Abstract. Airborne measurements of wind speed and direction, temperature (T), and relative humidity (RH) are critical due to their importance for atmospheric processes. Field campaigns with multiple coordinated aircraft present challenges when combining data from each platform due to atmospheric heterogeneity. To confront this issue, this work intercompares for the first time in situ measurements from the Turbulent Air Motion Measurement System (TAMMS) of horizontal winds and T, and a diode laser hygrometer (RH) deployed on a HU-25 Falcon flying mostly within the marine boundary layer over the northwest Atlantic to an independent set of measurements from dropsondes launched from a higher-flying King Air. Leveraging data from 162 joint flights from these two spatially coordinated aircraft during the NASA ACTIVATE campaign in winter and summer seasons between 2020-2022, a total of 555 pairs of Falcon-dropsonde data points are identified within 30 km horizontal separation, minimal vertical separation (usually < 1 m), and within 15 minutes. This analysis is based on the following range of conditions experienced: altitude = ~0.1-5 km; T = -19 – 27 °C; RH = 1 – 100%; wind speed = 0.2 – 42 m s⁻¹. Based on scatterplots, correlation coefficients, and mean (in situ – dropsonde) error (ME), intercomparisons reveal good agreement for wind speed ($r = 0.95$, $ME = 0.21 \pm 1.68 \text{ m s}^{-1}$), the u/v wind components ($r \sim 0.96$ -0.97, $ME \sim 0.03 - 0.16 (\pm 1.62 - 1.67) \text{ m s}^{-1}$), wind direction ($r = 0.94$, $ME = 0.00 \pm 0.22$ based on cosine of direction angles), T ($r = 0.99$, $ME = 0.00 \pm 0.71 \text{ °C}$), and RH ($r = 0.91$, $ME = -3.86 \pm 10.74\%$). Sensitivity analysis shows that binning data into categories of horizontal separation distance, clear versus cloud, winter versus summer, altitude range, and terciles of the values for examined variables did not yield major changes except for RH where there was more deviation especially above 70%. The effect of statistics was examined by relaxing the vertical separation distance criteria to expand the number of pairs to over 360,000, without much difference in intercomparison metrics. The effect of averaging more points for each instrument in the final 555 pairs was also shown to lead to minimal change in agreement. Overall, these results provide confidence in both the performance of the

measurement techniques compared and combining dropsonde data with in situ data from a separate coordinated aircraft for
ACTIVATE, which has relevance to other campaigns with multiple coordinated aircraft conducting similar types of
40 measurements.

1 Introduction

Wind speed and direction,, temperature, and humidity are among the most important features of the atmosphere driving
processes such as heat, momentum, and chemical fluxes, gas and particle spatial distributions, and cloud evolution (Lewis &
45 Schwartz, 2004; Nuijens & Stevens, 2012; Neukermans et al., 2018). These types of data are commonly obtained using surface
measurements and satellite remote sensing, with airborne measurements being a critical link between the two (e.g., Lenschow,
1986; Thornhill et al., 2003). Airborne measurements of these state variables, especially wind speed and direction, are
challenging due to changes in airflow around aircraft, which warrants calibrations only in flight rather than on the ground
where the same conditions cannot easily be simulated with air flowing past an airplane. There have been very limited reports
50 of cross-comparisons between air motion system instruments on aircraft flying next to each other (e.g., Lenschow et al., 1991;
MacPherson et al., 1992; Thornhill et al., 2003). Those studies relied on similar types of instruments on aircraft flying in close
formation and are important to gain confidence in reported data. It is critical to assess performance for techniques in airborne
field work that are the focus of this work including dropsondes, the Turbulent Air Motion Measurement System (TAMMS)
and the diode laser hygrometer (DLH). Dropsondes can be specifically compared to TAMMS for wind speed/direction
55 (including the u and v components of wind) and temperature (T) and to DLH for relative humidity (RH). Hereafter, references
to wind speed refer to $\sqrt{u^2 + v^2}$ whereas references to u and v components will be explicitly mentioned. Furthermore, a
growing number of field campaigns like ACTIVATE, CAMP²Ex, and ARCSIX involve multiple coordinated aircraft with one
platform launching dropsondes that is spatiotemporally removed from other aircraft. The dropsonde data and other datasets
from the same aircraft are used together with the other aircraft for various scientific applications, but the question remains as
60 to how valid this exercise is due to heterogeneity in atmospheric conditions. Intercomparisons between atmospheric state
variables between the different platforms can provide a view of how well this strategy can work. If such variable (e.g., winds,
temperature, humidity) values from independent measurements agree well between the two aircraft in a complex environment
like the northwest Atlantic (subject of this study), data from both aircraft can be used together in a meaningful way for certain
scientific applications.

65 To provide context for this study, Table 1 provides a summary of various intercomparison studies, highlighting the methods
used to validate wind speed/direction, temperature, and humidity measurements. While the primary focus of this study is the
unique comparison of dropsonde data with independent in situ measurements of similar variables from another aircraft,
intercomparisons based on other techniques are included in the table to provide important historical context, demonstrating
how different datasets have been compared and validated across platforms. These studies fall into the following categories of

70 how intercomparisons were conducted: (i) airborne lidar versus dropsondes launched from same aircraft; (ii) airborne
 radiometer versus dropsondes launched from same aircraft; (iii) airborne lidar versus surface measurements; (iv) multiple
 aircraft in close proximity with separate air motion systems; and (v) unmanned aerial vehicle measurements versus surface
 75 measurements. For instance, Baidar et al. (2018) compared wind measurements obtained from the Green Optical
 Autocovariance Wind Lidar (GrOAWL) with collocated dropsonde measurements during their validation process aboard the
 NASA WB-57 research aircraft. The campaign involved several flights over the Gulf of Mexico. The GrOAWL successfully
 measured winds with high accuracy compared to dropsondes, demonstrating excellent agreement ($R^2 > 0.9$). Bucci et al. (2018)
 compared wind speed observations from an airborne doppler wind lidar (ADWL) during tropical cyclones to dropsondes and
 reported a correlation coefficient of 0.96 and 0.92 for wind speed and wind direction, respectively. The average separation
 distance between the paired datasets was ~ 2 km (maximum of 5 km and 6 minutes of separation). Thornhill et al. (2003)
 80 compared air motion systems onboard two aircraft (NASA P3-B and NCAR EC-130Q) over the Sea of Japan during spring
 2001 as part of the TRACE-P and ACE-ASIA missions. Findings indicated a high degree of agreement between the two aircraft
 systems, particularly in measuring lower-frequency components of winds and potential temperature; the regression slopes for
 the mean wind components and potential temperature were nearly unity between the two aircraft. However, a limitation in that
 study was the use of data in only one research aircraft flight on 2 April 2001 due to stringent requirements to ensure aircraft
 85 were within 200 m and 10 m in the horizontal and vertical directions, respectively, as done in other works too (Nicholls et al.,
 1983). Table 1 reveals that these intercomparisons were usually based on very few flights for those studies involving airborne
 platforms, which is an aspect this current study aims to improve upon along with providing the first report of how an air motion
 system compares to dropsondes launched from a different aircraft. We note that Table 1 is not exhaustive of all intercomparison
 studies for atmospheric state parameters and that other studies have examined factors such as temperature (e.g., Barbieri et al.,
 90 2019) and water vapor mixing ratio (Vömel et al., 2007; Weinstock et al., 2009; Kaufmann et al., 2018), where small
 differences (i.e., < 1 ppm) can have major implications in the stratosphere for the radiation budget (Solomon et al., 2010).
 The goal of this study is to use this unique and comprehensive dataset from the NASA ACTIVATE field campaign to compare
 measurements of temperature, relative humidity, and wind speed/direction between various instruments on an aircraft flying
 mostly in the boundary layer and dropsondes launched from a separate higher-flying aircraft spatially coordinated at ~ 9 km.
 95 If the results show good agreement, this provides confidence in both the performance of the independent measurement
 techniques and confidence in integrating dropsonde data with the Falcon for specific scientific applications especially if there
 are no Falcon data for atmospheric state variables on a given flight such as when icing impacts data quality. This paper is
 structured as follows: Sect. 2 provides a summary of ACTIVATE, relevant instrumentation, and the co-location method to
 compare airborne and dropsonde data; Sect. 3 reports results of the intercomparisons of wind speed/direction, temperature,
 100 and relative humidity; and Sect. 4 wraps up with conclusions.

Table 1: Summary table of past intercomparison studies for atmospheric state variables using observational platforms. Quantitative findings are reported in the 4th column when they were available in the given text of a particular reference.

