Hernandez-Deckers and
309 Sherwood (2016) showed that the spherical shape approximation is generally valid and that
310 thermals, rather than plumes, are a more realistic building block for cumulus clouds. Hernandez-
311 Deckers and Sherwood (2018) used this algorithm to study the mixing properties of thermals in
312 more detail and contrast them with known parameterizations. Results from these studies have set
313 up the stage for a deeper understanding of cumulus dynamics and for further studies that use
314 different approaches (e.g., Gu et al., 2020; Morrison et al., 2020; Peters et al., 2020; Xu et al.,
315 2021; Morrison et al., 2023). Recently Hernandez-Deckers et al. (2022) used this algorithm to
316 study aerosol-deep convection interactions, highlighting the importance of the strong coupling
317 between microphysics and small-scale dynamics in convective clouds. Here we run this tracking
318 algorithm with the GCE model output for 5 hours starting at 1900Z (3 pm local time) on 09/07/14
319 (dry case) and 02/26/14 (wet case), using 1-minute interval output.

320
321

322 3. Results

323

324 3.1 Dry-Wet Contrast of Large-Scale Forcing

325 Campaign atmospheric thermodynamic profiles and the typical variability observed during
326 GoAmazon dry and wet seasons have been previously depicted using composite radiosonde skew-
327 T log-P diagrams (e.g., Giangrande et al., 2017, 2020, 2023). These depictions often show very
328 similar temperature profiles between dry and wet seasons, whereas the moisture profiles indicate
329 apparent differences, highlighting the mid-level deficit of the dew-point temperature profile in dry-

330 season composites. Since this study utilizes LSF to drive LESs, seasonal thermodynamics and
331 dynamics are re-characterized by the LSF (Tang et al. 2016).

332
333 In Fig. 1, we plot a time series of apparent moisture sinks (Q_2), vertical moisture advection, and
334 parcel potential buoyancy profiles with surface precipitation rate from GoAmazon LSF for the
335 IOPs. These time series of LSF profiles are integrated and contrasted in terms of Contoured
336 Frequency by Altitude Diagrams (CFADs, Yuter and Houze 1995) as the dry and wet season IOPs
337 (Figure 2).

338
339 Here, Q_2 is the sum of changes in moisture content, horizontal moisture advection, and vertical
340 moisture advection (Yanai et al. 1973), balanced with net condensation rate and turbulent transport
341 of moisture vertical advection. Large Q_2 corresponds to a large atmospheric moisture loss due to
342 net condensation loss (i.e., precipitation). Large Q_2 is associated with intervals with heavier or
343 more widespread surface precipitation; thus, dry-IOP Q_2 and surface precipitation are typically
344 smaller than wet IOP (Fig. 1a-b). Similarly, Figs. 1c-d shows that peaks of vertical moisture
345 advection term coincide with those peaks in the Q_2 rate. Note that the Q_2 rate in tropical
346 environments is mainly contributed by the vertical moisture advection term rather than the
347 horizontal advection term (not shown here). More importantly, positive (red shade) vertical
348 moisture advection of the wet IOP tends to be stretched up to higher altitude (up to 200 mb) than
349 the dry IOP (up to 600 mb) in most cases.

350
351 As previously discussed by Tang et al. (2016), the associated Amazon Q_2 CFADs show the largest
352 positive Q_2 between 700 and 400 mb, while the largest negative Q_2 is around 800 mb (Figs. 2a-
353 b). The Dry-wet composite CFAD highlights more frequent positive Q_2 values above the 800 mb
354 level during the wet IOP. In contrast, more frequent negative Q_2 during the dry IOP (Fig. 2c).
355 Vertical moisture advection depicts similar CFAD shapes (Figs. 2d-e). Still, it highlights high
356 frequencies of low-level positive vertical moisture advection and mid-to-low-level negative
357 moisture vertical advection in the dry IOP in comparison with the wet IOP.

358
359 Finally, in Figs. 1e-f we plot the time series of parcel potential buoyancy profiles (positive
360 components only), computed from LSFs by lifting surface airmass dry and moist adiabatically.

361 These potential buoyancy magnitudes are not necessarily associated with precipitation intensity.
362 Potential buoyancy CFADs show peak forcing between the 600 mb and 200 mb levels (Figs. 2g,
363 h, & i). The wet IOP suggests a larger variability of potential buoyancy at the upper troposphere
364 than the dry IOP (Figs. 2g-h). Potential buoyancy appears to be slightly stronger in the dry IOP,
365 and concentrated in a relatively lower troposphere than its wet IOP counterpart (Fig. 2i), which
366 agrees with findings in Giangrande et al. (2023). These results will be further discussed along the
367 thermal concentrations in the latter section.

368
369

370 3.2 Dry-Wet Composite of Doppler Velocity CFADs

371

372 Giangrande et al. (2023) highlighted dry-wet seasonal characteristics of storm vertical air motions
373 retrieved using RWP. They found that daytime isolated dry season convective cells tend to have
374 stronger updrafts at altitudes below the melting level. Yet, unlike their wet-season counterparts,
375 updrafts do not increase in intensity much above the melting layer. However, dry-season
376 convective cores were also characterized by stronger downdrafts at all altitudes, especially when
377 compared to wet-season counterparts aloft. Our present study utilizes similar direct measurements
378 of the mean V_{dop} from RWP to characterize the dry-wet contrast of deep convective cores. The
379 advantage of using V_{dop} measurements is that the quantity is the direct radar measurement and
380 helps reduce uncertainties from retrieval assumptions, such as requiring hydrometeor
381 identification or associated terminal fall speed corrections if the intent was to retrieve the vertical
382 air motion (Giangrande et al. 2013, 2016). Here, vertically-pointing V_{dop} measurements contain
383 sufficient information to evaluate storm characteristics, with the understanding that these
384 measurements represent the terminal velocities of hydrometeors combined with the vertical air
385 motion.

