Abstract. ~~The concept of~~ "~~radiative~~Radiative" or "rapid" adjustments ~~refers~~ refer to the response of the climate system to an instantaneous radiative forcing, independent of surface temperature changes. These adjustments ~~can~~ occur over time scales from hours (e.g.~~aerosol-cloud-interactions~~, aerosol-cloud interactions) to months (e.g., stratospheric temperature changes)~~or even longer, making it challenging to distinguish adjustments from feedbacks over longer time scales. Despite variations in~~

5 ~~definitions, understanding these processes is essential for advancing climate modelling.~~

~~Adjustments to radiative forcing are an important yet uncertain component of climate forcings. However, disentangling adjustment and feedback mechanisms~~, often overlapping with feedback mechanisms–making their separation in realistic scenarios ~~remains highly challenging. Therefore, analysis of more controlled experiments can shed light onto different kinds of adjustment mechanisms, improve understanding and can be an important contribution on our way to more realistic scenarios~~

10 challenging. Controlled simulation experiments can thus help isolate adjustment processes and improve understanding relevant to more complex cases like volcanic eruptions or ~~the current~~ ongoing climate change.

The abrupt-solm4p experiment ~~within~~ of the Cloud Feedback Model Intercomparison Project (CFMIP)~~as~~, part of the 6th Coupled Model Intercomparison Project (CMIP6), simulates an instantaneous 4% reduction in the solar constant ~~, starting~~ from a pre-industrial ~~run~~ state on 1 January 1850. This study ~~analysed~~ analyses changes in climate variables, cloud properties,

15 and radiative fluxes ~~over~~ across different time scales (hours, days, months and up to 150 years) to ~~understand adjustment processes~~identify adjustment mechanisms and characteristic fingerprints to a shortwave forcing scenario.

Four models ~~were evaluated, showing initial rapid cooling, particularly~~ show rapid adjustments of $3.57 \pm 0.46 \mathrm{W\,m^{-2}}$, offsetting $\sim$35% of the initial forcing. Distinct local patterns include initial rapid surface cooling—especially over Antarctica and the ~~southern hemisphere, slowing down~~ Southern Hemisphere. Stratospheric cooling slows the polar night jet, ~~disrupting~~

20 disrupts the polar vortex~~and increasing~~, and increases Arctic cloud cover.~~During~~, causing local warming. Within the first month, the troposphere cools ~~down faster~~ more quickly than the ocean surface, decreasing vertical stability and ~~increasing~~ enhancing cloud cover over ~~ocean, while the opposite effect happens in the tropics over land. This in turn affects land-sea-circulation. On longer time scaleswe find robust changes of cloudiness~~oceans, while tropical land regions show the opposite change. On monthly time scales, high clouds shift downward due to reduced convective heating.

1 Introduction

The Earth's climate is governed by radiative fluxes entering and leaving the atmosphere. In a steady-state system incoming and outgoing fluxes are balanced, maintaining an equilibrium of the Earth climate system. In case of any perturbation to this balance, known as a radiative forcing, the climate system reacts by heating or cooling, which leads to a new balance of energy fluxes on time scales of centuries. Different processes in the climate's response, called feedbacks or adjustments, either enhance or dampen the Earth's capability to reach a new equilibrium. Feedbacks act in response to global mean surface temperature change and typically take place over years and centuries. In contrast, adjustments happen in direct response to a forcing agent, are independent of surface temperature change and mostly evolve on shorter time scales of days, weeks and months (Andrews and Forster, 2008; Gregory and Webb, 2008; Sherwood et al., 2015). Radiative adjustments of the atmosphere to an external forcing are of particular interest to the scientific community and a growing number of studies have been conducted on the subject (Gregory et al., 2004; Zelinka et al., 2013; Myhre et al., 2013; Sherwood et al., 2015; Smith et al., 2018; Forster et al., 2021b; Quaas et al., 2024). By introducing radiative adjustments into the forcing-feedback-framework as part of the effective radiative forcing (ERF, Myhre et al., 2013), the resulting ERF is a better predictor of implied global surface temperature change, since it is more independent of the kind of forcing agent (Andrews and Forster, 2008; Gregory and Webb, 2008). However, this approach requires a precise estimate of ERF, which comprises the instantaneous radiative forcing (IRF) as well as (radiative or rapid) adjustments (RA), which are prone to high uncertainty, especially in case of cloud adjustments (Andrews and Forster, 2008).

The total global mean radiative imbalance at the top of atmosphere (TOA) $\bar{N}(t)$ can be written as

$$\bar{N}(t) = IRF + RA + \sum_i \lambda_i \Delta \bar{T}(t) \tag{1}$$

where the sum over the feedback parameters λ_i accounts for the different sources of feedbacks.

Although RAs are formally independent of global mean surface temperature change (Andrews and Forster, 2008; Gregory and Webb, 2008; Sherwood et al., 2015), local temperature changes and consequential atmospheric adjustments can contribute a considerable amount to the overall RA (Quaas et al., 2024). Furthermore, despite many adjustments happening on time scales from hours to days (e.g. precipitation and changes in some cloud properties), adjustments of the stratosphere, cryosphere or vegetation can take months to years (Forster et al., 2021b; Stjern et al., 2023). This leads to an overlap of adjustment and feedback time scales, which makes it difficult to disentangle both. Moreover, adjustments are often confounded by climate variability in magnitude, making it very hard to detect them in observations.

This is further complicated by the transient nature of most forcing processes happening in the Earth climate system, like the gradual increase of CO_2 from anthropogenic sources in the atmosphere. ~~In contrast to that~~

To circumvent these issues, climate models allow the application of instantaneous forcings ~~,~~ that exceed climate variability and are kept constant~~for longer time scales allowing for~~, facilitating a better analysis of adjustments and feedbacks. A common experiment using global climate models is the instantaneous two- or fourfold increase of the atmospheric CO_2 concentration (e.g., Gregory et al., 2004; Colman and McAvaney, 2011; Kamae and Watanabe, 2012; Zelinka et al., 2013; Andrews et al., 2015) in order to predict long-term consequences of anthropogenic climate change as well as short-term adjustments. ~~Special focus has been on adjustments of cloud optical properties and cloud fraction, since they are an important source of uncertainty in climate models. Reducing short-term uncertainty of cloud adjustments could also reduce uncertainty of long-term predictions (Andrews and Forster, 2008; Nam et al., 2018). Several studies have found a positive shortwave adjustment in 2x or 4xCO_2-simulations due to the reduction of cloud fraction in tropical and mid-latitudes associated with decreased relative humidity in reaction to the warming of the lower troposphere (e.g., Gregory and Webb, 2008; Colman and McAvaney, 2011).~~

However, these simulations are often highly idealised, using fixed sea-surface temperatures or omitting the existence of continents (aqua-planet-simulations). In order to compare and validate such results with observations ~~,~~ a natural forcing is required ~~,~~ that is applied nearly instantaneously and is of sufficient strength. Volcanic eruptions are considered such so-called "natural laboratories" (e.g., Malavelle et al., 2017; Christensen et al., 2022). ~~During large volcanic eruptions ,~~ Large volcanic eruptions emit huge amounts of aerosols ~~are emitted~~ into the atmosphere in a very short time frame of hours. If transported up to the stratosphere, depending on the location and season of the volcanic eruption, the aerosol can form a ~~scattering layer around the globe~~ global scattering layer with a lifetime of up to one to three years (Myhre et al., 2013). This way, volcanic eruptions exert a radiative forcing ~~,~~ that is approximately comparable to the instantaneous forcing that usually only models can realise. However, examining volcanic eruptions includes other challenges. The initial forcing is very localised and only after a few months the aforementioned scattering layer is formed around the globe. Depending on the location of the volcano, the strength of the manifold adjustment mechanisms and the distribution of the stratospheric aerosol layer varies. Hence, time scales of different adjustments might still overlap. Therefore, before analysing adjustments to a realistic volcanic eruption, it can be helpful to further simplify the problem. A reduced solar constant forcing can serve as a simplified analogue to a stratospheric volcanic aerosol layer, as both reduce the amount of shortwave radiation reaching the troposphere.