Type of Intercomparison	Reference	Data Compared, Measurement Notes, and Co-Location Details (if provided)	Findings	Study Area: Campaign	Number of Comparisons
Aircraft Lidar VS Dropsonde (same aircraft for both)	Weissmann et al., 2005	<ul style="list-style-type: none"> • Wind Speed Profile • Dropsonde measurements averaged into 100 m vertical segments to match the lidar's 100 m vertical resolution • Horizontal separation ranged from 0 to 23 km (mean = 6.5 km) • Time difference up to 11 minutes 	Standard deviation of the difference between dropsonde and lidar wind speeds ranged from 0.6 to 1.8 m/s. The mean difference (bias) between the lidar and dropsonde wind speeds was -0.31 m s^{-1} .	<ul style="list-style-type: none"> • Atlantic Ocean • Atlantic “The Observing System Research and Predictability Experiment” (THORPEX) Regional Campaign (A-TReC) 	8 flights, 33 dropsondes
	Kavaya et al., 2014	<ul style="list-style-type: none"> • Wind Speed Profile • ~10 km measurement separation • Time separation ~ 13 min for one intercomparison 	Notes of “very good” and “excellent” agreement in wind measurements.	<ul style="list-style-type: none"> • Marine areas by U.S. and Mexico • Genesis and Rapid Intensification Processes (GRIP) campaign 	1 flight, 1 dropsonde
	Baidar et al., 2018	<ul style="list-style-type: none"> • Wind Speed Profile • Dropsonde-measured winds were projected onto the lidar line of sight, interpolated to the center of the lidar measurement grid, and compared to the closest lidar measurement in that location 	High correlation ($R^2 > 0.9$) between wind speeds	<ul style="list-style-type: none"> • Gulf of Mexico • Atmospheric Transport, Hurricanes, and Extratropical Numerical Weather Prediction with the Optical Autocovariance Wind Lidar (ATHENA-OAWL) mission 	8 flights, 44 dropsondes
	Bucci et al., 2018	<ul style="list-style-type: none"> • Wind Speed/Direction Profile • Horizontal separation < 5 km (mean = 2.1 km) • Temporal separation < 6 min 	High correlation between lidar and dropsonde wind speeds ($r=0.96$) and direction ($r=0.92$).	<ul style="list-style-type: none"> • Marine areas by U.S. and Mexico 	5 flights, 49 dropsondes

2 Methods

2.1 ACTIVATE Campaign Description

The NASA Aerosol Cloud meTeorology Interactions oVer the western ATlantic Experiment (ACTIVATE) aimed to provide an important dataset to advance knowledge of aerosol-cloud-meteorology interactions including both improved parameterization of these processes in climate models and technological advances for instrumentation and retrievals of related geophysical variables (Li et al., 2022; Schlosser et al., 2022; Sorooshian et al., 2023). The project involved airborne flights over the western North Atlantic in different seasons of each year between 2020-2022 to generate a dataset covering different weather regimes (and thus cloud types) and aerosol types depending on the season. The flights are categorized into winter and summer seasons, but we emphasize that these categories are loose in that winter covers November-April and summer spans May-September (Sorooshian et al., 2023). Most flights were based out of NASA Langley Research Center (LaRC) in Hampton, Virginia. In June 2022, 17 flights were conducted based out of Bermuda for an intensive period of operations to extend the spatial range of ACTIVATE flights farther offshore. ACTIVATE involved a disciplined approach of conducting spatially coordinated flights with NASA Langley's HU-25 Falcon and King Air aircraft. The flight strategy coordinated a King Air flying at ~9 km and Falcon flying stair steps at various levels below 3 km, below, in and above boundary layer clouds. The coordinated approach allowed for near-simultaneous sampling of trace gases, aerosols, cloud microphysics, and atmospheric state parameters from both in-situ and remote sensing techniques between and ~9 km. Over 90% of the flights were able to utilize this coordinated approach and serve as the basis for the analysis in this paper. The primary instruments that we will use in this study are dropsondes from the National Center for Atmospheric Research (NCAR) Airborne Vertical Atmospheric Profiling System (NCAR AVAPS) instrument that was flown on the King Air and both the TAMMS and DLH instruments on the Falcon.

2.2 King Air: Dropsondes

The NCAR AVAPS (NSF-NCAR, 1993) was used on the King Air to control dropsonde operations. The project utilized the NCAR designed and built NRD41 sondes in lieu of the older RD41 model due to improved launch detection and electronics. During the three years of operations, a total of 801 sondes were launched, with 788 (98%) providing a complete profile from the aircraft altitude all the way to the surface. They are the ones that will be used in this study. Data were processed using NCAR's Atmospheric Sounding Processing Environment (ASPEN; <https://www.eol.ucar.edu/content/aspn>; Vömel et al., 2023). ASPEN ensures the integrity and accuracy of the data by applying dynamic corrections and smoothing algorithms, enhancing the reliability of the atmospheric profiles. The dropsonde data underwent a series of corrections and quality control steps to ensure accuracy and reliability, following the methods detailed in Vömel et al. (2023) and Abernethy et al. (2023). These included dynamic corrections to account for the lag in temperature and humidity sensors, with an equilibration time of 10

seconds applied to eliminate artifacts after release from the aircraft. Wind data were corrected for sonde inertia to address motion-induced errors during descent. A B-spline smoothing algorithm was employed for pressure, temperature, humidity, and wind components, with a 5-second smoothing window to maintain profile continuity while preserving critical gradients.

140 Post-smoothing, wind speed and direction were recalculated to ensure consistency. Additionally, outliers and suspect data points were removed, and surface pressure values were extrapolated using fall rates, followed by recalculating geopotential height and vertical wind velocity. Any telemetry issues, such as synchronization errors between the onboard computer and GPS, were addressed through post-processing and reconstruction of raw data. These steps collectively ensured high-quality datasets suitable for robust analysis (Aberson et al., 2023; Vömel et al., 2023).

145 The final science quality data archive includes vertical distributions of temperature, pressure, humidity, and winds (u, v, w components) at the sub-hertz acquisition rate at which they were required. The reported uncertainty in the zonal wind components is 0.5 m s^{-1} (Sorooshian et al., 2023). Uncertainties in the temperature and RH measurements are $0.2 \text{ }^{\circ}\text{C}$ and 3%, respectively. The vertical resolution of the dropsonde data is approximately $\sim 6 \text{ m}$. We conduct RH intercomparisons in this work with independent Falcon RH measurements only for dropsonde $\text{RH} < 100\%$. Customarily, RH measurements above

150 100% are set equal to 100% in quality controlled data (Vömel et al., 2023) to eliminate potentially erroneous measurements due to supersaturation and the potential presence of liquid water that could introduce biases into the analysis. Typically, raw measurements may exceed the 100% level by a few percent due to measurement uncertainty at saturation and due to environmental factors, mostly the presence of liquid water in clouds. However, here we decided to exclude all dropsonde RH values $\geq 100\%$, which represents less than 5% of the data with negligible impact on final results. Intercomparisons among

155 variables other than RH are still conducted if dropsonde $\text{RH} \geq 100\%$. Details on the uncertainty analysis for dropsondes, including sensor response times and calibration procedures, are provided in the Supplementary Material file (Text S1). This includes estimates for pressure, temperature, relative humidity, and wind speed uncertainties as supported by literature (Bärfuss et al., 2018; Bärfuss et al., 2023; Vömel et al., 2023).

160 2.3 Falcon Measurements

Fast response, high frequency measurements of the 3-dimensional wind field (horizontal (u and v) and vertical (w)), static air temperature, and pressure as well as position and altitude are provided from the NASA TAMMS instrument on the HU-25. Wind component measurements are derived from an inertial navigation system (Applanix 610) to provide the speed of the aircraft with respect to the Earth and a combination of pressure and temperature measurements used to derive the speed of the

165 air with respect to the aircraft. The difference in those two vectors provides the ambient 3-dimensional wind field. The static and dynamic pressures are sampled with Honeywell PPT2 pressure sensors and the Total Air Temperature (TAT) is measured with a Rosemount 102 non-deiced TAT sensor. The differential pressures needed for the angles of sideslip and attack are computed from five flush-mounted ports on the radome of the Falcon arranged in a cruciform pattern. Utilizing the radome minimizes any airflow biases around the aircraft. Extensive calibrations done over the course of the three flight years accounted

170 for well determined calibration coefficients for the angles of attack and sideslip and a good characterization of the heading
offset and pressure defect necessary to computer high precision ambient winds. For this study, we will focus on the TAMMS
horizontal wind component measurements. Ambient wind component data derived from aircraft are sensitive to deviations
away from straight and level flight conditions and artificial artifacts can be introduced. As such, we restrict our data usage to
times when the HU-25 is flying straight and level (pitch and roll angles less than 5 degrees (absolute)). Similar to dropsondes,
175 the reported uncertainty in the zonal wind component is 0.5 m s^{-1} (Sorooshian et al., 2023). A full explanation of the calibration
maneuvers for wind component measurements is provided in the Supplementary Material (Sect. S1). Temperature
measurements associated with the TAMMS have an uncertainty of $0.5 \text{ }^{\circ}\text{C}$. More details about the TAMMS can be found
elsewhere (Thornhill et al., 2003; Sorooshian et al., 2023). It has been used on the NASA P-3 aircraft for over 25 years, and
this was the first time it was used on the HU-25 Falcon.

180 Relative humidity (RH) is derived from water vapor measurements using a diode laser hygrometer (DLH), which has an
uncertainty of 5% or 0.1 ppmv (Sorooshian et al., 2023). RH calculations also depend on temperature and pressure
measurements, introducing additional uncertainties that propagate into the final values (Garcia Skabar, 2015). The saturation
vapor pressure, determined by temperature, is particularly sensitive, with small temperature uncertainties leading to noticeable
RH variations. The impact of pressure measurement uncertainties is relatively small, as the uncertainties represent a very small
185 fraction of pressure itself. As a result, the combined uncertainty of RH is higher than that of the water vapor mixing ratio
(WVMR), depending on conditions. References to RH in this work refer to the RH with respect to liquid water. The DLH is
an open-path and near-infrared absorption spectrometer (Diskin et al., 2002) with its open path completely on the Falcon's
exterior between a retroreflector on the starboard wing and a cabin window. The time resolution of the TAMMS and DLH is
 0.2 s (or $\sim 25 \text{ m}$ in horizontal distance) or better, but in this analysis we use data averaged to 1 s resolution.