386

387 In Fig. 3a, we provide the cumulative sample numbers of CFADs (for each bin of V_{dop} and altitude)
388 as simulated and subsampled from the LES hourly outputs from the combined dry and wet season
389 IOPs. If the sampling numbers are normalized for each altitude, ~~the V_{dop} CFADs will be formed.~~
390 Fig. 3b shows the sum of hydrometeor mass concentrations from each V_{dop} -altitude bin. Namely,
391 each hydrometeor mass concentrations from “cloud”, “rain”, “graupel-plus-hail”, or “ice-plus-

Formatted: English (US)

Deleted: is will form the V_{dop} CFADs to follow

393 snow” are separately accumulated for each bin. The larger number of samples associated with a
394 larger accumulated mass concentration of hydrometeor can generate the “representativeness” of
395 the hydrometeor class for a given V_{dop} -altitude bin location. Because V_{dop} is the sum of the vertical
396 velocity of the air and the terminal velocity of hydrometeor particles weighted by their reflectivity,
397 this plot facilitates understanding V_{dop} CFAD.

Formatted: Font: (Default) Times New Roman, 12 pt

Deleted: Because V_{dop} is the sum of the vertical velocity of the air and the terminal velocity of hydrometeor particles weighted by their reflectivity, this plot facilitates understanding V_{dop} CFAD.

398
399 As mentioned above, we defined four regimes based on the accumulated mass of each hydrometeor
400 category. The “cloud” category (CL) is centered around -5 m/s of V_{dop} and 4 km altitude, slightly
401 overlapping with other categories. A “rain” category (RA) is more narrowly concentrated around
402 -8 m/s of V_{dop} and below 4 km altitude. The “graupel-plus-hail” category (GH) is centered around
403 -14 m/s of V_{dop} at 5 km altitude. Finally, an “ice-plus-snow” category (IS) is narrowly concentrated
404 along -1 m/s of V_{dop} above 5 km altitude. These locations roughly correspond to each hydrometeor
405 category's altitude and terminal velocity when factoring in the background/ambient vertical air
406 velocity. Note that our “cloud” regime has no terminal velocity in GCE 4ICE microphysics, thus
407 V_{dop} represents or tracks the background vertical air velocity and overlaps with the other regimes.
408 Moreover, simulated V_{dop} and hydrometeor statistics are also sensitive to model physics and those
409 assumptions to some degree. For example, any real-world cloud regime may be extended to higher
410 altitudes, but the model 4ICE microphysics scheme tends to quickly convert cloud liquid to cloud
411 ice category due to saturation adjustment (See Figs. 14-16 of Matsui et al. 2023). Nevertheless,
412 this representative mapping will help discuss the variability of the V_{dop} CFADs between the dry
413 and wet season IOPs.

414
415 In Fig. 4, we provide an observed and simulated climatology of V_{dop} CFADs as sampled from deep
416 convective cores and summarized over the dry and wet season IOPs. In both the dry and wet season
417 IOPs, the observed CFADs depict a smoother transition of the V_{dop} at the freezing level into the
418 melting layer (4-5 km, Figs. 4a-b). At the same time, simulations show a more abrupt transition
419 around the freezing layer (Figs. 4d-e). This is primarily because bulk single-moment microphysics
420 more abruptly converts solid to liquid phases through autoconversion than explicit bin-resolving
421 microphysics (Iguchi et al. 2014). This rapid conversion also overestimates the terminal velocity
422 of raindrops near and just below the freezing level. Another possible reason is overestimating the
423 graupel/hail size, leading to larger melted raindrops with high terminal velocity.

Formatted: Font: (Default) Times New Roman, 12 pt

428
429 The CFADs have been summarized according to dry and wet season IOPs to explore these seasonal
430 contrasts between the deep convective cores (Figs. 4c, 4f). In the R regime (green box), the dry
431 IOP suggests more prevalent samples in strongly negative V_{dop} for our observations and
432 simulations, indicating that deep convective cores during the dry season IOP tend to have more
433 vigorous, faster-falling (larger) raindrops. In the GH regime (purple box), the dry season IOP
434 dominates the sampling. The observations indicate this dominance (red shade) up to 10 km altitude
435 (the extent that observations were included), while the simulation shows this behavior up to 8 km,
436 suggesting LES underestimation in graupel/hail altitudes. In the CL regime, the observations and
437 the simulations agree well, except that some sampling is overwhelmed by the dry season IOP
438 behaviors in the overlapped area. This likely indicates a shift in the presence of stronger low-level
439 updraft velocities, consistent with the analysis in Giangrande et al. (2023).

440
441 When considering the IS regime, there are examples of agreements and discrepancies between the
442 observations and simulations. One key agreement is that the wet IOP dominates the samples in the
443 area of positive V_{dop} above 8 km altitude. This indicates that observations and simulations suggest
444 a shift towards stronger upper-level vertical air velocity for the wet season IOP examples than for
445 the dry season IOP. This is consistent with the absence of dry mid-levels and the stochastic updraft
446 model expectations from Giangrande et al. (2023). On the other hand, the observations indicate a
447 more dominant sampling of velocities during the wet season IOP at around -3 m/s of V_{dop} , whereas
448 simulations change the dominant sampling mode from wet to dry IOPs at around 7 km altitude.
449 This is a potential bias in single-moment bulk microphysics, which tends to glaciate cloud droplets
450 or raindrops more quickly into ice particles than double-moment schemes (e.g., Fig. 16 of Matsui
451 et al. 2023). The observed composite also shows more dry-season dominant frequencies in GH
452 zones than the simulation, indicating the underestimation (overestimation) of raindrop/graupel
453 (ice/aggregate) particles above 7 km height.