In this study, we thus examine the results of the abrupt-solm4p experiment, which is part of the Cloud Feedback Model Intercomparison Project (CFMIP) as part of the 6th Climate Model Intercomparison Project (CMIP6) (Eyring et al., 2016; Webb et al., 2017). The output of four global climate models, which participated in this experiment, is available. ~~The simulation reduced the solar constant instantly~~ In the simulations the solar constant was reduced by 4% and kept constant at this value. This can be regarded as a simplified analogue for an aerosol scattering layer. ~~Both, volcanic~~ Volcanic eruptions and a reduced solar constant both lead to a reduced incoming shortwave flux at the surface, even if stratospheric adjustments are expected to differ. Hence, similar adjustment patterns are expected for both types of forcing, when the scattering sulfate layer distributes over the whole globe with time. ~~Several studies~~

90 There have been numerous studies that analysed the reaction of the Earth climate system to a number of different forcing agents ~~(e.g., Gregory et al., 2004; Smith et al., 2018), however~~ so far (e.g., Gregory et al., 2004; Smith et al., 2018), However only few studies quantified radiative adjustments after solar forcing and took a closer look at the specific processes happening in response to solar forcing (e.g., Salvi et al., 2021; Virgin and Fletcher, 2022; Aerenson et al., 2024).

Radiative adjustments to solar forcing in sum typically counteract the initial forcing (e.g., Smith et al., 2018; Russotto 95 and Ackerman, 2018; Virgin and Fletcher, 2022; Aerenson et al., 2024). Most of this is attributed to decreased temperature of the troposphere, stratosphere and land surface, which leads to a reduction in longwave radiation lost to space. The effect is partially offset by the reduction of water vapour in the atmosphere, following the Clausius-Clapeyron relationship, and thereby an increase in outgoing longwave radiation. Moreover, Smith et al. (2018) derive a positive adjustment due to change in surface albedo. Furthermore, differential heating of sea and land surface can lead to changes in circulation patterns, which 100 affects precipitation and cloud properties. On longer time scales also a change in vegetation might happen, but is not subject of this study and no further analysis was performed here.

However, when analysing rapid adjustments due to changes in cloud properties, the studies find contradictory results. This is in accordance with an overall high uncertainty linked to cloud property changes in climate models. Reducing short-term uncertainty of cloud adjustments could also reduce uncertainty of long-term predictions (Andrews and Forster, 2008; Nam et al., 2018) 105 . In case of solar forcing Smith et al. (2018) and Virgin and Fletcher (2022) find cloud adjustments that counteract the initial solar forcing. In response to a $+2\%$ solar constant forcing, Smith et al. (2018) describe an increase in cloud fraction in the boundary layer, a reduction of cloud fraction in the free troposphere, a small increase in cloud fraction at around $100\,\mathrm{hPa}$ and a decrease above this level. This is very similar to our findings, although of the opposite sign, since we examined the response to a reduction of solar constant. Using radiative kernels, Smith et al. (2018) show that cloud changes lead to negative long- 110 and shortwave effects, but with high model disagreement in the shortwave effects. In response to a $+2\%$ solar forcing, Virgin and Fletcher (2022) find that the shortwave component is dominated by changes in the boundary layer clouds, while changes in the troposphere contribute more to the longwave effects. In contrast to this, Aerenson et al. (2024) find cloud adjustments that further amplify the initial solar forcing. In response to a $+4\%$ solar constant forcing, they find an overall positive cloud radiative adjustment, which is strongest, where low-cloud fraction is reduced. The two main mechanisms are changes in cloud 115 fraction and cloud optical depth, which they find are of opposite sign in case of solar forcing. Moreover, short- and longwave effects tend to ~~cancel each otherout~~partially compensate each other, but shortwave effects are slightly stronger. Hence, in total, positive shortwave effects due to decreased cloud fraction dominate the overall cloud adjustments. However, they find that the participating models do not agree on the signs of cloud adjustment effects and the uncertainty of the total effect is high.

Even though the studies describe similar changes in cloud properties, the derived cloud radiative adjustments differ depend- 120 ing on the applied method and models used. This demonstrates ~~,~~ how radiative effects of cloud property changes are still one of the major sources of uncertainty in climate models, even in highly idealised solar forcing scenarios. Hence, this study is particularly interested in adjustments of cloud properties and characteristic patterns in response to shortwave forcing.

CFMIP provides outputs from $+4\%$ solar constant (solp4p) as well as -4% solar constant (solm4p). Using both experiments would increase the amount of data statistics could be based on. However, as e.g. Aerenson et al. (2024) found, response to

125 positive and negative solar forcing does not only differ in sign, but it also shows different patterns due to non-linearities and dependence on the base state. Hence, for this study, we decided to only look at rapid adjustments to a reduction in solar constant (solm4p), which in a later step could be compared to adjustments to volcanic forcing.

Reduced solar constant simulations are also of interest for the increasing number of solar radiation modification (SRM) studies ~~,~~ that often aim to balance the forcing due to anthropogenic emissions of CO_2 by reducing the absorbed solar radiation

130 (e.g., Bala et al., 2008; Cao et al., 2015; Schmidt et al., 2012; Huneeus et al., 2014; Russotto and Ackerman, 2018). Having a better understanding of not only the long-term effects of SRM methods, but also knowing about short-term adjustments, can improve the risk assessment of these endeavours. In these scenarios, not only the global mean ~~development~~ evolution of climate variables, but also, if not even more, local processes are of high importance. Especially short-term adjustments of clouds and precipitation can lead to local droughts or floods, with possibly important effects for local communities. ~~Hence, a~~

135 ~~better understanding of adjustments to certain types of forcing, will not only reduce the uncertainty of long-term predictions of~~ ~~climate models but also improve short-term forecast.~~

There are several methods to quantify radiative adjustments in climate models. On the one hand, the linear regression method (Gregory et al., 2004), based on Eq. 1, allows for a simultaneous determination of ERF, equilibrium climate sensitivity (long-term trend) and climate feedback parameter ($\sum \lambda_i$). In order to derive radiative adjustments from ERF, knowledge of the

140 instantaneous forcing is necessary. For most forcing agents, it is possible to diagnose the IRF by separate radiative transfer modelling. However, the regression method is only feasible for the global mean and it relies on the assumption ~~,~~ that all rapid adjustments happen ~~,~~ while the global mean surface temperature change is still zero. This is an oversimplification, as inert systems like cryosphere or vegetation might still adjust to the initial forcing, while global mean surface temperature ~~already~~ ~~begins~~ has already begun to change.

145 On the other hand, the fixed surface temperature method (Hansen et al., 2005) or rather fixed-sea-surface temperature (~~SST),~~ ~~which is easier to implement in global climate models (Forster et al., 2016), is~~ fixed-SST) is widely used and has the advantage of suppressing feedbacks (Forster et al., 2016). This allows for the disentanglement of adjustments and feedbacks. However, this method artificially suppresses adjustments of ocean surface temperature and introduces unrealistic land sea contrast, which hinders a realistic estimate of circulation adjustments. Andrews et al. (2021) showed a significant difference in ERF depending

150 on whether only sea surface temperature or all surface temperature was kept to zero. Possible adjustments to localized warming or cooling, cannot be simulated in this kind of ~~setups~~setup, although in some concepts they are considered adjustments relevant to TOA ERF (Quaas et al., 2024).

The simulations analysed in this study apply an instantaneous solar forcing that is kept constant, while allowing the whole climate system to adapt in a fully coupled general circulation model. The regression method was used to quantify ERF and RA,

155 but non-linear behaviour was found for the first 4-10 years, when the more inert systems like ocean, cryosphere or vegetation still adjust to the forcing, while global mean surface temperature change starts to dampen TOA effective flux imbalance.

Nevertheless, this model setup allows us to examine adjustment processes on time scales of hours, days and months, where, as we show, TOA effect flux change is still dominated by adjustment processes rather than temperature mediated change.

In a reduced solar constant experiment a variety of adjustment processes can be analysed. Thermodynamical and dynamical adjustments due to cooling or heating of the atmosphere, but also, visible in the anomaly of surface and atmospheric temperature, lead to changes in pressure systems and circulation patterns. Changes in cloud properties and precipitation during the first hours are a result. On longer time scales also a change in vegetation might happen, but is not subject of this study and no further analysis was performed. An important focus of this study are cloud adjustments, which even in this simple experiment are clearly the source of highest uncertainty. The aim of this study is to identify typical response patterns as well as global mean radiative adjustments to solar forcing.

Section 2 contains a more detailed description of the experiment setup as well as an overview of the available data. Section 3 first shows the results of the classical regression method by Gregory et al. (2004), in order to quantify ERF and RA. It then discusses , how time scales of hours, days and months are dominated by adjustment processes, to proceed and examines TOA radiative fluxes and cloud radiative effect anomaly. Afterwards, it proceeds with a closer analysis of adjustment processes of a number of different climate variables. These include surface and atmospheric temperature, relative humidity, vertical velocity and cloud fraction. In the end, we take a closer look on the radiative flux anomalies and finally analyse cloud adjustments by examining adjustments in the cloud radiative effect. Section 4 discusses the results of this study in the context of studies that have been conducted on adjustments to solar forcing in recent years and discusses the limitations of the dataset and the approach. Section 5 contains a summary and provides an outlook on how this studies study's findings can contribute to future research in the field of radiative adjustments.