190

2.4 Data Processing and Statistical Methods

A key component of the analysis was finding the best spatial and temporal match between data collected from dropsondes and
the HU-25. During joint flights, the two aircraft were collocated within 5 min and 6 km approximately 73% of the time
(Sorooshian et al., 2023), providing a relatively large sample set for intercomparison. However, due to the inhomogeneity of
195 the northwest Atlantic and the fact that dropsondes are carried along the mean wind direction and do not descend straight down
from the time they are launched to the time they reach the altitude of the HU-25, rugged constraints must be used in order to
get closer to an “apple to apples” comparison. Figure 1 summarizes the criteria applied to identify the best match between the
Falcon aircraft measurements for a given dropsonde launched from the King Air altitude down to the ocean surface, which
ideally should be done for other campaigns involving multiple coordinated aircraft involving dropsonde launches. First, they
200 had to be collocated within 30 km, vertically within 25 m, and within 15 min to strike a balance between having a good sample
size for analysis and reduce the chances of the two measurements reflecting very different dynamical regimes. These criteria

(except the vertical requirement) were also used in the recent wind intercomparison analysis by Dmitrovic et al. (2024) using ACTIVATE data (Table 1). For context, the Falcon's air speed was typically 120 m s^{-1} , and 30 km represents 250 s of flight. The calculation of distances between points was conducted using the haversine formula, which is needed for determining the great-circle distances on a spherical surface based on longitude and latitude (Hoover et al., 2013; Schlosser et al., 2024). As noted in the previous section, this analysis only uses wind component data collected during straight and level flight legs. We also aimed to keep the two instruments both in cloud or both out of cloud (i.e., avoid one in cloud and the other in clear air). Criteria for identifying whether the TAMMS was in cloud relied on the Fast Cloud Droplet Probe (FCDP; Spec Inc.), which measured aerosol and cloud droplet size distributions between 3 and $50 \text{ }\mu\text{m}$ (Kirschler et al., 2022; Kirschler et al., 2023). Cloud sampling was based on both liquid water content (LWC) exceeding 0.01 g m^{-3} and cloud drop number concentration (N_d) exceeding 10 cm^{-3} . Conversely, clear-sky conditions were defined by LWC values less than 0.001 g m^{-3} and N_d being below 5 cm^{-3} . For dropsonde measurements, criterion for being in and out of cloud were assumed to be when relative humidity (RH) $> 97\%$ and $\text{RH} < 94\%$, respectively.

After those criteria were met, candidate pairs emerge between the dropsonde and the Falcon whereby the final pair was based on finding the minimum altitude difference between the two. We did this as we viewed a better intercomparison being at a closer altitude versus a closer spatial distance. For instance, temperature is much more sensitive to vertical changes rather than horizontal changes in the atmosphere. A total of 555 pairs were identified after all these criteria were applied to all dropsonde data points and all Falcon data points (locations in Figure 2). We note that for some geophysical variables compared in this work, there were times when data were collected and thus there were not a full set of 555 pairs to compare. We also examine pairs of data points using the method in Figure 1 excluding the final step of finding just one pair of data points per dropsonde launch with the minimum altitude difference to allow for a much larger population of data pairs ($>360,000$ pairs). Additional analysis in this paper examines how intercomparisons changed when using more points collected before and after those respective single points.

For context, Figure 3a-b shows histograms for the distribution in the vertical and horizontal distances between the final data points comprising the 555 pairs. While our criteria allows up to 25 m, the majority of the pairs ($\sim 90\%$) exhibit vertical differences of less than one meter because of the final step to use a pair of points with the smallest vertical gap while adhering to the other criteria. This observation highlights the stringent nature of our selection process, where minimizing the altitude difference is an important factor due to the sensitivity of atmospheric state variables to altitude variations. The median horizontal separation distance between pairs was 18.8 km. The median geopotential altitudes of the final pairs were (Falcon/dropsonde) 966/965 m with minimum and maximum values of 112/112 m and 4948/4937 m, respectively (Figure 3c-d).

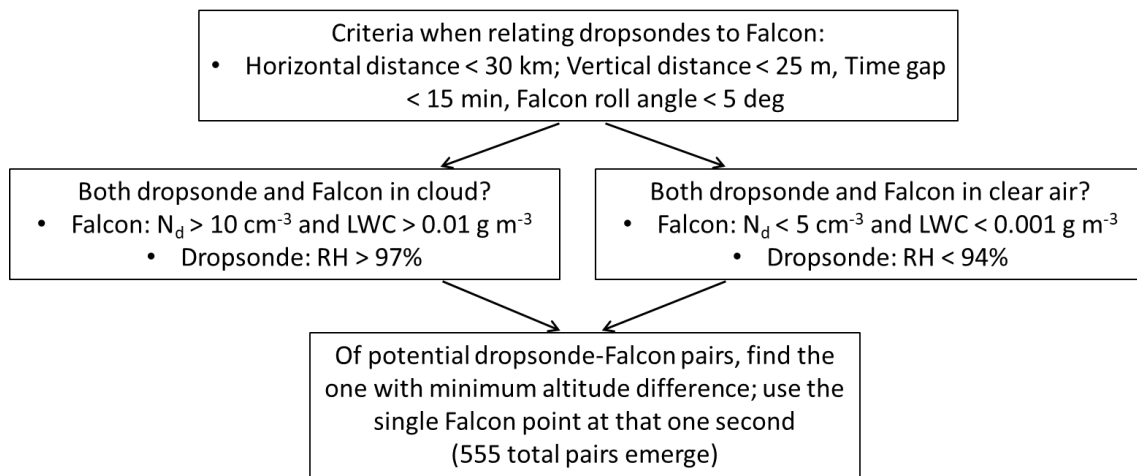

Figure 1: Methodology of finding the closest points between the Falcon and dropsondes launched by the King Air during ACTIVATE 2020-2022 flights.

Figure 2: Spatial map of dropsondes released from the King Air that are utilized for intercomparison with the Falcon measurements. A total of 555 dropsondes are shown that are used after the data screening procedure in Figure 1.

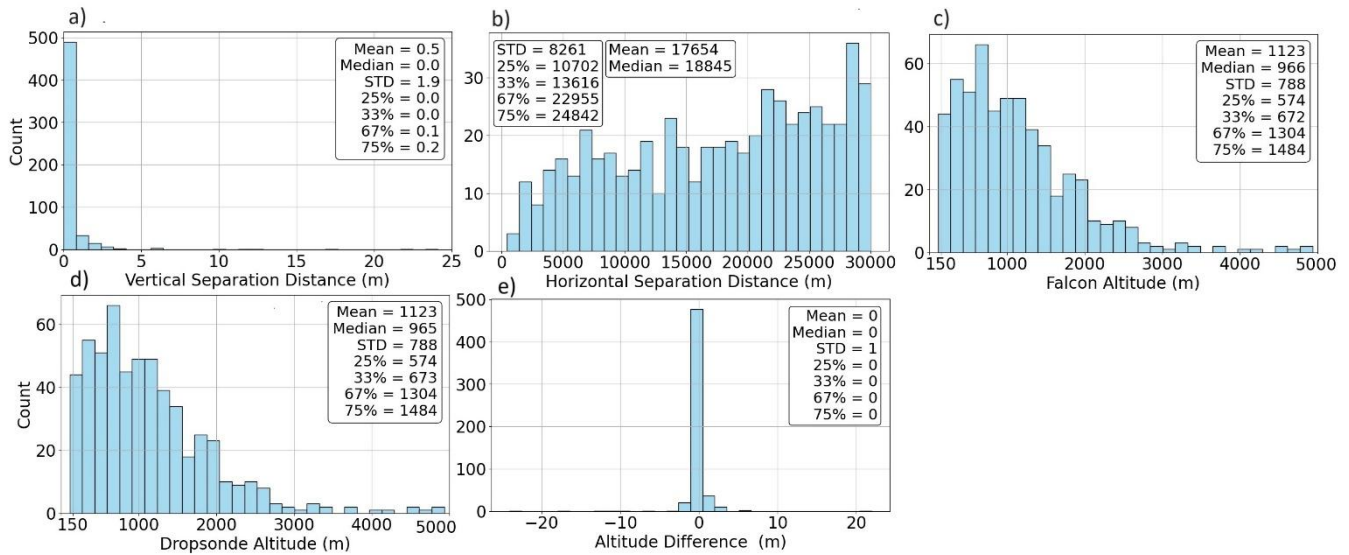

Figure 3: Histogram showing the (a) vertical separation distance and (b) horizontal separation distance between the final 555 pairs. Also shown are histograms of the final altitude for each pair of points for (c) the Falcon and (d) dropsondes, and (e) altitude difference between datasets: Falcon - dropsonde.