454
455 Excepting this discrepancy in the IS regime, dry-wet composites of V_{dop} CFAD agree well between
456 observations and simulations, suggesting that LES could successfully represent the important
457 nature of dry-wet contrast, i.e., dry-season convection tends to generate stronger low-level updraft

Deleted: As before, t

459 velocity, generating more graupel/hail, and vigorous raindrops accompanied with stronger low-
460 level downdraft than the wet season.

461

462 To further investigate these seasonal shifts in core properties, golden cases are selected to analyze
463 deep convection lifecycle and processes. ~~Golden cases are two single-day simulation cases, one
464 for dry and one for wet season, representing V_{dop} CFADs of each season.~~ For this, the V_{dop} CFADs
465 are constructed for each day during the wet and dry season IOPs, and these daily CFADs are
466 compared to the composites of seasonal CFADs (not shown here). After day-to-day analysis of
467 correlation and root-mean-square errors between daily and seasonal CFADs, the convective event
468 on the 2/26/14 case is selected to represent the wet IOP convections. In contrast, the 9/7/14 case is
469 chosen to represent dry IOP convection. Fig. 5 shows a dry-wet composite of V_{dop} CFAD using
470 these two case studies. This figure compares quite well with the seasonal composite of V_{dop} CFAD,
471 having the dry convective vigor signals and model biases of the seasonal composite (Fig. 4f).

472

473 In Fig. 6, we show a time series of domain-mean profiles of convective cores drawn from these
474 dry- and wet-season golden cases, highlighting from 1600Z (1200 local time) of the starting day
475 to 0400Z (0000 local time) of the next day. The dry season golden event shows a clear diurnal
476 convection cycle, peaking at 2100-2200Z (local 5-6 pm). In contrast, the wet season golden event
477 shows an already ongoing, continuous sequence of deep convection with several embedded strong
478 pulses. Convective top heights reach up to 17 km for both the dry and wet events (Figs. 6a-b).
479 Low-level positive upward vertical velocity is more ubiquitous in the dry case, while upward
480 vertical velocity of the wet case extends to the middle-to-upper troposphere up to 15km (Figs. 6c-
481 d).

482

483 Dry-case graupel-plus-hail (GH) mass concentrations peak around 2100-2300Z when the
484 convective clouds reach their deepest cloud top heights, and the maximum GH concentration
485 exceeds that of the wet case. Rain mass concentrations peak between 2200Z and 00:30Z on the
486 subsequent day for the dry case, and this appears to be slightly more intense than the rainfall
487 simulated for the wet cases. Note that precipitation areal fraction is expected to be larger for the
488 wet season (i.e., Giangrande et al. 2016, 2023), such that dry-season convection is often
489 characterized by narrow yet intense isolated convection, while wet-season convection is

Formatted: Font: (Default) Times New Roman, 12 pt

Deleted: Namely, we select two single-day simulation cases representing typical dry and wet-season convection.

492 characterized by widespread moderate to deep convection (although with higher domain mass
493 flux). The intense surface rainfall rates are generally correlated with the generation of graupel,
494 frozen drops, and/or small hail particles during the dry-season convection, but there are some time
495 lags from 21Z to 22:50Z in the dry-case convection. This is because the initial convective core is
496 much narrower, and near-surface relative humidity is slightly low (~80%) around 21Z, and later
497 convective area increases so as near-surface relative humidity (~96%) around 21:50Z. Thus, more
498 surface rain evaporation likely suppresses surface precipitation during earlier convective periods.
499 These time series behaviors are generally consistent with the observed characteristics in the time-
500 integrated V_{dop} CFADs (Fig. 5).

501
502 One key question is why larger or heavily rimed particles tend to be preferentially generated in
503 dry-season convection compared to wet-season convection, given that both seasons indicate
504 convection with intense updraft velocity. This question follows previous efforts of Williams and
505 Stanfill (2002) for simulations of deep convection that contrasted land and oceanic clouds. For
506 example, while land and ocean environments may have similar convective available potential
507 energy (CAPE), differences in detailed potential buoyancy and vertical velocity profiles enable
508 additional graupel/hail particles to form in continental deep convection when compared to the
509 maritime environments (Matsui et al. 2020). A Lagrangian tracking analysis is performed to
510 examine this question for Amazon dry and wet season contrasts to investigate the dynamics and
511 microphysics within cumulus thermals for these dry and wet golden events (Section 3.3).

512
513

514 **3.3 Thermal Tracking Analysis**

515
516 Thermal tracking analysis (Section 2.3) was conducted over 5-hour periods from 1900Z to 0000Z
517 for the dry and wet season events using 1-minute LES outputs. Fig. 7 depicts normalized x-z cross-
518 sections of thermal properties at the moment of maximum vertical velocity in the dry and wet cases
519 and dry-wet differences. Thermals typically experience development and decaying stages in their
520 lifetime. During development, moist thermals increase their vertical velocity and size by releasing
521 latent heat and entraining surrounding air (Morrison et al. 2021). After defining and tracking each
522 thermal from the LESs, our normalizing procedure first defines the reference time from each

523 thermal's lifetime based upon peak vertical air velocity (denoted as thermal maxima) and then
524 conducts a weighting average of each thermal property at the thermal maxima only. Our weights
525 are based on the magnitude of thermal mass flux to avoid under-representing properties of less-
526 populated but vigorous thermals. Because these heights at thermal reference time are different for
527 each thermal in dry and wet case studies, averaging properties are somewhat biased toward thermal
528 vertical distributions (discussed later).