2   Methods

In the solm4p-experiment, the solar constant is reduced instantaneously by $4\,\%$ and kept constant at $96\,\%$ of the solar constant of the control run (pi-Control). It branches off the pi-Control simulation on 1 January 1850. No other forcing is considered in the experiment. The diagnostics of four models, which participated in this experiment, are available: IPSL-CM6A-LR, CESM2, CanESM5 and MRI-ESM2-0 (further information provided in Table 1). For each model one experiment run corresponding to one pre-industrial control run (piControl) is provided. While some models provide 3-hourly output for several parameters, CESM2 only provides daily data. In case of vertically resolved atmospheric cloud fraction, only monthly data was available from all four models. More information on the four models, including their horizontal and vertical grid spacing is provided in Table 1.

For all variables examined in this study, the difference attributable to the reduction in solar constant was calculated for each parameter by subtracting the piControl-run from the solm4p-run for each point in time and space.

Following Stjern et al. (2023), four different time scales were considered: the first 100 hours, the first 30 days, the first year and the following years until 150 years after the onset of forcing. For the first time scale (up to 100 hours) 3-hourly data was used, when available, else daily data was used. For the second time scale (days 5–30) daily averages were used, for the third time scale (months 2–12) monthly data was used and for the long-term development (years 2–150) yearly means were plotted.

The transitions between the plots of different time scales often display a small jump, because the next frequency does not contain the last ~~datapoint~~ data point of the preceding frequency, but an average.

For all time scales the global mean was calculated for each model. Moreover, a multi-model mean was calculated by first interpolating all models to the time axis of the MRI-ESM2-0 model. This model was chosen as reference, because it provided the most extensive database for the abrupt-solm4p experiment. If not all models provided data of the same frequency, the highest available resolution was plotted for each model, respectively and for the multi-model mean, the other models were interpolated to the 3-hourly time axis of MRI-ESM2-0.

In addition to the temporal development of global means, a geographical distribution of the respective parameter was plotted, averaging over the respective time scales. For the mean of the first three time scales, all time steps were averaged, while for the fourth time scale only the years 120-150 after the onset of forcing were averaged to obtain an estimate for the long-term new approximate equilibrium state. For the global distribution, a multi-model mean was calculated by interpolating the other models to the CanESM5 horizontal grid, which was the coarsest out of the four models.

Besides the grid spacing, also the height levels varied between the models in case of the atmospheric cloud fraction data. For the other climate variables, all models used the same 19 height levels. In case of cloud fraction, the other models were interpolated to the CanESM5 pressure axis.

In order to account for uncertainty, the multi-model standard deviation was plotted together with the temporal development of multi-model global mean. In case of global distributions of anomalies, areas were dotted in which less than three of four models agreed on the sign of anomaly.

To analyse differences in land and sea surface response, some climate variables, e.g. relative humidity, were averaged only over ocean and only over land. This was done by applying a land-sea-mask, based on the CanESM5 grid, before performing the zonal averaging.

This study focuses on cloud adjustments and the cloud radiative effect, which was calculated from the difference between simulation runs with clouds (all-sky) and a second radiative transfer calculation for each step without clouds (clear-sky), both provided by each of the four models. Then, the total cloud radiative effect anomaly at TOA was calculated as the combined effect of solar (shortwave) and terrestrial (longwave) radiation changes due to cloud changes.

The linear regression method introduced by Gregory et al. (2004) was applied for a number of TOA fluxes, in order to estimate their influence on the overall ERF. For that purpose, the yearly global mean of the respective TOA flux change was plotted over the yearly global mean of near-surface temperature change and a linear regression was used, which determined the intercept with the TOA flux axis.

3 Results

In order to estimate the rapid adjustments to a 4% solar constant reduction, we applied the regression method developed by Gregory et al. (2004) to the solm4p-CFMIP data. The results are shown in the following section. We then move on to examine different time scales after the onset of forcing and motivate, how the first three time scales (hours, days and months) are

dominated by rapid adjustments, while the fourth time scale shows the long-term adaptation and is therefore dominated by surface temperature mediated processes. Afterwards, we analyse the response of different climate variables like temperature, humidity and cloud ~~properties~~ fraction on the different time scales and ~~finally examine how these climate variables influence top of atmosphere fluxes and the cloud radiative effect~~ identify characteristic adjustment patterns of these variables.

3.1 Effective radiative forcing and rapid adjustment estimate

We applied a linear regression to the yearly global means of TOA radiative budget change (Δ TOA budget or N following Eq. 1) and near surface temperature change (ΔT) of the four available models.

The results are shown in Fig. 1 ~~a together with the same plots for the individual TOA budget components~~.

The TOA radiative budget anomaly shows the expected behaviour for all four models, starting with negative values for $\Delta T = 0$ and then approaching a new radiative balance. The ~~development is mostly linear, however, especially for the first 10 years all models exhibit a slightly steeper slope than in long term. This deviation could either be interpreted as radiative adjustments developing as long as a decade or it might suggest, that the overall relation between ΔT and TOA radiative budget anomaly changes after about a decade, due to the inertia of the ocean. The~~ multi-model mean IRF was estimated as the difference between downward and upward shortwave anomaly for the first month after onset of forcing (shortest output frequency available for all models). The intercept of the linear regressions with the y-axis provides the ERF and the difference between ERF and IRF yields the RA. Multi-model mean ERF and RA are given at the bottom of the figure and are also provided in Table 2. The negative IRF of approximately $-10\,\mathrm{W\,m^{-2}}$ is reduced by radiative adjustments of $3.6\,\mathrm{W\,m^{-2}}$, resulting in an ERF of $6.4\,\mathrm{W\,m^{-2}}$. While some models, like CanESM5 and IPSL-CM6A-LR, simulate a strong temperature decrease in

response to the radiative forcing, CESM2 and MRI-ESM2-0 reach a new equilibrium at a significantly weaker change in surface temperature.

The development is mostly linear. However, especially for the first 10 years all models exhibit a slightly steeper slope than in the long term. This deviation could either be interpreted as radiative adjustments developing on time scales as long as a decade, similar to the ocean-atmosphere adjustments found by Rugenstein et al. (2016), or it might suggest a change in the relation between ΔT and N, with the deep ocean heat uptake dominating the SST-pattern after a decade of forcing, changing the overall ocean heat uptake efficacy (Andrews et al., 2015). Other studies like Gregory and Webb (2008) found similar non-linearities and attributed those to shortwave cloud radiative effects. In this study the non-linearity was predominant in the clear-sky shortwave component over ocean, but no further analysis was conducted, as this study concentrates on the adjustment processes during the first year after onset of forcing.

Analogous to the total TOA radiative budget, ~~also the yearly mean of the~~ linear regressions were also performed for the single components of the TOA budget, i.e. downward shortwave flux change $\Delta sw^{\downarrow}_{\mathrm{allsky}}$ $\Delta sw^{\downarrow}$, upward shortwave flux change $\Delta sw^{\uparrow}_{\mathrm{allsky}}$ $\Delta sw^{\uparrow}$ and upward longwave flux $\Delta lw^{\uparrow}_{\mathrm{allsky}}$, ~~were plotted against the surface temperature change and linear regressions were applied in Figures 1b, 1c and 1d. Again~~ $\Delta lw^{\uparrow}$ (Fig. A1 in the Supplements). Approximating the instantaneous response of the respective radiative components as the offsets after one month of simulation ~~were marked as red crosses to provide insight into the contribution to overall RA~~, the contributions of the single ~~radiative components . The multi-model mean intercepts of the linear regression with the radiative flux axis~~ components to the overall IRF and ERF can be estimated and are shown in ~~the respective figures as well as in~~ Table 2. ~~As determined by the experiment conditions, $\Delta sw^{\downarrow}$ (Fig. 1b) is held constant over the whole experiment time. However, a seasonal variation occurs due the elliptical orbit of the Earth and produces a small offset between the first month value (January) and the yearly mean values. This offset is considered as part of the IRF not the RA.~~

~~In contrast, $\Delta sw^{\uparrow}$ (Fig. 1c) exhibits a clear approximately linear relation to ΔT.~~ All models simulate an instantaneous response of $\Delta sw^{\uparrow}$ $\Delta sw^{\uparrow}$ of around $-4\,\mathrm{W\,m^{-2}}$ in reaction to the reduction of solar constant ~~(red cross)~~, depending on the planetary albedo. ~~However, the contribution of $\Delta sw^{\uparrow}$ to the ERF is more negative than this initial value (~~This is considered to be a part of the IRF, since it is an immediate response to the initial solar constant reduction, not requiring any atmospheric changes. However, the $\Delta sw^{\uparrow}$ ERF component is $-6.3\,\mathrm{W\,m^{-2}}$~~)~~, indicating shortwave radiative adjustments of $-6.3\,\mathrm{W\,m^{-2}} - (-4)\,\mathrm{W\,m^{-2}} = 2.3\,\mathrm{W\,m^{-2}}$. ~~All models display a deviation from the overall linear behaviour during the first decade. Other studies like Gregory and Webb (2008) found similar non-linearities. However, in their studies those were attributed to shortwave cloud radiative effects, while we found the source of this non-linearity to be in the clear-sky shortwave component over ocean, which is linked to short-term changes in sea-ice extent and snow cover, but were not further analysed in this study. The respective intercepts are provided in Table 2.~~