In this study, we use geopotential altitude for intercomparison between the Falcon and the dropsonde measurements. The analysis comparing the dropsonde and the Falcon measurements relies on intercomparisons in the form of scatterplots and statistical metrics that closely follow the related work of Dmitrovic et al. (2024), which intercompared ocean surface wind speeds using dropsondes and the High Spectral Resolution Lidar – generation 2 (HSRL-2) during ACTIVATE, with the HSRL-2 having been on the higher-flying King Air too. We compare the single points from the dropsondes and the Falcon that comprise the final 555 pairs, but we also intercompare those 555 pairs using more data points before and after the single points identified using the process shown in Figure 1. More specifically, a subset of results relies on taking the mean of the single dropsonde point and the preceding and subsequent points (for a total of 3 points and thus ~30 m of vertical distance). Analogously, we also use various numbers of points (2, 5, 10) before and after the identified single Falcon point amounting to a total of 5, 11, and 21 points (i.e., ~0.6 km, ~1.3 km, ~2.5 km horizontal distance, respectively) used in averaging. We present correlation coefficients (r), linear best-fit regressions, and geometric mean bisector regressions (hereafter referred to as bisector regressions). The bisector technique differs from the linear regression in that for the former there is no clear distinction between dependent and independent variables and so both the x and y variables are subject to error (e.g., Ricker, 1973); in contrast, for linear regressions only the y variable is the dependent variable, which arbitrarily is chosen to be the Falcon data in this study while the dropsonde measurements represent the independent variable. In this analysis, we used the standard error of the slope to assess the precision of the regression model. Standard error helps assess how close the regression line fits the data and gives insight into the variability or confidence in the slope estimate. A lower standard error means a more reliable slope estimate.

Histograms are also presented to provide a visual sense of the distribution and frequency of values in various measurements and calculations.

For intercomparisons, mean error (ME) is computed to quantify discrepancies between the two measurement methods. Mean error is the average difference between the measurements taken by the Falcon instruments (TAMMS and DLH) and dropsondes:

270

$$\text{Mean Error} = \frac{1}{N} \sum_{i=1}^N (\text{Falcon}_i - \text{Dropsonde}_i) \quad (\text{Eq. 1})$$

A low ME suggests a better agreement while a higher ME shows higher systematic bias between the instruments. A positive mean error indicates that the TAMMS/DLH measure the higher values relative to the dropsondes. We also report a standard deviation alongside the mean error values to quantify how spread out the errors are around the mean error. A low standard deviation means that the errors are consistently close to the mean error.

We further caution that due to the nature of comparing dropsondes launched from an aircraft distinct from another one doing independent measurements, intercomparisons are conducted with the possibility of natural horizontal variability in the variables compared. For context, Table 2 shows the typical standard deviation for temperature, RH, and wind speed (along with u/v components) for level leg types flown by the Falcon during ACTIVATE. To put the standard deviations in perspective, we calculated the median value of each variable for a given leg and then took the mean of those medians for that same leg type for a given season. The reported standard deviations in Table 2 also represent the mean value of all the standard deviations for individual legs of a given leg type and season. Typical legs were ~3.3 min long and covered almost 25 km horizontal distance (Dadashazar et al., 2022), which exceeds the aforementioned median separation distance (18.8 km) between the Falcon and dropsondes for the final 555 data pairs in this study. The analysis in Table 2 was conducted for cloud-free conditions using the criteria provided already. As shown, standard deviations for given leg types and seasons were usually less than 0.3°C for temperature, less than 5% for RH, and less than 1 m s⁻¹ for the wind variables, which is comparable to the uncertainties in these measurements. Horizontal variability tended to be larger in the summer versus the winter based on the Falcon leg types, which afford the only way with ACTIVATE in situ data to compare horizontal changes at a fixed vertical level. Based on Table 2, the intercomparisons presented subsequently are found to be meaningful.

Furthermore, showcasing data across different seasons over three years naturally presents differences in atmospheric stability and boundary layer structure, which is relevant to consider in this study focused on intercomparisons of temperature, humidity, and wind speed and direction. For context, recent work relying on 506 dropsondes launched during ACTIVATE (Xu et al., 2024) revealed that the median cloud fraction for ACTIVATE flights was 0.22 with the median planetary boundary layer height for cloud fractions below and above 0.22 being 659 m and 1,169 m, respectively. Further, ~28% of those dropsondes indicated the presence of decoupled boundary layers. In light of this type of variability, steps are still taken to enhance

meaningful intercomparisons between dropsondes and in situ data such as accounting for separation in time and horizontal/vertical distances along with comparing data between similar seasons and when clouds are present or not.

305

Table 2. Summary statistics (median and standard deviation) for temperature, relative humidity, and winds (including u and v components) based on Falcon measurements in specific legs flown (ABL = above boundary layer top; BBL= below boundary layer top; ACT = above cloud top; BCT = below cloud top; ACB = above cloud base; BCB = below cloud base; MinAlt = minimum altitude flown and typically ~150 m above sea level). These legs were typically between 3-4 min long and the median and standard deviations of each leg were then compiled with the final values shown below being the mean value of all those median and standard deviation values of all legs for a particular leg type and season (shown in format of “summer value/winter value”). The farthest right column represents the number of legs used for the calculations.

3 Results and Discussion

3.1 Case Studies

315

320

We begin by first demonstrating through two case studies how the co-location and comparisons were done between the dropsondes and the Falcon instrumentation. Research Flight 25 on 20 August 2020 was a case of measurements being compared in cloud-free conditions at the collocated time identified using the method in Figure 1. Figure 4a shows the aircraft flight tracks overlaid on GOES 16 visible imagery (15:41 UTC), Figure 4b shows a time series of both the Falcon flight altitude and dropsonde altitude, while Figures 4c-d zoom in on the ~30 min where the final points were selected along with time series of TAMMS wind speed/wind direction/temperature and DLH measurements of RH. Figure 4e shows dropsonde vertical profiles of temperature and RH for this case. The Falcon was conducting its routine stairstep flight profile at various levels below, in, and above clouds on this particular day and the final Falcon (red marker) and dropsonde (green marker) data points

identified as a matching pair were coincidentally both out of cloud at their respective times. The altitudes of the chosen Falcon and dropsonde points were 502.8 m and 502.5 m, respectively, with a horizontal separation distance between them of 3.1 km and a time difference of 14 minutes and 2 seconds. The temperature time series expectedly shows clear differences at the various Falcon legs at the different altitudes with higher temperatures at the lower altitude legs; this helps support the choice of trying to keep the vertical separation distance narrow in the methodology (Fig. 1) even though it comes at expense of greater time and horizontal separation. Relative humidity from the Falcon was highly variable along this time segment, ranging from as low as 51.8% to as high as 98.7%. The lower values are due to the early portion of the time segment shown (Fig. 4c-e) when the aircraft was above cloud tops where there were drier conditions. The wind speed time series show variations from as low as 4.0 m s⁻¹ to as high as 9.7 m s⁻¹ during the 30 min time segment shown. The final pair of points chosen yielded the following wind speed, wind direction, T, and RH values (in that order): Falcon = 6.6 m s⁻¹, 242.6°, 20.6 °C, 75.1%; dropsonde = 5.1 m s⁻¹, 244.2°, 21.9°C, 56.4%. This case shows that the co-location method is prone to limitations due to the horizontal separation distance where atmospheric conditions can vary due to spatial gradients, especially for RH in areas of considerable spatial gradients with regards to cloud top and marine boundary layer (MBL) heights (Xu et al., 2024); however, still the intercomparison shows reasonable agreement at least for wind speed/direction and temperature.

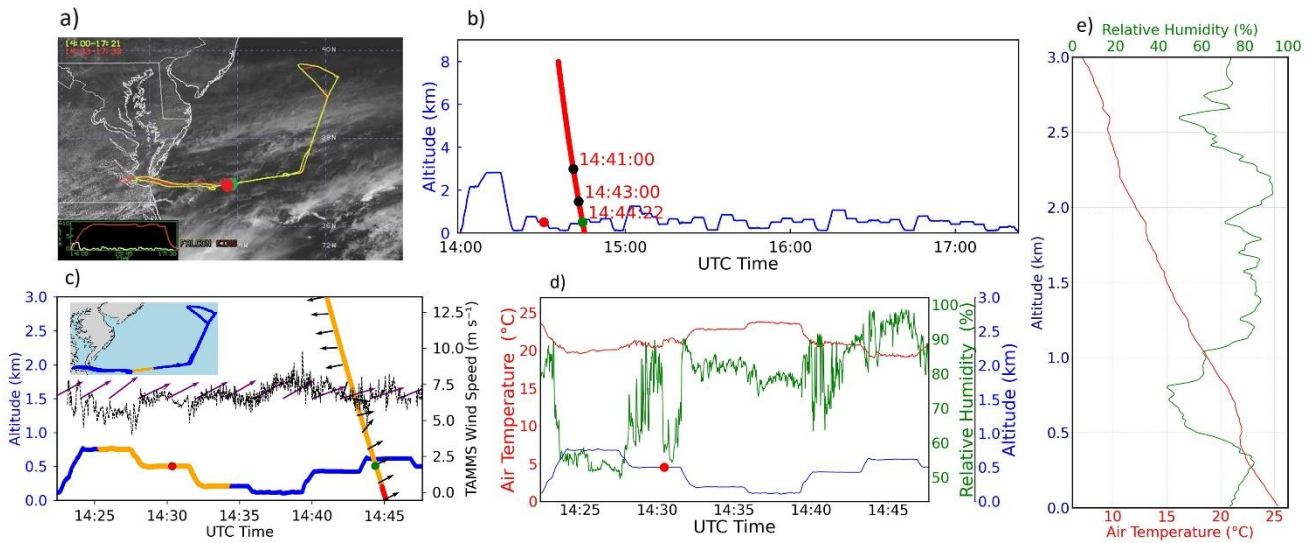

Figure 4: Visualization of the Falcon aircraft's flight path for Research Flight 25 on 20 August 2020 along with additional panels to demonstrate the methodology of collocation following the approach shown in Fig. 1 with cloud-free conditions at the point of data point selection for the dropsonde (green marker in all panels) and the Falcon instruments (red marker in all panels). (a) Flight tracks of the King Air (red) and the Falcon (yellow) overlaid on

GOES-16 imagery at 15:41 UTC. (b) Time series of the Falcon altitude and the dropsonde altitude. c) Close-up of panel (b) between 14:22 UTC and 14:47 UTC focusing on where the final points were identified as a dropsonde-Falcon pair (red = TAMMS point at 14:30:21, green = dropsonde point at 14:44:23). Falcon altitude is on left y-axis and its colors (blue and orange) match the colors on the inset map to show the location of the orange area that includes the Falcon data within 30 km horizontal separation and 15 min temporal separation of the falling dropsonde. TAMMS wind speed is on the right y-axis and its wind direction measurements are shown as purple arrows. For the dropsonde profile (shown as the steep diagonal line), wind directions are shown as black arrows and the orange portion indicates that those points are within the 30 km horizontal separation and 15 min separation criteria (i.e., red parts of the diagonal line at bottom violate the criteria). (d) Time series of the Falcon's temperature and relative humidity measurements along the same time segment as panel (c) with the red colored marker again showing the time of the final selected TAMMS point for this identified pair. (e) Dropsonde vertical profile of temperature and relative humidity.