529

530 For example, in Fig. 7a we plot the weighted-average peak vertical air velocity (W) for the dry-
531 case thermal (9.6 m/s) and the wet-case thermal (10.6 m/s). Perhaps surprisingly, the flux- and
532 radius-weighted average dry-case thermal is slightly slower in W than that found for the average
533 wet-case. Here, we find that the vertical air velocity of the wet-case thermal is more
534 homogeneously distributed than its counterpart for the dry-case thermal, leading to higher
535 weighted-mean W despite weaker values at thermal centers (red shade in Dry-Wet plot, Fig. 7a).
536 Also, unexpectedly, supersaturation and cloud droplet mixing ratio (Q_c) of the dry-case thermal
537 are elevated compared to the wet-case thermal (Fig. 6b-c), since wet-case thermals may be
538 expected to instead have higher supersaturation and/or more condensation owing to the higher
539 availability of water vapor (e.g., Giangrande et al. 2023).

540

541 Exploring the other classes, the rain mixing ratio (Q_r) is similar between the dry-case and wet-case
542 thermals (0.17 g/kg), but graupel-hail concentrations (Q_{g+h}) are significantly larger in the dry-
543 case thermals (0.95 g/kg) compared to the wet-case thermals (0.79 g/kg); this latter result is
544 consistent with previous discussions from event time-series in Fig. 6e. Cloud ice and snow mixing
545 ratio (Q_{i+s}) values are slightly larger in the wet-case thermal (3.5 g/kg) than in the dry-case thermal
546 (3.2 g/kg). While this difference is not significant, this is also potentially a surprising outcome
547 since dry-case deep convective clouds might otherwise be expected to be deeper/stronger and thus
548 characterized by additional ice hydrometeor concentrations. However, some absence of these
549 media may be partially explained by following Giangrande et al. (2020; 2023) suggestions that
550 drier mid-to-upper levels in the dry season may limit periphery precipitation aloft (i.e., enhanced
551 evaporation). Overall, Q_r and Q_{g+h} seem to be concentrated in these composite averages
552 downward from the thermal core due to the gravitational sedimentation process. Supersaturation
553 and Q_c , however, are also more vertically elongated than thermal properties established by

554 Hernandez-Deckers et al. (2022) using the Weather Research and Forecasting (WRF) model for a
555 case of scattered convection over Houston, Texas. Q_i+s is more homogeneously distributed across
556 the defined borders of thermals. Also, dry-wet differences show slight asymmetric results,
557 particularly in W, Qr, and Qg+h. These could be attributable to differences in horizontal wind
558 shear, evidenced by a greater tilt in the thermal centerline flow in the dry case (gray streamlines),
559 leading to greater concentrations in the tilt direction of more rapidly sedimenting quantities that
560 are formed within thermals (i.e., Qr and Qg+h); since thermal composites are not aligned with the
561 mean wind, such preferential outflow may not be fully captured by this analysis (i.e., asymmetric
562 signatures could be greater or lesser along other directions than X alignment).

563
564 An initial leading question is why the dry-case thermals have greater cloud water and
565 supersaturation on average. To further untangle these results in Fig. 7b-c, we derive the vertical
566 profiles of flux-weighted mean thermal states, now including all thermal times (Fig. 8a-g).
567 Immediately, these plots reveal striking differences between the thermal number concentration
568 (N) profiles for dry-case and wet-case examples (Fig. 8a; the number of thermals per km height
569 within the 102 km x 12.8 km domain). For instance, dry-case convection shows a larger
570 concentration of thermals below the 8 km height, while wet-case convection promotes a more
571 homogeneous thermal concentration that extends across most heights. This behavior is somewhat
572 reminiscent of the distribution for the difference in vertical moisture advection and potential
573 buoyancy profiles between the parent dry and wet season conditions (e.g., Fig. 1 and 2, discussions
574 in Section 3.1). Moreover, thermal generation in our LES responds to these terms partially from
575 the seasonal large-scale forcing.

576
577 According to the classic similarity theory of Morton et al. (1956), the width of [dry/moist](#) thermals
578 should increase with increases in the boundary layer depth (William and Stanhill 2002). For the
579 Amazon basin, previous GoAmazon studies such as Giangrande et al. (2017, 2023) showed that
580 dry season boundary layer height is generally deeper than that of the wet season, potentially on the
581 order of 200 m deeper for isolated deep convective events they tracked. Following this logic, dry-
582 case convection may anticipate larger thermals. However, LES thermal tracking analysis suggests
583 that the sizes (R) of thermals upon initiation appear to be quite similar between the wet and dry
584 events and then appear to grow at similar rates for several km before the dry-case thermal size

Deleted: f

586 catches up with the moist size around 6 km in height, only to be overtaken again by the deeper
587 wet-case thermals around 9 km (Fig. 7b). Further, Fig. 8c shows the mean vertical velocity of
588 thermals, showing nearly identical updraft velocity below 4 km. However mean updraft velocity
589 profiles above 4 km are quite different between the dry and wet cases; e.g., the dry case peaks
590 around 8 km, while the wet case peaks at 6 and 10 km. This result implies that differences in moist
591 convection between dry and wet cases are poorly characterized by thermal sizes.

Deleted: perhaps better characterized by thermal numbers rather than thermal sizes.

592
593 Q_c in thermals also shows very similar profiles between the dry and wet cases (Fig. 8d). However,
594 because thermal numbers of the dry case are more concentrated at the lower troposphere (Fig. 8a),
595 all-height mean properties of dry-case thermals are characterized by more Q_c (Fig. 7c). Q_r of the
596 wet case is nearly twice as large as the dry case (Fig. 8e); however, normalized x-z cross-section
597 (Fig. 7d) does not show such a large difference (explained below). Q_{i+s} also shows similar
598 distributions (Fig. 8f). Still, total x-z mean Q_{i+s} is larger in the wet case than the dry case due to
599 larger thermal numbers in the upper troposphere (Fig. 7e). Uniqueness appears in thermal Q_{g+h}
600 (Fig. 8g). While both dry and wet cases show similar magnitude of the peak values (~ 0.9 g/kg),
601 the peak height in the dry case is approximately 3 km higher than the wet case. This Q_{g+h} peak of
602 the dry case coincides with the peak of vertical velocity (Fig. 8c).