~~Figure 1d shows the same linear regression for upward longwave radiation anomaly ($\Delta lw^{\uparrow}$).~~ In contrast to that, no longwave contribution to the IRF is expected and models show no initial response of $\Delta lw^{\uparrow}$. All models simulate a clear linear relationship between $\Delta lw^{\uparrow}$ $\Delta lw^{\uparrow}$ and ΔT with an intercept of around $-1\,\mathrm{W\,m^{-2}}$, which is the longwave adjustment. Hence ~~, the upward~~ the longwave component contributes about $1/3$ to the overall RAs, while the shortwave RAs make up the other $2/3$. ~~In contrast~~
9

Figure 1. Linear regression plots for yearly global mean TOA radiative ~~flux anomalies~~ budget anomaly in W m^{-2} vs. change in yearly global mean surface temperature (ΔT). ~~Plotted are (a)~~ Increasing saturation of the ~~TOA radiative budget, (b) the downward shortwave flux at TOA, (c) the upward shortwave flux at TOA and (d) the upward longwave flux at TOA~~ colours indicates temporal development. ~~The respective initial offsets after one month are marked as a red cross.~~

~~to the upward shortwave component, there is no systematic deviation from linear behaviour in the longwave component during the first decade.~~

The same method was applied to the cloud radiative effect anomaly ($\Delta\text{CRE}_\text{TOA}$) and its ~~long- and shortwave~~ short- and longwave components ($\Delta\text{CRE}_\text{TOA,sw}$ and $\Delta\text{CRE}_\text{TOA,lw}$), respectively ~~.~~ (Fig. A2 in the Supplements). If an approach, similar to the IRF-ERF approach is applied and the ~~instantaneous CRE~~ initial $\Delta\text{CRE}_\text{TOA}$ is subtracted from the intercept, as it is purely a cloud masking effect, the remaining cloud adjustment is $3.3\,\text{W}\,\text{m}^{-2} - 2\,\text{W}\,\text{m}^{-2} = 1.3\,\text{W}\,\text{m}^{-2}$, mostly stemming from $\Delta\text{CRE}_\text{TOA,sw}$, which is a substantial contribution to the overall RA of $3.6\,\text{W}\,\text{m}^{-2}$. Hence, we find that cloud adjustments counteract parts of the initial solar forcing as was found by several other studies (Smith et al., 2018; Salvi et al., 2021; Virgin and Fletcher, 2022). ~~However, the uncertainty~~ The reason for the positive shortwave cloud adjustment found in this study might be the decrease of tropical cloud cover in the boundary layer, as the location of strong positive $\Delta\text{CRE}_\text{TOA,sw}$ (shown in the Supplements, Fig. A4) often coincides with decreased cloud cover at 850hPa (Fig. 10). However, our approach does not allow for a quantification of single contributions to the overall cloud adjustments. Moreover, the uncertainty of cloud radiative effect anomaly is high and ~~no clear pattern emerged, because~~ models disagreed on the sign of slope of the linear fits. The intercepts for the cloud radiative effect anomaly and its components are also provided in Table 2.

3.2 Rapid adjustments on different time scales

In ~~this study, we are interested in rapid adjustments~~ ~~to solar forcing in fully coupled climate models~~ the following section we analyse the temporal development of TOA radiative budget anomaly and its components, as well as of the surface temperature anomaly. The aim is to better understand the contributions of the single components to the total TOA budget anomaly and its

Table 2. Multi-model-mean intercepts of different TOA fluxes derived via regression method (ERF contribution in $\mathrm{W\,m^{-2}}$) and its deviation from the initial response (RA contribution in $\mathrm{W\,m^{-2}}$) calculated as the difference between linear regression intercept and the first month response ($\sim$ IRF contribution).

295 interaction with surface temperature change. In contrast to the linear regression method, in this section we look at temporal developments over the first hours, days and months, in order to learn more about the underlying adjustments. ~~Hence,~~

3.2.1 Temporal development of ΔTOA radiative budget and ΔT

Figure 2 shows the global mean of the three components of the TOA radiative budget, downward and upward shortwave flux anomaly ($\Delta sw^{\downarrow}$ in orange, $\Delta sw^{\uparrow}$) and upward longwave flux anomaly ($\Delta lw^{\uparrow}$), together with the TOA radiative budget

300 anomaly. Fluxes are defined positive downwards, so that added up, the three flux anomalies yield the total TOA budget anomaly. Only MRI-ESM2-0 provided TOA shortwave radiative fluxes as daily data, while the other three models only provided monthly data. Hence, Fig. 2 only shows the results of one model for shortwave flux anomalies and the total TOA budget anomaly for the first two time scales. The upward longwave radiative flux was provided as daily output by all models and is plotted accordingly.

305 $\Delta sw^{\downarrow}$ anomaly shows the reduction of the solar constant. It stays constant over all time scales and only displays a yearly periodic deviation due to the elliptical orbit of the Earth around the sun. It is the same for all four models, since the underlying assumption of the abrupt-solm4p experiment is an instantaneous and constant reduction of the solar constant by $4\,\%$, corresponding to a decrease of downward shortwave flux by $-13\,\mathrm{W\,m^{-2}}$.

As described before, $\Delta sw^{\uparrow}$ shows an instantaneous reaction, which is part of IRF, since it is a change in TOA radiation in

310 reaction to forcing, without any changes in atmospheric state. Hence, the IRF is the sum of incoming and outgoing shortwave anomaly at $t = 0$ and is around $-10\,\mathrm{W\,m^{-2}}$ according to experimental design. $\Delta sw^{\uparrow}$ shows first changes after 10 days, although no clear trend can be recognised. This is a reaction to changes in surface albedo, beginning after roughly 10 days and mostly connected to increased snowfall over land in high northern latitude and first changes in snow cover and sea ice extent in Antarctica. Furthermore, changes in cloud properties, beginning after a few hours, influence $\Delta sw^{\uparrow}$ over the first

315 month, but there is not one dominating process, but rather a complex interplay of mechanisms that result in the global mean
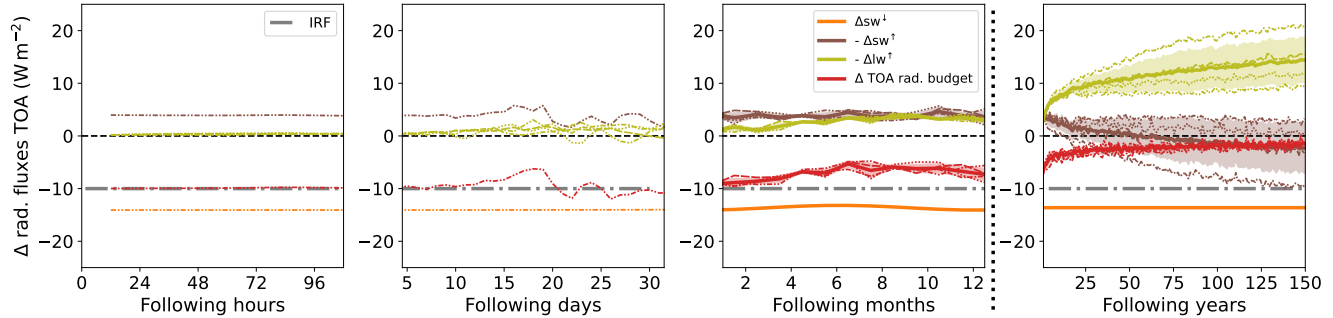

Figure 2. Global mean anomaly of radiative fluxes at TOA in $\mathrm{W\,m^{-2}}$ for four different time scales after onset of forcing (100 hours, 30 days, 12 months, 150 years). Plotted are the downward shortwave flux anomaly at TOA (orange), the upward shortwave flux anomaly at TOA (brown), the upward longwave anomaly at TOA (olive) and the effective flux anomaly at TOA (red). Shading around the multi-model mean shows multi-model standard deviation. If available, the results for all four models (thin lines) were plotted together with the model-mean (thick line). In addition to that, the instantaneous radiative forcing (IRF) is plotted as a grey dash-dotted line. Upward fluxes were multiplied by $\cdot(-1)$, such that the three radiative flux anomalies (orange, olive and brown) add up to the effective flux anomaly at TOA (red), which is the same as the black curve in Fig. 4.

temporal change. Over the first year, albedo and cloud properties show significant changes. Nevertheless, the upward shortwave anomaly stays relatively constant, indicating that the different climate variables and local variability approximately cancel out each other's shortwave radiative effects. Over longer time scales, the multi-model mean of upward shortwave flux anomaly decreases, changes its sign around 50 years after onset of forcing and continues to decrease up until 150 years. However, the

320 individual model runs do not agree on the sign of the anomaly on these longer time scales. This is due to opposing signs in high latitudes and tropical regions, and the models disagree, which region dominates the global mean effect (see Figure A3 in the Supplements). This is a significant difference in the long term prediction of the models, but was not further analysed here, since this study is focused on short term effects.