The second example from Research Flight 33 on 11 September 2020 was a case such that the final dropsonde and Falcon points were in cloud (Fig. 5a-e). The altitudes of the chosen Falcon and dropsonde points were 320.3 m and 319.6 m, respectively, with a horizontal separation distance of 3.7 km and a time difference of 8 minutes and 30 seconds. The final pair of points chosen yielded the following wind speed, wind direction, T, and RH values (in that order): Falcon = 6.6 m s^{-1} , 61.8° , 24.6°C , 91.8%; dropsonde = 5.7 m s^{-1} , 79.4° , 24.3°C , 97.7%.

360

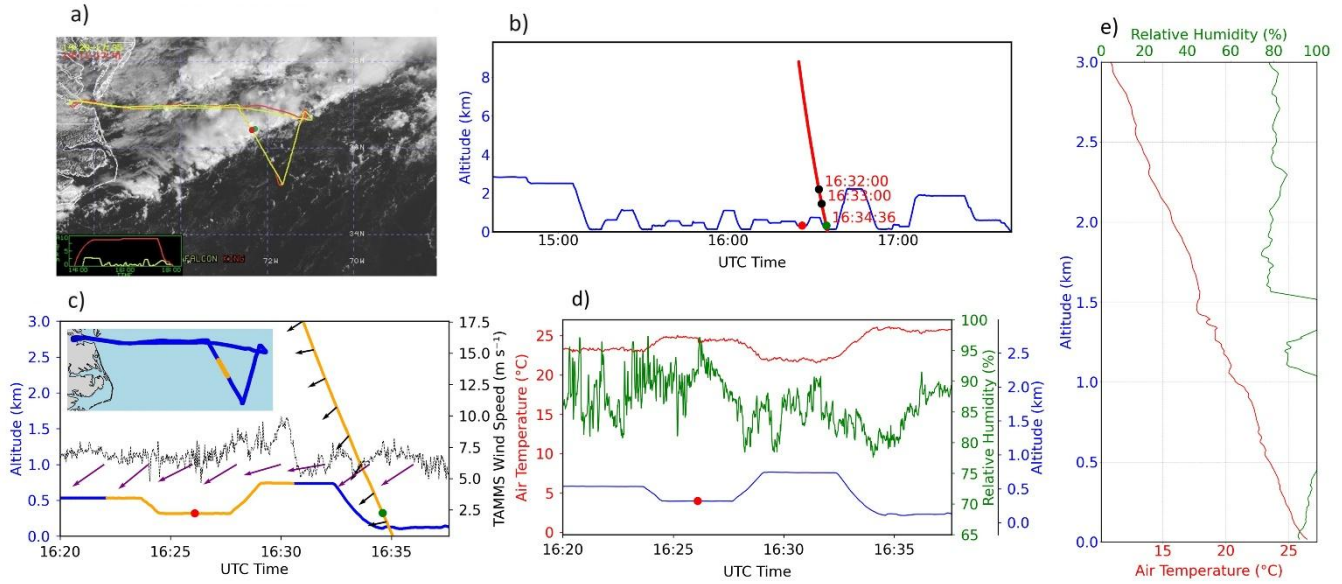

Figure 5: Same as Fig. 4 but for a Research Flight 33 on 11 September 2020, coinciding with the final chosen points being in cloud.

3.2 TAMMS – Dropsonde Wind Variable Intercomparisons

Figure 6 intercompares wind speeds from the TAMMS-dropsonde pairs two different ways. First we examine pairs (369,677 pairs) using the method shown in Figure 1 excluding the last step of finding just one pair of points for a dropsonde launch with the minimum altitude difference. In other words, all pairs are allowed if vertical separation is within 25 m, while keeping other criteria still in place (i.e., horizontal separation < 30 km, time separation < 15 min, Falcon roll angle < 5°, and clear/cloud criteria). To give a sense of wind speed values, the resultant 555 pairs when applying the final step of Figure 1's criteria exhibit a range of wind speeds from (TAMMS) 0.30 m s⁻¹ to 40.83 m s⁻¹ and (dropsonde) 0.17 m s⁻¹ to 42.16 m s⁻¹, as shown by histograms in Figure 7a-b, which report various statistics (mean, standard deviation, 25/33/50 (median)/67/75 percentiles). The median wind speeds (TAMMS/dropsonde) were 7.64/7.23 m s⁻¹.

The intercomparison results are comparable between relaxed (Figure 6a) and stricter vertical separation criteria (Figure 6b). Results in Figure 6a show that the slopes are 0.97 and 1.02 and y-intercepts are 0.43 and 0.01 for the linear and bisector regressions, respectively, while the correlation coefficient was 0.95. For the bisector regression results, which assume both variables are subject to error, the slope and y-intercepts demonstrate excellent agreement between the two datasets. Figure 6b shows slopes of 0.98 and 1.03 and y-intercepts of 0.39 and -0.08 for the linear and bisector regressions, respectively, with a correlation coefficient of 0.95. The mean errors (\pm STD) corresponding to Fig. 6a and 6b are 0.21 ± 1.62 m s⁻¹ and 0.21 ± 1.68 m s⁻¹, respectively (Table 3). Therefore, the TAMMS had slightly higher wind speed values on average. This is assuring that

the stricter criteria of using just one TAMMS-dropsonde pair per dropsonde launch by applying the full method in Fig. 1 is
380 representative of more loose criteria that would provide more data points. We conducted these two methods of
intercomparisons with vastly different datapoints to the other geophysical variables of interest in this study (u/v wind
components, wind direction, T, RH) and the same general conclusion is reached that the final intercomparison metrics are
similar between the two approaches.

To dig deeper into wind speed intercomparisons, we stick with the final 555 pairs and show, in Table 3, results comparing
385 winter-summer, clear-cloud, and different terciles of (i) overall wind speed, (ii) altitude at which the final pairs were identified,
and (iii) horizontal distance between the two data points in each pair. The terciles were meant to keep the data points the same
for three categories (185) being compared using the 33rd and 67th percentile values reported in Figure 7. The summer and
winter data intercomparisons show similar correlation coefficients (0.94 for both), mean errors ($0.17 \pm 1.29 \text{ m s}^{-1}$ = summer,
 $0.27 \pm 2.02 \text{ m s}^{-1}$ = winter), and slopes (0.97-1.05 depending on season and regression type). There also was no major difference
390 in the agreement when using pairs in cloud versus no cloud with correlation coefficients being between 0.89 (cloudy) and 0.95
(clear), mean errors between $-0.13 \pm 1.98 \text{ m s}^{-1}$ (cloudy) and $0.26 \pm 1.60 \text{ m s}^{-1}$ (cloudy), and slopes between 0.87 and 1.04.

Intercomparisons of wind speed for terciles of altitude and horizontal separation distances revealed generally good agreement
with the six possible slopes shown for these different categories and regression types being between 0.92 and 1.06 with
correlation coefficients between 0.92 and 0.96. The mean error though increased for the highest altitude tercile ($> 1304 \text{ m}$),
395 with a value of $0.58 \pm 1.82 \text{ m s}^{-1}$ as compared to mean errors between -0.01 m s^{-1} and 0.07 m s^{-1} for the lower two altitude
tercile categories. It was hypothesized that the agreement should be best for the lowest horizontal separation distances. This is
partly confirmed since the highest separation tercile ($> 22,955 \text{ m}$) exhibited the highest mean error ($0.45 \pm 1.84 \text{ m s}^{-1}$) as
compared to the lowest two terciles that had mean errors of 0.06 to 0.13 m s^{-1} . The mean errors for the three wind speed terciles
($< 5.80 \text{ m s}^{-1}$, $5.80\text{-}9.71 \text{ m s}^{-1}$, $> 9.71 \text{ m s}^{-1}$) were between 0.09 m s^{-1} and 0.41 m s^{-1} with more variability in values for slopes,
400 y-intercepts, and correlation coefficients compared to the other comparison factors in Table 3. For instance, based on the
bisector method, which assumes error in both datasets, the slopes and y-intercepts were much more improved for the low (1.37
and -1.05 m s^{-1} , respectively) and high wind speed categories (1.14 and -1.81 m s^{-1} , respectively) as compared to the medium
speed category (2.28 and -9.50 m s^{-1} , respectively). Correlation coefficients ranged widely from 0.55 for the medium wind
tercile to as high as 0.90 for the high wind speed tercile. The standard deviation in the mean errors increased as a function of
405 wind speed, but if divided by the mean wind speed in each tercile, the standard deviations are similar.