Deleted: c

Deleted: d

Deleted: e

Deleted: f

603
604 Fig. 8h-k displays these hydrometeor mixing ratios averaged over the same periods, including all
605 convective grids defined by vertical velocity greater than 1 m/s. Vertical profiles and dry-wet
606 differences are similar to the results in Fig. 6. However, compared with the in-thermal profile
607 results (Fig. 8d-g), it facilitates understanding of the convective core microphysics process. First,
608 mean in-thermal convective-grid hydrometeor concentrations are smaller than in-thermal profiles;
609 particularly in-thermal Q_c values are roughly six times larger than convective-grid average Q_c
610 (Figs. 8d & 8h), suggesting that thermals are major cloud droplet generators (Hernandez-Deckers
611 et al. 2022).

612
613 The convective-grid Q_{g+h} of the dry case is nearly twice as high as that in the wet case, peaked
614 around the melting layer (Figs. 8g & 8k), whereas in-thermal Q_{g+h} shows similar peak values
615 between the dry and wet cases. As indicated by Fig. 7g, these larger and heavier rimed particles
616 sediment from thermals and further collision with supercooled liquid must enhance the graupel

633 growth during the sedimentation process, as suggested from aircraft measurements (Blyth and
634 Latham 1993). Thus, elevated in-thermal Q_{g+h} in dry-case convection can have further riming
635 growth after falling out from thermals. This vigorous growth of Q_{g+h} in dry-case convection
636 eventually generates vigorous raindrops after the melting process. This could explain why
637 convective-grid Q_r in the dry case is larger than that in the wet case (Fig. 8i), opposite from the
638 result of in-thermal Q_r (Fig. 8e). Thus, in-thermal Q_r values are not directly related to total Q_r in
639 the convective core (or surface precipitation rate) because of this cold precipitation microphysics
640 process in deep convection.

641
642 A second leading question is why the height at the peak value of dry-case in-thermal Q_{g+h} is more
643 elevated than the wet-case thermal (Fig. 8g). Fig. 9 shows histograms of thermal properties from
644 the dry and wet cases. Consistent with the mean vertical profiles (Fig. 8a), more thermals are
645 initiated below 7 km in the dry case than in the wet case (Z0, Fig. 9d). Thermal radius in the wet
646 case is also larger than the dry case regardless of shallower boundary layer depths in the wet case
647 (Fig. 9a), consistent with R in thermal vertical profiles reaching larger sizes at most elevations in
648 the wet case (Fig. 8b). However, here we see that thermal vertical velocity (W, Fig. 9b), travel
649 distance (dZ, Fig. 9c), and lifetime (Fig. 9e) in the dry case are all greater than in the wet case.
650 Thermal entrainment rate is smaller in the dry case than the wet case. These results indicate that
651 the thermals in the dry-case deep convection can travel longer distances with an extended lifetime
652 due to a lesser dilution.

653
654 Interestingly, slightly smaller thermal radii in dry-case convection can have a lower entrainment
655 rate than in wet-case convection. Hernandez-Deckers and Sherwood (2018) also found that the
656 variability of thermal radius can only account for 20% of the total variance of thermal dilution rate,
657 i.e., larger thermal tends to have a lesser dilution rate. This was concluded through similar thermal
658 tracking analysis from different LESs. Therefore, thermal size is not the sole parameter for
659 determining dilution rate.

660
661 Giangrande et al. (2022) suggest that the convective area is smaller in dry-season convection over
662 this region. Thus, this indicates that stronger low-level buoyancy in dry-season environments can
663 more narrowly concentrate updraft and low-level thermals in the area, thus creating less diluted

Formatted: Font: (Default) Times New Roman, 12 pt

669 environments probably due to the impact of thermal drag (Roms and Charn 2015). This is merely
670 speculative and requires further investigation to confirm or refute. Takahashi et al. (2022)
671 investigated cloud-scale entrainment between continental and maritime environments and found a
672 larger dilution rate in maritime convection than in continental convection. Our results suggest that
673 this difference in cloud dilution happens from the thermal-process level. These conditions elevate
674 dry-case thermals and graupel peak concentration toward higher altitudes than the wet-case
675 convection (Fig. 7f), leading to greater graupel production.

676
677 Finally, time series of thermal properties in the x-z cross-section are constructed for the dry case.
678 For this, each thermal at its maximum w value is centered and defined as the time of zero, and
679 prior (later) steps are represented in negative (positive) time steps. Because of the 1-minute LES
680 output, the time series from -3 to 3 encompasses 7 minutes of time steps. This averaging process
681 also weighs upon the magnitude of the thermal mass flux (Hernandez-Deckers et al. 2022); thus,
682 thermals at larger values in positive and negative time steps tend to have a fewer sampling numbers.
683 Also, to make the composites, equal-sized thermals are sampled to characterize the mean time
684 series of thermal properties, avoiding sampling too small thermals, which often has no
685 supersaturation (Hernandez-Deckers and Sherwood. 2016). This normalization procedure ends up
686 with the result that maximum W values do not appear at reference time (t=0), but better capture
687 the evolution of the largest flux-bearing thermals (Fig. 10). We also note that a typical thermal
688 travel distance is 1.3 km (Fig. 9c) and a minority of dry-case thermals therefore contain either no
689 ice phase (Fig. 8e-f) or no liquid phase (Fig. 8c-d), but most contain both phases between 3 and 7
690 km. Note that this flux-weighting is the one way to present the results, while simple non-weighting
691 averaging can also show similar results.