In contrast to the shortwave fluxes, there are no immediate effects of the reduction of the solar constant on the $\Delta \mathrm{lw}^{\uparrow}$. This

325 is expected, because it is closely linked to changes in surface and atmospheric temperature, which need some time to adapt. Similar to $\Delta \mathrm{sw}^{\uparrow}$, $\Delta \mathrm{lw}^{\uparrow}$ displays first changes around 10 days after the ~~surface temperature begins to adaptfrom the~~ onset of forcing~~, thereby possibly overlying adjustments of the atmosphere to the forcing with temperature mediated effects~~. It is overall slightly increased over the following days and only temporarily changes its sign. The multi-model mean always stays positive, indicating a reduction in the amount of longwave radiation to space, because the atmosphere and surface reduce their

330 temperature in reaction to the reduced incoming solar energy (the Planck effect). This effect continues and all models simulate a further increasing $\Delta \mathrm{lw}^{\uparrow}$ for longer time scales.

The TOA radiative budget anomaly is overall negative due to the negative forcing and corresponds to the IRF at $t = 0$. It is dominated by the shortwave effects on the time scales of hours and days, but in the course of months, the increasing longwave gain slowly reduces the TOA imbalance until it approaches a new balance over the following decades and centuries.
Figure 3. Global mean of near surface temperature anomaly in K for four different time scales after the onset of forcing (100 hours, 30 days, 12 ~~month~~months, 150 years). The results of the four participating models are plotted (cyan: CESM2, orange: CanESM5, blue: IPSL-CM6A-LR and green: MRI-ESM2-0) together with a multi-model mean (red, bold) and multi-model standard deviation (shaded area around multi-model mean). For the fourth timescale, the y-axis has been adjusted to account for the stronger changes on longer time scales.

335   ~~The~~ Analogous to the TOA radiative flux anomalies, the global mean near surface temperature anomaly ΔT is shown in Fig. 3. It ~~starts to become~~ becomes increasingly negative immediately after the onset of forcing due to decreased absorption of shortwave radiation ~~. The global mean near surface~~temperature decrease at the surface. ΔT is of the order of ~~0.25 K over the the~~ $-0.25\,\mathrm{K}$ over the first month, continuously ~~growing to values $> 1\,\mathrm{K}$~~ decreasing to values $< -1\,\mathrm{K}$ after four months. The four participating models agree well on the global mean ΔT during the first year~~in terms of this global average~~, but differ in

340   their long-term ~~surface temperature change~~ΔT, depending on the ~~models~~ model's climate sensitivity.

~~Changes of the global mean surface temperature of more than 1 K lead to changes of the TOA radiative forcing.~~

3.2.2   Simulated vs. calculated Δ TOA radiative budget

In this study, we are interested in rapid adjustments to solar forcing in fully coupled climate models. In those models, the surface temperature begins to adapt from the onset of forcing, leading to a possible overlap of adjustments and temperature

345   mediated effects (feedbacks).

However, when calculating the TOA ~~flux anomaly~~ budget anomaly N via Eq. 1 by multiplying the ~~surface temperature change~~ ΔT with the feedback parameter λ and adding the ERF, both derived from the linear regression in Sect. 3.1, a significant disagreement ~~between calculated TOA effective flux anomaly and~~ simulated TOA ~~effective flux anomaly becomes apparent~~budget anomaly (Fig. 2) and TOA budget anomaly calculated via Eq. 1 becomes apparent on the shorter time scales.

350   Figure 4 shows the simulated TOA ~~effective flux anomaly (~~budget anomaly anomaly (N_{sim} in black) together with the ~~TOA flux~~ surface temperature mediated TOA budget anomaly calculated from ~~the simulated global mean surface temperature change and~~ ΔT adding only the IRF ($N_{\mathrm{calc,IRF}}$ in red) and the complete ERF ($N_{\mathrm{calc,ERF}}$ in blue) for the four different time scales.

During the first time scale no adjustments or feedbacks take place that would ~~change the global mean TOA flux anomaly considerably~~lead to considerable changes in N. Hence, the red and black curves do not show a strong deviation. ~~But~~ However,

355 on all other time scales there is a significant offset between ~~the two~~ N_{sim} and $N_{\text{calc,IRF}}$. Especially for the time scales of days and months after the onset of forcing, the trend of ~~surface mediated TOA flux change~~ $N_{\text{calc,IRF}}$ cannot explain the trend of ~~the simulated TOA flux anomaly~~ N_{sim}. For the fourth time scale, both model means show the same trend, but with a constant offset~~. When adjusting the surface temperature mediated TOA flux change in Fig. 4 by the~~, which corresponds to the rapid adjustments (~~blue curve)from Sect. 3.1~~RA). When adding the RA and IRF yielding $N_{\text{calc,ERF}}$ (blue), the long term ~~trend~~

360 trends of calculated and simulated TOA flux change ~~agrees~~ agree well. However, the first three time scales show considerable deviations between ~~calculated and simulated TOA effective flux change and temperature mediated flux change is~~ N_{sim} and $N_{\text{calc,ERF}}$ and changes in surface temperature are clearly not sufficient to explain the simulated TOA ~~flux change.~~ radiative budget variability.

Hence, we argue ~~,~~ that the first three time scales are dominated by adjustment processes ~~and~~ while temperature mediated

365 changes only play a minor part. Clearly, this does not allow for a perfect distinction between adjustments and feedbacks~~, however, .~~ However, this approach has the advantage that no restrictions have to be made to surface temperature (e.g. fixed SST experiments), which fail to capture all changes in circulation and no assumptions are made on the linearity of adjustment processes, as is done in case of radiative kernels. This study aims to understand changes in the atmospheric state during the first year after onset of forcing and based on the beforehand arguments, we assume this time scale to be dominated by adjustment

370 processes.

Unfortunately, only one model (MRI-ESM2-0) provided daily TOA radiative flux data. Therefore, although a deviation of N_{sim} and $N_{\text{calc,ERF}}$ is clearly visible, a clear attribution to rapid adjustments to the forcing is difficult, as internal variability can also lead to difference between N_{sim} and $N_{\text{calc,ERF}}$. However, all models provide data for the following months after onset of forcing. Although there is some deviation between the models which is likely caused by internal variability there is also a

375 common trend (model-mean, thick black line), which cannot be explained by the changes in surface temperature or surface albedo (not shown). Instead, adjustments in atmospheric temperature profile, water vapour and cloud properties seem to be the dominating source of variability during the first days and months. Hence, the TOA budget variability is a result of a complex interplay of several atmospheric and cloud variables, with partly compensating effects. Changes in cloud properties have been found to be one of the major sources of model uncertainty on all time scales. Reducing the uncertainty on short time scales

380 would allow for a better quantification of the ERF, thereby improving long term predictions. Therefore, the aim of this study is to identify characteristic patterns of cloud adjustment in response to a negative shortwave forcing.

The next section analyses the temporal development of the cloud radiative effect anomaly over the three adjustment time scales as well as the fourth time scale representing the long term temperature mediated response. The cloud radiative effect can be an indicator to cloud adjustments, which are a major source of uncertainty in climate models. However, the cloud radiative

385 effect also includes changes in other atmospheric variables (cloud masking), which is discussed in the following section.

### 3.2.3 Adjustments of the cloud radiative effect at TOA

Figure 4. Same as Fig. ~~3~~2, ~~but for~~ simulated and calculated TOA ~~effective flux change~~radiative budget changes. Shown are TOA effective flux change, based on the simulated surface temperature change, only considering IRF ($N_{\text{calc,IRF}}$, red), the calculated TOA effective flux change considering IRF+RA ($N_{\text{calc,ERF}}$, blue) and the simulated TOA effective flux change (N_{sim}, black).