Lastly, Table 3 additionally summarizes intercomparison metrics for TAMMS-dropsonde pairs but with the inclusion of 5, 11,
and 21 data points for TAMMS rather than 1, and 3 points for dropsondes rather than 1 (all sets of points are centered by the
single point used for the previous discussion). The results show very similar results with mean errors between 0.21 and 0.23 m s^{-1} ,
correlation coefficients of 0.94-0.95 for all three types of comparisons, and slopes being between 0.94 and 0.96. In terms
410 of wind's two horizontal components, Tables S1 and S2 show improved results in terms of how well different categories
compare when contrasted with Table 2 for total wind speed.

Another type of analysis shown on the right hand side of Fig. 7 for all compared variables is the frequency histogram of the difference in values between the Falcon and dropsonde measurements. For wind speed and u and v components, the median difference shown was 0.18, 0.09, and -0.03 m s⁻¹, indicative of the lack of a substantial bias between the TAMMS and dropsonde measurements.

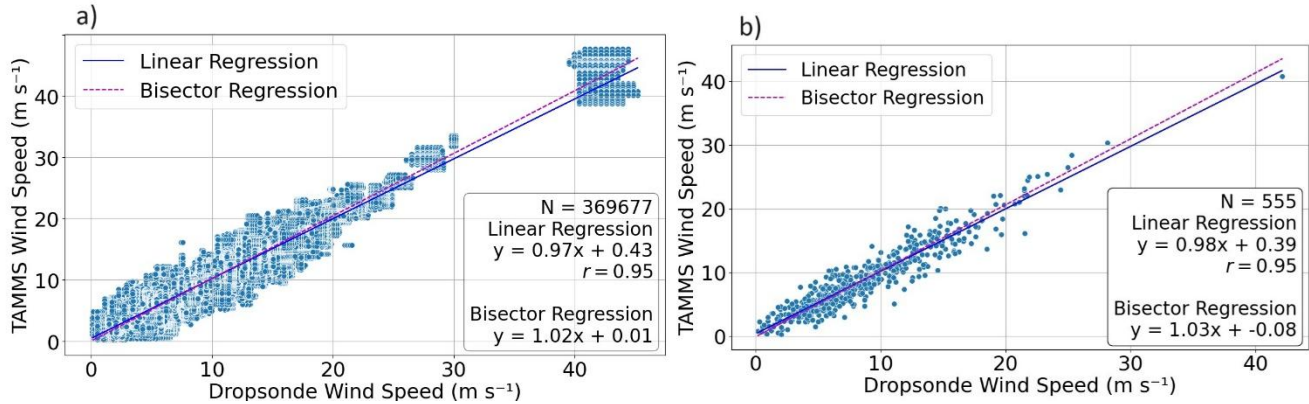

Figure 6: (a) Wind speed scatterplot between dropsonde and TAMMS pairs of single points following the method of Figure 1 (within 30 km, 15 min, and 25 m vertical spacing) excluding the last step to find the single points with the minimum altitude difference. (b) Same as (a) except showing only pairs following the full method of Figure 1 including the last step.

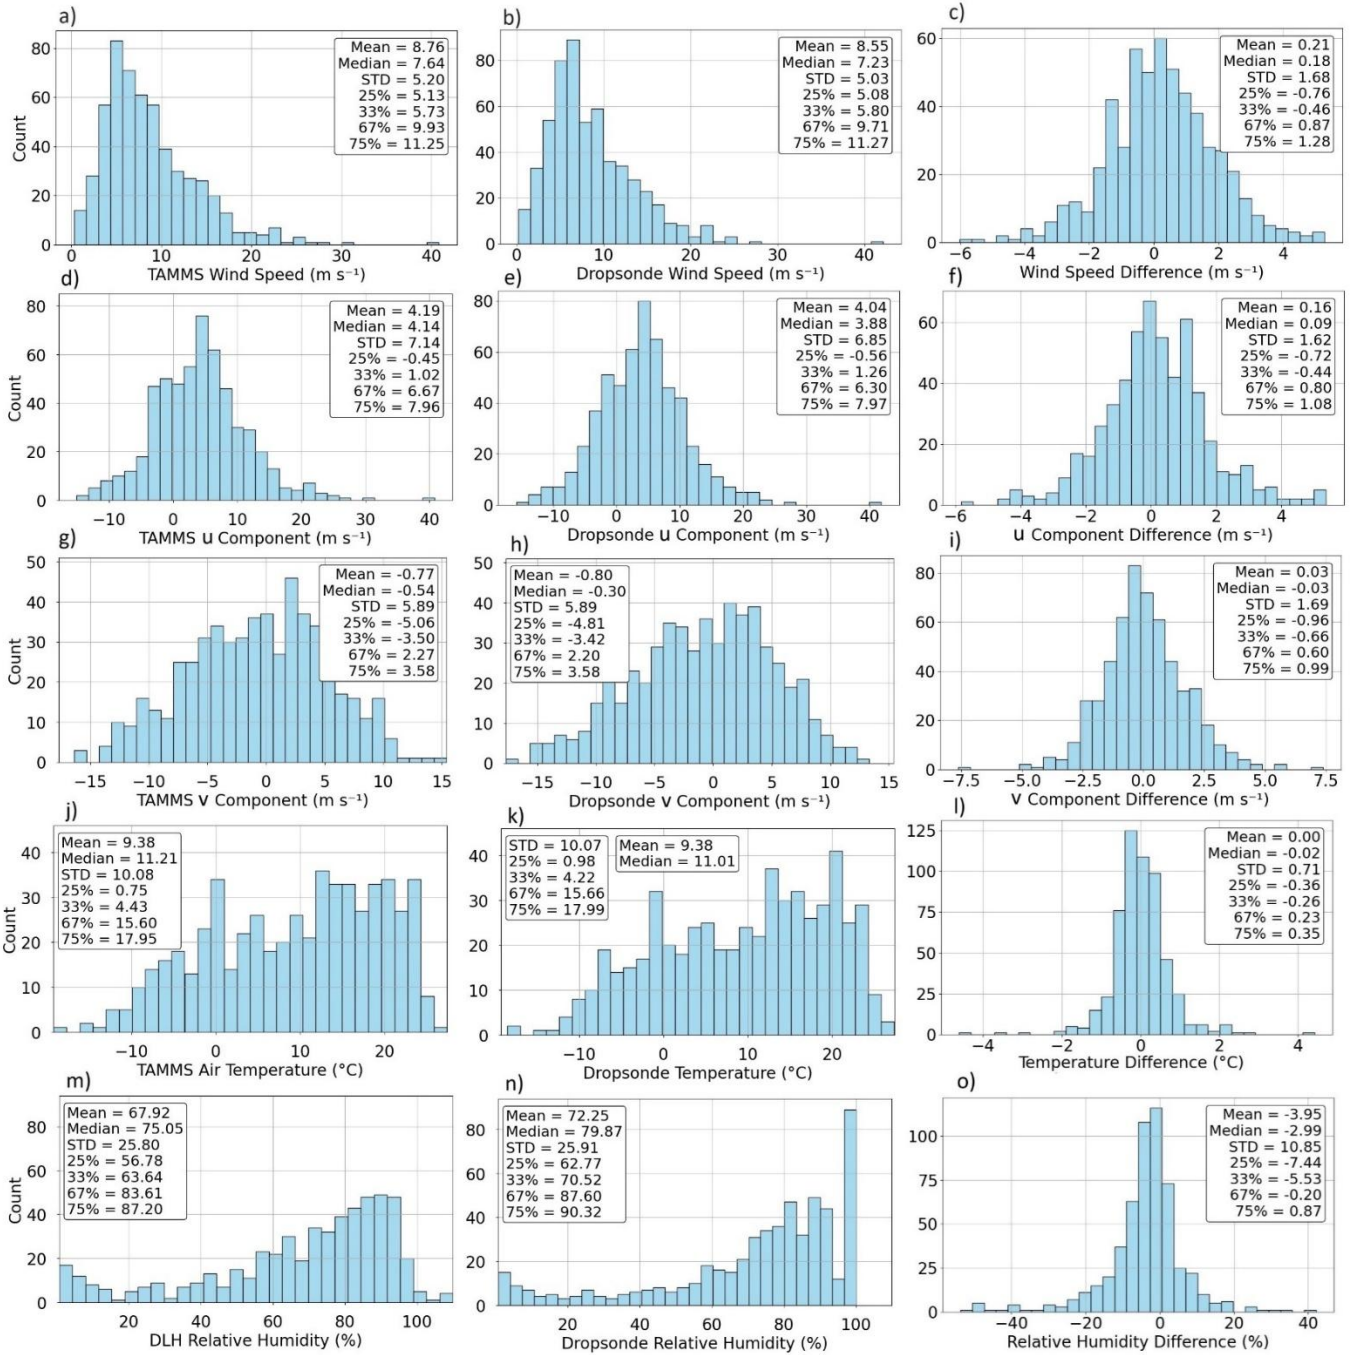

Figure 7: Histogram TAMMS and dropsonde (a-b) wind speed, (d-e) u component, (g-h) v component, (j-k) TAMMS and dropsonde temperature, (m-n) DLH and dropsonde relative humidity. Note that this study only uses dropsonde RH values below 100%. Panels c/f/i/l/o show histograms of the differences of each variable calculated as such: Falcon measurements (i.e., TAMMS or DLH) minus dropsonde measurements.