692
693 In the dry case (Fig. 10), within thermals that experience an extended peak in W (6–11 m s⁻¹), the
694 average supersaturation, cloud, and rain mixing ratio peaks at the earlier steps and decreases
695 toward the end of the time steps. This indicates that a chunk of condensation heating is the main
696 initial driver of moist thermal growth. These thermal properties are typically centered around the
697 thermal core. By contrast, Qi+s properties are more homogeneous and less concentrated at the core
698 of thermals, and they tend to increase toward the end of the time series. Especially, the early stages
699 (t=-3, -2, & -1) indicate thermals are approaching an existing ice layer rather than generating ice

Formatted: Font: (Default) Times New Roman, 12 pt

Deleted: lesser

Deleted: ing

702 around the thermal core. In the later stages ($t=1, 2, \& 3$), the Q_{i+s} is weakly concentrated toward
703 the upper thermal cores. This evolution of Q_{i+s} suggests that thermals are not the main initiator of
704 Q_{i+s} ~~at the beginning~~, while Q_{i+s} is rather entrained into the thermal within the early stages of the
705 mixed-phase zone, at least using the single-moment bulk microphysics. On the other hand, after
706 liquid saturation is no longer contributing substantially to Q_c , Q_{i+s} becomes a leading destination
707 of the overall transfer from vapor to hydrometeor phases within thermals that remain vigorous,
708 ~~probably due to the Bergeron process (Bergeron, 1935). Further research is needed to investigate~~
709 ~~the ice nucleation and growth process in greater detail throughout the different stages of thermals'~~
710 ~~lifecycle.~~

711
712 On the other hand, Q_{g+h} increases toward the peak time of thermals ($t=0$), and starts decreasing
713 toward the later time steps ($t=3$). The spatial concentration of Q_{g+h} is also peaked around the
714 thermal cores, similar to W , rh , Q_c , and Q_r . The increase of Q_{g+h} coincided with the timing of
715 thermal entrainment of Q_{i+s} and a reduction in Q_c and Q_r for time steps between -3 and 0 . This
716 suggests that large concentrations of in-thermal Q_c and Q_r collide with entrained Q_{i+s} to enhance
717 the riming process, generating graupel and hail particles ~~at the thermal core. Note that the 4ICE~~
718 ~~scheme only allows wet growth (collecting supercooled liquid) of graupel, while dry growth~~
719 ~~(collecting ice and aggregate) of graupel has been suppressed due to unrealistic graupel in~~
720 ~~convective anvil (Lang et al. 2014).~~ After the reference time step ($t=0$), Q_{g+h} decreases, most
721 likely due to sedimentation exceeding production. As indicated by Fig. 8g & 8k, this spilled
722 graupel and hail can further grow by colliding with supercooled liquid particles until melting.
723 Taken together, this analysis also suggests that this vigorous Q_{g+h} -generation process in the
724 convective core *does not* occur through the classic parcel-driven convection. Instead, these graupel
725 and hail generations are most likely driven by sequential interactions of thermal ensembles and
726 microphysical processes. Note that the time series of the wet case also shows a similar finding but
727 is biased toward the thermals in the upper atmosphere (not shown here).

728
729 ~~In addition to reference time, we composited thermal properties at different altitude levels (Fig.~~
730 ~~11). The method for sampling and compositing is the same as in Fig. 10. However, it characterizes~~
731 ~~vertical profiles of thermal composites using altitude references from 2.5km up to 10.5km,~~
732 ~~including the mean air temperature.~~ ~~Despite of different reference methods, altitude-reference plots~~

751 appear to be similar patterns to time-reference plots. Vertical velocity (W) increases toward the
752 peak level at 8.5 km, similar to the mean profile in Fig. 8c. There is strong supersaturation (S)
753 between 4.5 km and 6.5 km, which rapidly decreases above 8.5 km. Q_c , Q_r , Q_{i+s} , and Q_{g+h}
754 profiles also resemble thermal-mean profiles in Figs. 8d, 8e, 8f, and 8g, respectively. In thermal
755 cores, Q_c , Q_r , and Q_{g+h} are initially concentrated but sediment as thermals ascend. Even
756 compared with the lifetime composite in Fig. 10, Q_{i+s} are more stratified horizontally rather than
757 toward thermal cores, particularly from 3.5 km to 6.5 km, suggesting entrainment of Q_{i+s} within
758 thermals at these altitudes. Simultaneously, Q_c and Q_r decrease while Q_{g+h} increases at these
759 altitudes. Because wet growth (ice collecting supercooled liquid) is the primary graupel growth
760 process within 4ICE microphysics in the GCE (Lang et al. 2014), the droplet-loaded thermal
761 penetration toward ice layers appears to be the important graupel/hail generation process within
762 tropical deep convection.

764 4. Conclusion: Thermal-driven Convection Invigoration Process

765
766 We have investigated seasonal differences of the measured and simulated V_{dop} between the dry
767 and wet seasons to confirm dry-season convective vigor associated with enhanced cold
768 precipitation (graupel and hail) processes. Tracked thermal properties from the selected case
769 studies reveal unique updraft microphysics processes in the convective core that explain the dry-
770 wet contrast in deep convection. To summarize our findings in graupel-hail development
771 sequences, a thermal-driven process is proposed in the following steps (Fig. 12a).

- 772
773 1. Where condensation may occur within moist turbulent structures in the lower atmosphere,
774 local moist thermals may be initiated, which are characterized by dipole vortex rings with
775 intense vertical velocity, supersaturation, cloud droplets, and raindrops around the thermal
776 core.
- 777 2. When moist thermals penetrate the 0°C isothermal layer and dissipate in the mixed-phase
778 zone, cloud droplets are detrained and gradually glaciated to form ice-particle layers.
- 779 3. As additional thermals fill with droplets at the thermal core and penetrate the glaciated
780 mixed-phase zone, they entrain ice particles and collide with each other, generating graupel
781 and hail embryos.