Figure 5. Global mean of TOA cloud radiative effect anomaly ($\Delta\text{CRE}_{\text{TOA}}$, red) in W m^{-2} for four different time scales after onset of forcing (100 hours, 30 days, 12 months, 150 years). Additionally, shortwave and longwave TOA cloud radiative effect anomalies ($\Delta\text{CRE}_{\text{TOA,sw}}$ and $\Delta\text{CRE}_{\text{TOA,sw}}$) are shown in brown and orange. Their respective intermodel standard deviation is shown as shading around inter-model means.

Figure 5 shows the temporal evolution of the global mean cloud radiative effect anomaly at TOA ($\Delta\text{CRE}_{\text{TOA}}$) and its short- and longwave components ($\Delta\text{CRE}_{\text{TOA,sw}}$ and $\Delta\text{CRE}_{\text{TOA,lw}}$). As described before, only MRI-ESM2-0 provided daily data, which is plotted for the first two time scales.

390    $\Delta\text{CRE}_{\text{TOA}}$ is positive for all time scales, indicating a decrease of the generally cooling effect of clouds, partially counteracting the negative forcing. However, since this positive anomaly is apparent from the first time step, the initial value is not attributable to changes in cloud properties. It rather is a result of clouds masking changes in the clear-sky budget. After five days $\Delta\text{CRE}_{\text{TOA}}$ starts to deviate from its initial value and varies with no clear pattern during the first month. During this time period it follows the same shape as the total TOA budget anomaly. Hence, changes in cloud properties seem to be the dominant source of

395   variability of N_{sim} during the first months. This is supported by the fact that global mean clear sky fluxes show near to no variability during the first five months (not shown). After six months, the initial forcing moves from the southern high latitudes

to the northern high latitudes. Due to differing surface albedo on the two hemispheres and therefore changes in the clear-sky TOA radiative budget, cloud masking is expected to change at this point.

ΔCRE_{TOA} further increases over the following years. After about 10 years ΔCRE_{TOA} remains relatively constant at 400 $4\,\mathrm{W\,m^{-2}}$. A slight decreasing trend is visible in the multi-model mean, even though three out of for models simulate a stabilization of ΔCRE_{TOA} for longer time scales. This is due to the continuous decrease of $\Delta CRE_{TOA,lw}$, simulated by the CanESM5 model. Although this model shows the strongest temperature decrease out of the four models, it does not systematically predict the strongest changes in other cloud properties. Hence, the continuous decrease of $\Delta CRE_{TOA,lw}$ likely is a strong cloud masking effect that dominates over any possibly positive $\Delta CRE_{TOA,lw}$ effects due to changes in cloud 405 properties.

$\Delta CRE_{TOA,sw}$ is overall positive on all time scales and dominates ΔCRE_{TOA}. It seems to be the major source of variability, while $\Delta CRE_{TOA,lw}$ shows no clear sign over the first three time scales and overall less variability than $\Delta CRE_{TOA,sw}$.

As discussed before, especially signals during the first days will also be influenced by internal variability. However, in the 6th Intergovernmental Panel on Climate Change (IPCC) report anthropogenic forcing in 2019 was quantified to be of the 410 order of $2.7\,\mathrm{W\,m^{-2}}$ (Forster et al., 2021a). Sippel et al. (2021) showed that this allows a robust detection of forced warming, significantly exceeding climate variability. Hence, an instantaneous forcing of $-10\,\mathrm{W\,m^{-2}}$, which is four times stronger, is expected to lead to adjustments that exceed internal variability. Nevertheless, to account for possible effects of internal variability, in the following section on characteristic fingerprints we only assume a signal to be a rapid adjustment, if three out of the four participating models agree on the sign.

415 ## 3.3 Characteristic adjustment fingerprints in climate variables

The following sections explore the response of surface and atmospheric temperature, as well as relative humidity, vertical velocity and cloud cover in order to identify characteristic adjustment fingerprints to reduced shortwave radiation availability. Since the global mean TOA budget variability is an effect of a complex interplay of several variables and local effects, the following sections examine global distributions of the beforehand mentioned variables, in order to better understand the 420 underlying mechanisms.

3.3.1 Adjustments of surface and atmospheric temperature

The effects of the reduction of the solar constant are visible in a variety of climate variables already a few hours after the onset of the perturbation.

Figure 6 shows the geographical distribution of the near surface temperature anomaly averaged over the first three time scales 425 depicted in Fig. 3 (hours, days and months, respectively) and a fourth time scale averaged over the years 120–150 representing the long-term development.

During the first 100 hours the land surface responds to the forcing by cooling down, while the ocean surface temperature stays approximately constant due to its higher heat capacity. The strongest cooling occurs over Antarctica, because of the 24 hour exposure to solar radiation at time of forcing onset (1 January). Areas of low heat capacity (e.g. Antarctica and
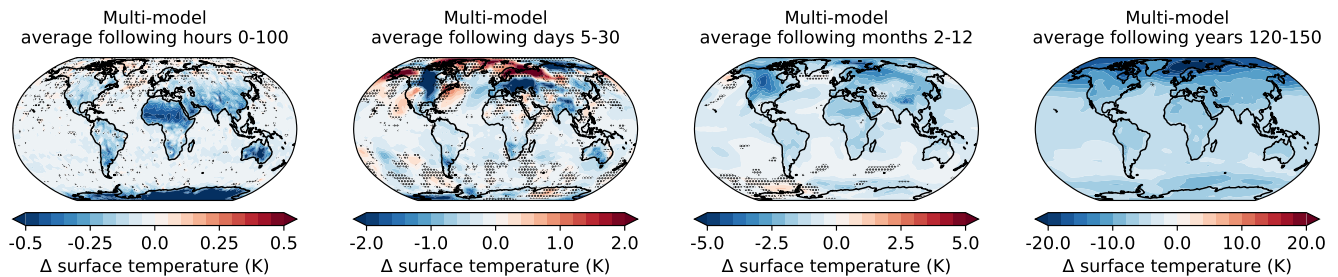

16

Figure 6. Multi-model mean global distribution of near surface temperature anomaly in K averaged over four different time scales after onset of forcing (100 hours, days 5–30, months 2–12, years 120–150). The multi-model mean was calculated by interpolating the other models to the grid spacing of the CanESM5 model. Regions, where less than 3 of 4 models agreed on the sign of anomaly, are dotted. Note the different scales of the colour bars for better contrast.

430   Sahara) generally exhibit a stronger surface temperature decrease compared to other regions on the same latitude, because the same amount of heat reduction will lead to stronger decrease in temperature. In contrast to the overall cooling of surface temperature, the Arctic, which does not experience any solar forcing in January, warms up during the first hours and days after onset of forcing. The reduced temperature gradient between the Tropics and the Arctic leads to a reduction in polar night jet strength, which perturbs the polar vortex. Cold air outbreaks as well as warm air intrusions result in strong changes of

435   surface temperature over days and the first month. Intrusion of warm, moist air masses into Arctic latitudes increases cloud cover, which reduces the amount of longwave radiation lost to space, leading to local surface temperature rise. However, the individual pattern of surface temperature increase will depend on the base state of the respective model. Hence, although all models simulate an increase in Arctic temperatures, the specific location varies, which leads to higher uncertainty in the Arctic response compared to other regions. Also the southern hemisphere shows a pattern of warming and cooling, however less

440   pronounced, due to the positioning of the forcing.

After one year, Arctic amplification begins to emerge as an overall stronger cooling of the surface over Arctic latitudes compared to lower latitudes and ~~the~~ Antarctica. The ocean surface starts to cool down, although the decrease is still smaller compared to land surfaces.

The average over years 120–150 shows an overall cooling in all regions. Arctic Amplification is apparent as a stronger

445   cooling over Arctic latitudes. North of Antarctica, where sea ice extent is increased compared to the piControl-runs, the surface cooling is slightly stronger compared to the land surface of Antarctica, due to more severe changes in surface properties compared to the control run. The differences between land and sea surface are less apparent compared to the shorter time scales because also the deeper ocean adapts to the new energy balance.

Figure 7 shows the zonal mean of atmospheric temperature anomaly averaged over time scales of hours, days and months

450   and the years 120–150, respectively.

During the first 100 hours, the stratosphere cools down quickly, especially above Antarctica, where the radiative forcing is strongest. Since the stratosphere is nearest to the source of forcing, the cooling of the stratosphere is ~~particularly~~ stronger than
17

Figure 7. Multi-model mean, temporal and zonal mean vertical profiles of atmospheric temperature anomaly in K as a function of latitude for four different time scales after onset of forcing (100 hours, days 5–30, months 2–12, years 120–150). Regions, where less than three out of four models agree on the sign of anomaly, are dotted. Note the adjusted colour scales for the different time scales.

the cooling of the troposphere during the first hours and days. The cooling effects are strongest on the highest altitudes, where ~~a lot of~~ most of the high frequency radiation is absorbed.