As it relates to wind direction, the overall wind rose for the final 555 pairs (based on single points) is shown in Figure 8a and 8b for the TAMMS and dropsondes, respectively. Both wind rose plots show similarity with wind direction predominantly being from the northwest but extending usually to southwesterly, as is expected based on the climatology of the region and documented atmospheric circulation patterns (Sorooshian et al., 2020; Painemal et al., 2021). As quantitative intercomparisons for wind direction are complicated owing to its native values not being conducive to such an analysis (e.g., 0° and 360° essentially being the same), Figure 8c intercompares the cosine of the respective wind directions with generally good agreement between the two datasets ($R = 0.94$, linear/bisector regression slopes of 0.94/1.00 and mean error of 0.00 ± 0.22). Markers are colored by TAMMS wind speed to see if deviations in wind direction have any dependence on speed but the results do not show such a dependence.

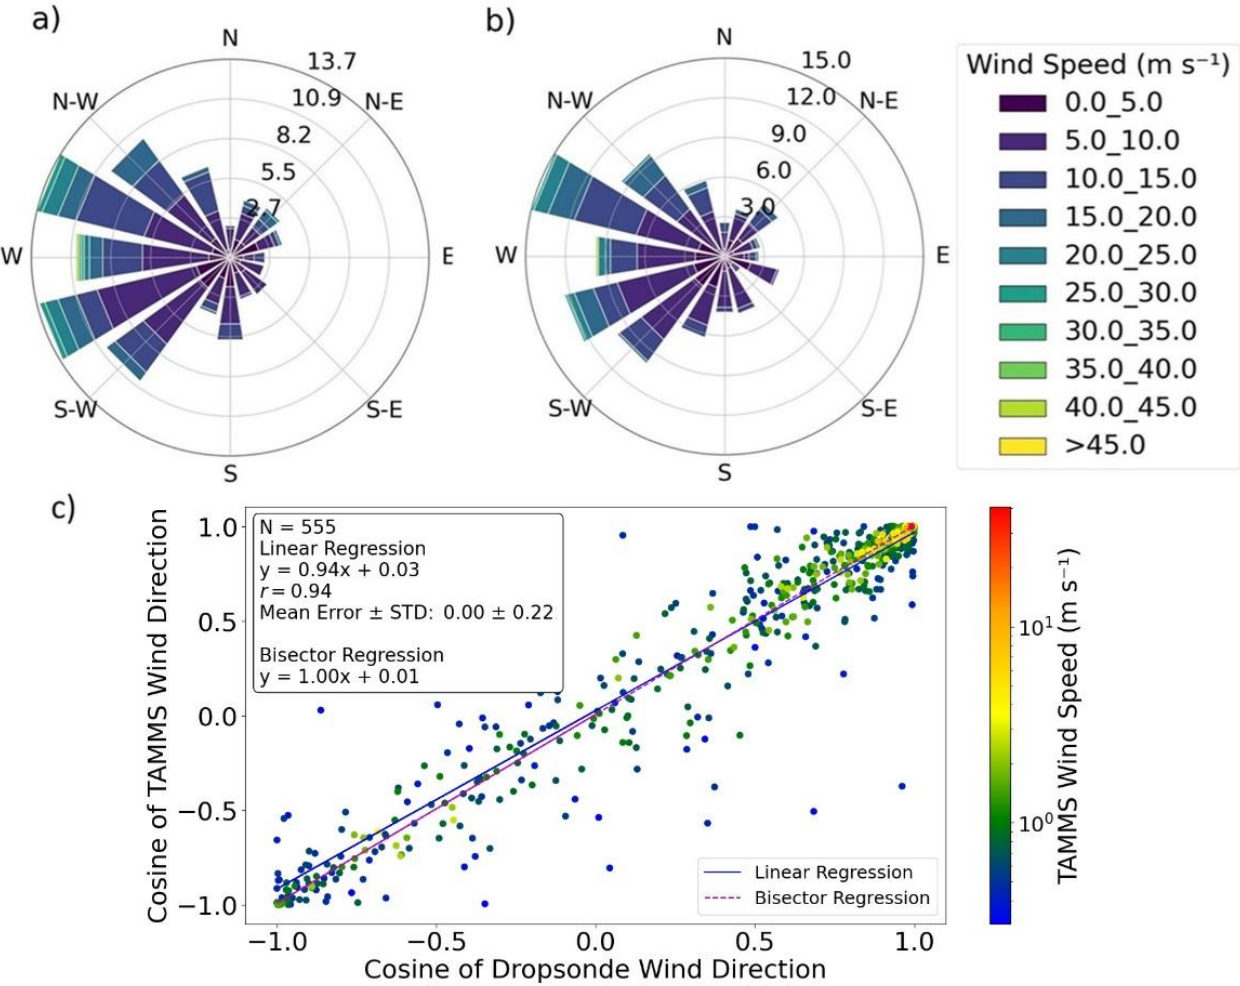

Figure 8: Wind rose for the final 555 pairs of points for a) TAMMS and b) dropsonde. c) Wind direction scatterplot between dropsonde and TAMMS pairs of single points following the full method of Figure 1 including the last step. Note that the cosine of wind direction is used to handle values close to 0/360° in a more meaningful way. Markers are colored by TAMMS wind speed on a logarithmic scale.

3.3 Intercomparison of T and RH

Following the same format of the wind speed results in Figure 6, Figure 9 intercompares T and RH measurements between the Falcon and dropsondes. Statistics associated with the intercomparisons for T and RH are in Table 4 and 5, respectively. Histograms of these two variables (Figure 7i-l) reveal median values of temperature (Falcon/Dropsonde) of 11.21/11.01 °C with a minimum of -19.24/-18.47 °C and maximum of 27.36/27.30 °C. Median values of RH (Falcon/Dropsonde) are 75.05/79.87% with a minimum of 0.70/0.72% and maximum of 109.90/99.99%.

The overall correlation coefficients are 0.99 for T when using all data pairs with relaxed vertical gap criteria (369,859 pairs). For the final 555 pairs, T intercomparisons revealed almost perfect results with a mean error of 0.00 ± 0.71 °C, correlation coefficient of 0.99, and slopes of 1.00 for both linear and bisector regressions. Y-intercepts were between -0.01 and 0.01 °C. For all the various other categories examined, T results generally remained nearly perfect in terms of agreement with low mean errors (between -0.13 and 0.12 °C) and correlation coefficients ≥ 0.98 . The median difference in temperature (TAMMS – dropsonde) was -0.02 °C (Fig. 7l).

Relative humidity data values did not agree as well as T due at least partly to more general spatial heterogeneity that exists with RH in the atmosphere as confirmed with previous studies using the ACTIVATE data (e.g., Crosbie et al., 2024; Dadashazar et al., 2022). Figure 9c-d shows RH scatterplots colored by the temperature difference between TAMMS and dropsondes because the DLH RH values are a derived quantity and depend on temperature; thus it is of interest to identify possible sensitivity of the RH instrument differences to a temperature bias. Figure 9c-d indeed does show that some of the larger RH differences exhibit the largest temperature biases too. For the first two categories compared in Table 5, the mean error was (relaxed vertical criteria) $-3.08 \pm 11.22\%$ and (strict vertical criteria) $-3.86 \pm 10.74\%$, with correlation coefficients being 0.93 and 0.91 for those two categories, respectively. Thus it seems that the dropsondes usually measured higher RH on average, which is a consistent theme throughout Table 5 when examining the mean error for the various categories shown. Figure 7o shows that the median difference between the DLH and dropsonde RH was -2.99%, further confirming a slight bias with higher dropsonde values. The RH agreement appeared to be best when examining the lowest RH tercile ($< 70.52\%$) as compared to any other category shown, which indicates that this comparison is not favorable in more humid conditions such as near clouds with substantial spatial variability. This was already demonstrated in Figure 4's case study flight. For that lowest tercile of RH conditions, the mean error is $-0.30 \pm 10.16\%$ with a correlation coefficient of 0.91 and linear/bisector slopes of 0.98/1.08. Still even for that category, the standard deviation was considerable. Given that RH is temperature-dependent, we also examined water vapor mixing ratio (WVMR). With relaxed vertical criteria, the correlation between DLH and dropsonde WVMR values remained strong ($r = 0.97$; Fig. 9e), similar to the RH intercomparisons ($r = 0.93$). With stricter vertical criteria

(Fig. 9f), the intercomparison was still strong ($r = 0.84$) and consistent with the RH intercomparisons ($r = 0.91$). This further confirms the robustness of our humidity measurements across different instruments, regardless of temperature differences.