Deleted: In addition to reference time, we composited thermal properties at different altitude levels (Fig. 11). The method for sampling and compositing is the same as in Fig. 10. However, it characterizes vertical profiles of thermal composites using altitude references from 2.5km up to 10.5km. Despite of different reference methods, altitude-reference plots appear to be similar patterns to time-reference plots. Vertical velocity (W) increases toward the peak level at 8.5 km, similar to the mean profile in Fig. 8c. Strong supersaturation (S) are present from 4.5 km to 6.5 km., but rapidly decreases above 8.5 km. Q_c , Q_r , Q_{i+s} , and Q_{g+h} profiles also resemble thermal-mean profiles in Figs. 8d, 8e, 8f, and 8g, respectively. In-thermal Q_c , Q_r , and Q_{g+h} are concentrated at the thermal cores initially but sedimented as thermals ascend. Only Q_{i+s} are more homogeneously distributed around thermal boundaries. ¶

Deleted: 1

799 4. Once graupel and hail particles grow sufficiently large, they start falling out from thermals
800 and develop further by collecting supercooled droplets and ice particles during
801 sedimentation.

802
803 The process of generating ice layers (Step 3) could be the largest source of uncertainty in this study.
804 To prove the convective vigor process, this study used the simple bulk single-moment
805 microphysics parameterization (Lang et al. 2014, Tao et al. 2016). This parameterization tends to
806 convert droplets into ice particles through the saturation adjustment process. Cloud droplets are
807 glaciated much more quickly when compared to two-moment microphysics (e.g. Matsui et al.
808 2023). Time series as well as altitude reference composite also shows some ice generation within
809 the thermal core in later lifecycle stages (~10 km altitude), which may be associated with the
810 Bergeron process. Yet, ice crystal formation processes remain one of the largest sources of
811 microphysics uncertainty (Kanji et al. 2017; Korolev and Leisner 2020) and need further
812 investigation to establish with adequate parameterizations. Furthermore, updrafts passing through
813 the melting layer containing both large drops and ice crystals (which are identified here as a source
814 of graupel) have also been pinpointed as a leading source of secondary ice production in oceanic
815 convection sampled extensively via aircraft (Korolev et al. 2020). Thus, all quantitative
816 components of the proposed ice-graupel generation process described here remain uncertain and
817 subject to future investigations via instrumental observations and more detailed numerical
818 simulations.

819
820 Nonetheless, building on the ability of existing knowledge and simulations to reproduce some
821 basic features of observations during GoAmazon, Fig. 12b shows a newly proposed process that
822 can explain why dry-season convection has more graupel and intense precipitation than wet-season
823 counterparts in the following steps.

- 824 1. Dry-case (wet-case) convection tends to generate more (less) numbers of droplet-loaded
825 thermals from the lower atmosphere because of larger potential buoyant energy at a low
826 level in the dry season.
- 827 2. Once an ice layer is built from initial cumulus thermal ensembles (Fig. 11a), more (less)
828 numbers of droplet-loaded thermals penetrate ice layers to generate more (less) graupel and
829 hail embryos in dry-case (wet-case) convection.

Deleted: ¶

838 3. Individual dry-case (wet-case) thermals can rise to higher (lower) elevations via weaker
839 (stronger) dilution with faster (slower) updraft, elevating in-thermal graupel at higher
840 (lower) altitudes.

841 4. During sedimentation, graupel in dry-case (wet-case) thermals has a higher (lower) chance
842 to grow due to the longer (shorter) distance toward the melting level.

843 These new processes are proposed from the “golden” cases from the dry and wet seasons. Further
844 investigation with more case studies will augment our hypothesis in the future.

845
846 The “hotter” surface in the dry season must be the physical origin of step 1, similar to L-O contrast
847 (William and Stanfill, 2002). The dry season typically has clearer skies, less soil moisture, and
848 stronger surface heating, leading to more turbulent heat flux and energy at the lower troposphere
849 even during GoAmazon experiment (Biscaro et al., 2021; Ghate and Kollias, 2016). In contrast,
850 the wet season is characterized by frequent precipitation and increased release of atmospheric
851 latent heat with the weak surface sensible heat flux caused by wet soil moisture (Rocha et al.,
852 2004). As a result, the entire troposphere experiences upward motion during the wet season, unlike
853 its dry season counterpart (Tang et al., 2016).

854
855 Contrary to the speculation made by William and Stanfill (2002), it has been found that stronger
856 surface heating and deeper PBL during the dry season do not increase the thermal "size" based on
857 the classic similarity theory of Morton et al. (1956). Instead, our analysis of simulations indicates
858 that the numbers, and updraft velocity profiles of cumulus thermals become more important,
859 particularly those initiated in the lower troposphere. Even for similar CAPE, the concentration of
860 potential buoyancy profiles in the lower troposphere can trigger more vigorous convection. This
861 is similar to the difference between mid-latitude continental and tropical maritime environments,
862 where the mid-latitude continental environment tends to have more potential buoyancy in the mid-
863 to-lower troposphere, leading to continental convective vigor (Matsui et al., 2020). For this, we
864 need to investigate boundary layer dry thermals and deep-convective moist thermal seamlessly
865 between various continental and maritime environments.