455 At the near surface layers, cooling above Antarctica is further amplified, because the surface temperature drops rapidly, which reduces sensible heat flux.

After one month atmospheric temperature change is highly variable in northern latitudes, due to the beforehand described perturbation of the polar vortex. Warm air intrusions into Arctic latitudes strongly increase the atmospheric temperature in surface near layers.

460 Over the first year, the troposphere adjusts to the solar forcing via an overall reduction of tropospheric temperature, especially in the mid and upper troposphere in the tropics. This pattern ~~is similar to the long term pattern~~resembles the long-term climate response, where it ~~produces~~ contributes to a lapse rate feedback. However, similar atmospheric temperature adjustments ~~were found for solar forcing experiments by~~ have been documented under solar forcing in fixed-SST experiments (e.g. Salvi et al. (2021)~~, for fixed SST experiments.~~). In these experiments, land surface temperatures can still respond, but their change is

465 strongly tied to nearby ocean temperatures through atmospheric coupling. Consequently, this limits any substantial climate feedbacks from developing, leaving predominantly fast adjustment processes. This indicates that ~~this pattern also~~ the pattern found in this study could be driven by changes in atmospheric absorption, humidity and convection in reaction to the forcing itself, rather than being a surface temperature mediated effect. We discuss this point further when analysing the results for humidity and cloud fraction.

470 On longer time scales the tropospheric temperature continues to decrease. ~~While in the tropics ,~~ In the tropics this is most pronounced in the higher troposphere, while at high latitudes the cooling is stronger in the lower troposphere, because the characteristic atmospheric temperature profiles in these regions react differently to a decrease in surface temperature.
Figure 8. Same as Fig. 7 but for atmospheric relative humidity anomaly in %.

In higher latitudes, the ~~upper troposphere/lower stratosphere (UTLS) is shifted towards lower altitudes (visible when comparing absolute atmospheric temperatures of solm4p- and piControl-experiment)~~<u>tropopause descends</u>. Hence, stratospheric vertical in-
crease of temperature starts at lower altitudes, which manifests as a warming at $200\,\mathrm{hPa}$ at the poles. At $\pm 30°$ the stratosphere cools at all pressure levels.

3.3.2 Adjustments of humidity, vertical velocity and cloud fraction

Figure 8 shows the vertical distribution of zonal mean relative humidity anomaly. While specific humidity reacts to the cooling air temperature by decreasing in the whole atmosphere, especially strong in the tropics and over all time scales <u>(not shown)</u>,
relative humidity displays ~~an overall increase during~~ <u>a pattern of increase and decrease. During</u> the first 100 hours, ~~apart from a decrease in~~ <u>relative humidity increases, apart from</u> southern tropical latitudes <u>that show a decrease</u>. During the first month, an overall increasing pattern remains in the tropics, while higher latitudes show decrease. During the first year, the high troposphere dries, while the middle tropospheric layers experience a moistening. The lower troposphere shows a regular pattern of moistening and drying and only at $\pm 65°$ the whole troposphere dries. The pattern further intensifies on long-term
time scales.

To further analyse the short-term adjustments of relative humidity, it makes sense to differentiate between trends on land and over sea, since they react very differently to the forcing on short time scales due to their different heat capacities. Hence, Fig. ~~??~~ <u>9</u> shows the zonal means of relative humidity change for the first two time scales averaged over ocean (Fig. ~~??~~<u>9</u>a) and land (Fig. ~~??~~<u>9</u>b) only. To investigate the effects of changing vertical atmospherical stability Fig. ~~??~~ <u>9</u> <u>also</u> shows the same for
~~vertical velocity change.~~ <u>change of vertical velocity (Δ wap) (averaged over ocean (c) and land (d)). As wap is defined positive downwards, red colours of Δ wap indicate an increase of downward movement or a decrease of upward movement and vice versa for blue colours.</u>

Over <u>the</u> ocean, the lower troposphere cools down quicker than the sea surface on time scales of hours to days. This leads to a decrease in vertical stability, which then increases convective activity, especially over tropical oceans (see Fig. ~~??a~~<u>9c</u>).
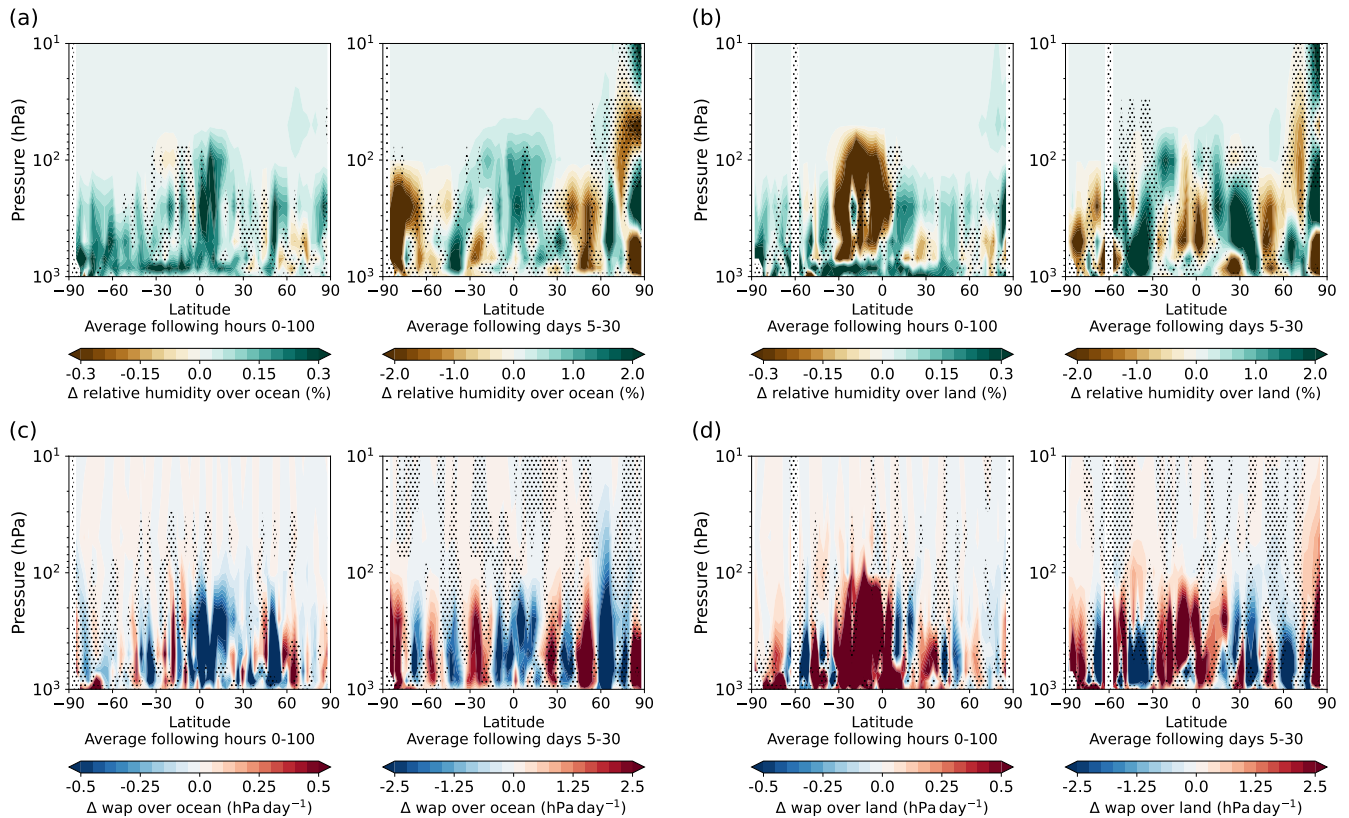

19

Figure 9. Zonal mean of relative humidity anomaly in % for the first 100 hours and days 5–30 (corresponds to the first two time scales of Fig. 7) averaged over ocean (a) and land (b) only and the same plots for vertical velocity (wap, positive downwards) anomaly in $hPa\,day^{-1}$ averaged over ocean (c) and land (d).

Increased convection dries the boundary layer, thereby reducing near surface specific humidity. In order to compensate for the deficit in humidity, evaporation and thereby latent heat flux increases, which then results in an increase in surface relative humidity (see Fig. ~~??~~9a) and precipitation in tropic latitudes. ~~Cao et al. (2012) described very similar effects, although of opposite sign for 4xCO₂ and +4% increase of solar constant experiments.~~

Over land, vertical stability ~~does not show a clear sign and~~ very much depends on location, albedo and heat capacity of the respective surface type. There is a strong reduction of convection over the tropics due to the reduced radiative forcing (see Fig. ~~??b~~9d) and resulting reduction in sensible heat flux, especially over the Sahara~~, which~~. This leads to trapping of moisture in the boundary layer and an increase in relative humidity in surface near layers ~~.~~ (see Fig. 9b). Latent heat flux is reduced in equatorial regions and overall less moisture is transported into the higher troposphere, which reduces relative humidity in the free troposphere (see Fig. ~~??~~9b).
Figure 10. Same as Fig. 7 but for atmospheric cloud fraction anomaly in % on 49 pressure levels (the three other models were interpolated to CanESM5 levels). Only monthly data was provided. Hence, the first time scale (hours 0-100) is missing.