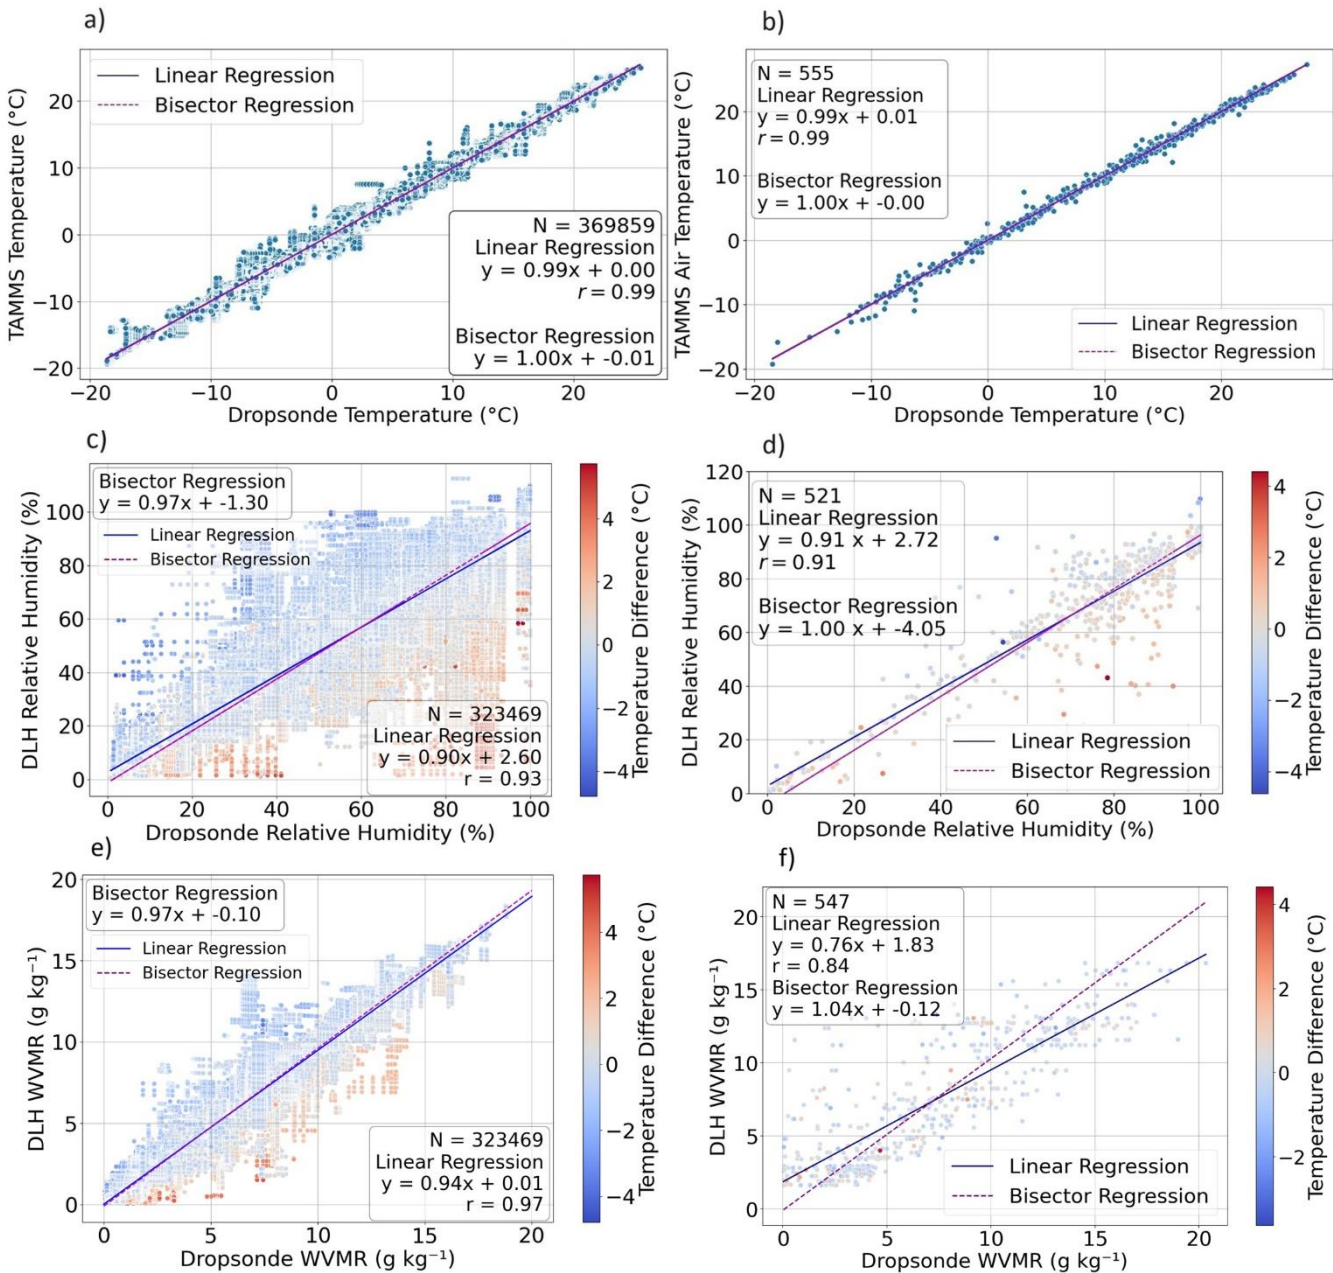

Figure 9: (a) Temperature scatterplot between dropsonde and TAMMS pairs of single points following the method of Figure 1 (within 30 km, 15 min, and 25 m vertical spacing) excluding the last step to find the single points with the minimum altitude difference. (b) Same as (a) except showing only pairs following the full method of Figure 1 including the last step. (c-d) Same as (a-b), but for RH with markers colored by temperature difference: TAMMS – dropsonde. (e-f) Same as c-d, but for water vapor mixing ratio (WVMR).

Table 3: Summary table of all TAMMS – dropsonde wind speed intercomparison metrics. The first row uses all data points following the Fig. 1 method excluding the last step, which allows for vastly increased statistics by allowing all pairs to be used that were within 25 m vertical distance. The second row includes the final step of Fig. 1 using only the data points with minimized vertical separation (i.e., one pair per dropsonde launch). Remaining rows examine all the data from the second row but in various categories. SE = standard error; STD = standard deviation.

	N	Linear (SE)/Bisector Slope (SE)	Linear /Bisector Y-Intercept (m s ⁻¹)	r	Mean Error ± STD (m s ⁻¹)
All: Relaxed vertical criteria	369677	0.97 (0.00)/1.02 (0.00)	0.43 /0.01	0.95	0.21 ± 1.62

4. Conclusions

This study provides a novel intercomparison of wind components, T, and water vapor measurements by comparing data from 555 dropsondes launched from a high-flying King Air to independent in situ instruments on a lower-flying Falcon during the 2020-2022 ACTIVATE campaign over the northwest Atlantic. This effort is largely motivated by the importance of assessing

airborne instrument performance and determining the validity to integrate dropsonde data with data collected from another coordinated aircraft, especially in light of a growing number of field campaigns with spatially coordinated aircraft. ACTIVATE’s large set of statistics was leveraged to compare the level of agreement for these geophysical variables in various categories related to season, cloudiness, altitude of comparison, horizontal separation distance, terciles of the variable values, and other categories associated with the amount of data points used. The overall results reveal good agreement, with the best being for temperature ($r = 0.99$, mean error = $0.00 \pm 0.71^\circ\text{C}$) and the weakest being for RH ($r = 0.91$, mean error = $-3.86 \pm 10.74\%$). Overall wind speed from the TAMMS agrees very well with dropsondes ($r = 0.95$; mean error = $-0.21 \pm 1.68 \text{ m s}^{-1}$), with its u and v components showing even better agreement. The mean errors are comparable or less than the respective instrument uncertainties (i.e., $\leq 0.5 \text{ m s}^{-1}$ for u/v winds, $\leq 0.5^\circ\text{C}$, $\leq 15\%$ RH). Wind directions also exhibited good agreement between the TAMMS and dropsondes. No significant biases between the respective instruments compared were noted except a small bias with slightly larger RH values with dropsondes relative to the DLH, although it is shown that some of the differences can be explained by higher T values measured by the TAMMS, which are used to derive RH values with the DLH.

Our results are comparable to what is reported in the literature (Table 1) although it is not an “apples to apples” comparison between studies owing to the various filtering methods employed, conditions incorporated for intercomparisons (e.g., cloudiness, altitudinal preferences, land versus ocean), and the widely ranging amount of data used between studies as demonstrated in Table 1. Our results align with findings in the literature (Table 1). For context, Dmitrovic et al. (2024) reported a HSRL-2 wind speed accuracy of $0.15 \pm 1.80 \text{ m s}^{-1}$ compared to dropsondes during ACTIVATE when focusing on ocean surface wind speed only, which is quite comparable to the intercomparison between dropsondes and the TAMMS in this study.

When comparing air motion systems (including a TAMMS) on aircraft next to each other in flight, Thornhill et al. (2003) showed that u/v wind components and temperature intercomparisons during carefully chosen flight legs within 200 m horizontal separation exhibited slopes and y-intercepts of 1 and 0, respectively, which is not too different than values in this work. Wind direction intercomparisons by Bucci et al. (2018) between a lidar and dropsondes revealed a correlation coefficient of 0.92, which is comparable to this study ($r = 0.94$) albeit our comparison is based on cosine of angles. Scicluna et al. (2023) reported a r^2 value of 0.95 when comparing wind directions between a remotely piloted aircraft system and a ground-based lidar, with their comparisons limited to only the lowest 100 m. This work provides added confidence in data quality for the instruments compared and highlights the suitability of using dropsonde data launched from a higher flying aircraft to another one flying lower with a fair degree of spatial and temporal coordination for conditions such as the northwest Atlantic where there can be heterogeneity in atmospheric conditions.

535 **Data Availability**

Data from the ACTIVATE airborne campaign can be accessed at <https://asdc.larc.nasa.gov/project/ACTIVATE> (ACTIVATE Science Team, 2020).

Author Contribution

540 EC, YC, JPD, GSD, RAF, JWH, SK, JBN, KLT, CV, HV contributed to the collection of the aircraft data. SN and SD conducted data analysis and investigation. SN and AS drafted the manuscript. All co-authors participated in the review and editing process.

Competing Interests

The authors declare that they have no conflict of interest.