866
867 It is also hypothesized that the low-altitude concentrated cumulus thermal trains could additionally
868 enhance the cold precipitation process by improving the residence time of graupel and hail within

874 the mixed-phase zone if thermal-spilled graupel and hail encounter subsequent new cumulus
875 thermals. Previous trajectory modeling (Heymsfield 1983) also suggested a similar mechanism for
876 enhancing graupel and hail residence time and growth by multiple convective cores. Heymsfield
877 (1983) used the multi-Doppler technique to generate a three-dimensional wind field, but it needed
878 more spatio-temporal resolution to characterize cumulus thermal. However, a stronger updraft core
879 mentioned in his study must be cumulus thermals. This investigation further requires a more
880 complex set of numerical simulations in the future.

881
882 The proposed thermal-driven invigoration process is based solely on thermodynamics and does
883 not consider aerosols' effect on deep convection, as demonstrated by previous studies over the
884 Amazon (William et al. 2002, Lin et al. 2006). Our choice of single-moment microphysics does
885 not consider the variability of background aerosols to initiate cloud droplets. However, this simple
886 microphysics can generate a fundamental dry-wet contrast characterized by the V_{dop} statistics. This
887 suggests that thermodynamics is the primary factor determining convective vigor, while aerosols
888 may have a significant but secondary role in invigorating convection (Matsui et al. 2020). Future
889 studies will require a higher-order moment of microphysics scheme to examine the impact of
890 aerosols on droplet and primary ice nucleation in thermals to confirm our hypothesis that dry-wet
891 aerosol contrast plays a secondary role.

892
893 It is well known that severe hailstorms and large hails are more frequently observed over the central
894 plains of North and South America (Liu and Zipser 2015, Bang and Cecil 2019). The hailstorms
895 in these regions are often associated with supercells, and mesocyclones play a crucial role in the
896 growth of very large hail by enhancing the residence time of the hails within the mixed-phase zone
897 (e.g., Nelson 1983; Ziegler et al. 1983). However, it is not known how a mesocyclone affects
898 thermal-like or plume-like updraft characteristics (Morrison et al., 2020), though satellites have
899 captured thermal chain-like periodic overshooting signals at the top of the supercells (Borque et
900 al. 2020). Thus, further observational and modeling investigations are required for the mid-latitude
901 regions to determine whether our proposed graupel/hail generation mechanisms can be applied.

902
903 The proposed process for graupel-hail generation and convective vigor is a time-dependent,
904 sequential, coupled dynamics-microphysics process. Although the traditional plume-based mass

Formatted: Font: (Default) Times New Roman, 12 pt

Formatted: Font: (Default) Times New Roman, 12 pt

905 ~~flux scheme has been successful in representing the moist convection process in climate models~~
906 ~~(e.g., Arakawa and Schubert 1974), our proposed convective microphysics process is not linear~~
907 ~~and cannot be adequately represented by the traditional convective mass flux method.~~ To represent
908 this process, thermal chain concepts with detailed microphysics processes must be introduced in
909 the parameterization for large-scale models (Morrison et al., 2020). Fine-resolution simulations
910 produce better continental convective vigor because they can resolve thermal dynamics and
911 microphysics (Robinson et al., 2011; Matsui et al., 2020). The mean radius of the tracked thermal
912 in this study, conducted using a 200 m mesh LES, is around 1 km, with a maximum size of around
913 2 km, which is comparable to the LES study using a 65-m horizontal grid spacing (Hernandez-
914 Deckers and Sherwood, 2016). However, due to the effective resolution being 5-10 times the actual
915 grid spacing, cumulus thermals, and graupel-hail generation processes are difficult to resolve for
916 storm-resolving models and perhaps any ~~coarser~~ Eulerian-type numerical atmospheric models
917 (Matsui et al., 2016). Conducting LES for regional and global weather and climate models is
918 impractical in the foreseeable future. Therefore, new types of dynamics-microphysics-coupled
919 cumulus thermal parameterization should be developed to better represent deep convection for
920 storm-resolving and coarse-resolution weather and climate models.

921
922 New ground-based Doppler phased array radar (PAR) technology (Kollias et al. 2022b) or multi-
923 Doppler agile scans (Kollias et al. 2022a) hold promise in observing and characterizing cumulus
924 thermals. Emerging PAR instruments have started capturing storm motion and microphysical
925 details at spatial and temporal resolutions akin to those seen in LES output (e.g. Takahashi et al.
926 2019, Kikuchi et al. 2020). These new observational capabilities are necessary for refining the
927 dynamics and microphysics in LESSs, particularly in elucidating the process behind thermal-driven
928 convective vigor. Moreover, the advent of vertical motion estimates from high-resolution space-
929 based radars [EarthCARE, Wehr et al. 2023; Investigation of Convective Updrafts (INCUS),
930 <https://incus.colostate.edu>; the Atmosphere Observing System (AOS), <https://aos.gsfc.nasa.gov>)
931 will soon enable the global mapping of convective updrafts. These new satellite radar
932 measurements will generate a comprehensive global catalog detailing convective vigor and the
933 speed of intense thermals.

1317
 1318 Figure 7. Cross sections along the x-z plane of flux-weighted thermal values of (a) vertical velocity
 1319 (W), (b) supersaturation (S), (c) cloud droplet mass concentration (Q_c), (d) rain mass concentration
 1320 (Q_r), (e) ice and snow mass concentration (Q_{i+s}), and (f) graupel and hail mass concentration
 1321 (Q_{g+h}), for composites of all tracked thermals at the point of their maximum vertical velocity,
 1322 scaled by their radius (horizontal and vertical coordinates are in units of mean thermal radii). Left,
 1323 middle, and right column corresponds to the dry-season golden case, the wet-season golden case,
 1324 and dry-wet case difference, respectively. Upper left values in each panel are the flux- and radius-
 1325 weighted mean over all samples. Arrows indicate the average flow streamlines in the rising thermal
 1326 reference frame. The dashed contour in supersaturation values corresponds to 100% relative
 1327 humidity. These are reference-time ($t=0$) mean values.