505   The significant differences between land and ocean surface response are strongest during the first hours after onset of forcing, but they are still clearly visible during the first month and lead to changes in land-sea-circulation and moisture transport.

    ~~Zonal mean of relative humidity anomaly in % for the first 100 hours and days 5–30 (corresponds to the first two time scales of Fig. 7) averaged over ocean (a) and land (b) only.~~ Cao et al. (2012) described similar effects, although of opposite sign in response to a +4% increase of solar constant experiment. After five days they found a decrease of relative humidity in the

510 boundary layer of 1% over land and an increase of around 0.1% over ocean. This is a similar magnitude compared to our findings, however, with our approach we also found an increase in surface near relative humidity in response to a negative solar forcing, as the drying of the boundary layer due to reduced stability is compensated by increased latent heat flux.

    ~~Same as Fig. **??** but for vertical velocity (wap) anomaly in hPa day^{-1}.~~

    For vertically-resolved atmospheric cloud fraction the four models only provided monthly data. Hence for the zonal mean

515 of atmospheric cloud fraction anomaly, shown in Fig. 10 ~~)~~ no data was available for the first time scale and the first monthly mean was plotted as the "first 31 days" time scale. This is not fully identical to other plots of this kind, because, if available, the daily data from day 5–30 was averaged, not including the first 4 days, while in case of the atmospheric cloud fraction, the average of the whole month is plotted.

    As expected, the atmospheric cloud fraction anomaly pattern in Fig. 10 is overall very similar to the pattern of relative

520 humidity in Fig. 8.

    During the first month, the atmospheric cloud fraction increases in the tropics over ocean, while it decreases over land. However, the increase over the ocean dominates the zonal mean. Higher latitudes show a pattern of decreasing and increasing cloud fraction, where circulation strength changes (also visible in the vertical velocity anomaly in Fig. ~~??~~9).

    Over the first year, tropical regions experience the strongest negative radiative forcing leading to less absorption of shortwave

525 radiation in the troposphere and reduced convective heating from the lower troposphere. Because the colder air contains less water vapour, also the greenhouse effect is reduced, a positive feedback. This way, condensation levels are reached at lower

altitude and high clouds shift downwards. This leads to a decrease in cloud cover at $150\,\mathrm{hPa}$ and an increase in cloud cover around $250\,\mathrm{hPa}$, mirroring the same effects in relative humidity. An exception of the overall increasing cloud fraction in the troposphere is just above $\pm 60°$, where the subtropical jet stream strength is reduced, due to reduced temperature contrast between mid- and high latitudes and weaker storm systems produce less dynamic lifting, reducing cloud formation in those regions.

On longer time scales, the overall pattern further intensifies, as do atmospheric temperature and relative humidity ~~pattern~~patterns.

A distinct drying pattern in the relative humidity at the lower troposphere in the tropics (see Fig. 8), is not visible in the atmospheric cloud fraction, because it appears at a height of generally low cloud cover.

3.3.3 ~~Effects on the radiative budget anomaly at TOA~~

~~Figure 2 shows the three components of the TOA radiative flux anomaly, downward and upward shortwave flux anomaly (orange and brown) and upward longwave flux anomaly (olive), together with the effective flux anomaly at TOA (red, same as black curve in Fig. 4). Fluxes are defined positive downwards, so that added up, the three flux anomalies yield the effective flux anomaly. Only MRI-ESM2-0 provided TOA shortwave radiative fluxes as daily data, while the other three models only provided monthly data. Hence, Fig. 2 only shows the results of one model for shortwave flux anomalies and the effective flux anomaly for the first two time scales. The upward longwave radiative flux was provided as daily output by all models and is plotted accordingly.~~

~~Global mean anomaly of radiative fluxes at TOA in $\mathrm{W\,m^{-2}}$ for four different time scales after onset of forcing (100 hours, 30 days, 12 month, 150 years). Plotted are the downward shortwave flux anomaly at TOA (orange), the upward shortwave flux anomaly at TOA (brown), the upward longwave anomaly at TOA (olive) and the effective flux anomaly at TOA (red). If available, the results for all four models (thin lines) were plotted together with the model-mean (thick line). In addition to that, the instantaneous radiative forcing (IRF) is plotted as a grey dash-dotted line. Upward fluxes were multiplied by $\cdot (-1)$, such that the three radiative flux anomalies (orange, olive and brown) add up to the effective flux anomaly at TOA (red), which is the same as the black curve in Fig. 4.~~

~~The downward shortwave flux anomaly shows the reduction of the solar constant. It stays constant over all time scales and only displays a yearly periodic deviation due to the elliptical orbit of the Earth around the sun. It is the same for all four models, since the underlying assumption of the abrupt-solm4p experiment is an instantaneous and constant reduction of the solar constant by $4\,\%$, corresponding to a decrease of downward shortwave flux by $-13\,\mathrm{W\,m^{-2}}$.~~

~~The upward shortwave anomaly also shows an instantaneous reaction, because the planetary albedo initially stays the same, but the amount of incoming shortwave radiation that could be reflected is reduced. This instantaneous effect is part of the instantaneous radiative forcing (IRF), because it is a change in TOA radiation in reaction to the reduction of the solar constant, without any changes in atmospheric state. Hence, the IRF is the sum of incoming and outgoing shortwave anomaly at $t = 0$ and is around $-10\,\mathrm{W\,m^{-2}}$ according to experimental design. The upward shortwave anomaly shows first changes after 10 days, although no clear trend can be recognised. This is a reaction to changes in surface albedo (beginning after roughly 10 days and mostly connected to increased snowfall over land in high northern latitude and first changes in snow cover and sea ice extent in~~

Antarctica) and cloud properties (beginning after a few hours, as described above). Although there are clear changes in albedo and cloud liquid water path and also variation in cloud cover over the first year, the upward shortwave anomaly stays relatively constant, indicating, that the different climate variables and local variability cancel out each other's shortwave radiative effects. Over longer time scales, the multi-model mean of upward shortwave flux anomaly decreases, changes its sign around 50 years after onset of forcing and continues to decrease up until 150 years. However, the individual model runs do not agree on the sign of the anomaly on these longer time scales, due to opposing effects in high and low latitudes, discussed further below.

In contrast to the shortwave fluxes, there are no immediate effects of the reduction of the solar constant on the upward longwave flux. This is expected, because it is linked to changes in surface and atmospheric temperatures, which need some time to adapt. Similar to the upward shortwave flux anomaly, the upward longwave flux anomaly displays first changes around 10 days after the onset of forcing. It is overall slightly increased over the following days and only temporarily changes its sign. The multi-model mean always stays positive, indicating a decreased loss of longwave radiation to space, because atmosphere and surface reduce their temperatures in reaction to the reduced incoming solar energy. This effect continues and all models simulate a further increasing longwave flux anomaly for longer time scales. The effective flux anomaly at TOA is overall negative due to the negative forcing and corresponds to the IRF at $t = 0$. It is dominated by the shortwave effects on the time scales of hours and days, but in the course of month, the increasing longwave gain slowly reduces the TOA imbalance until it approaches a new balance over the following decades and centuries.

Figures A3a, A3b and A3c show the respective geographical distributions of the TOA radiative fluxes. Because only MRI-ESM2-0 provided daily data, the first time scales does not display a multi-model mean, but only the data of the MRI-ESM2-0 model. For the following 30 days, the January model mean of all four models were averaged.

Figure A3a clearly shows the uneven distribution of downward shortwave flux anomaly due to the chosen starting point of the experiment on 1 January. As the region of maximum sun exposure moves further north during the following month, the averages over the first year and the following 120–150 years then show the expected symmetric distribution after a full seasonal cycle with the strongest forcing in the tropics.

Multi-model mean global distribution of TOA radiative fluxes in $\mathrm{W\,m^{-2}}$ averaged over four different time scales after onset of forcing (100 hours, 31 days, months 2–12, years 120–150). Plotted are (a) the downward shortwave radiative flux anomaly at TOA, (b) the upward shortwave radiative flux anomaly at TOA, (c) the upward longwave radiative flux anomaly at TOA and (d) the effective radiative flux anomaly at TOA. For the first time scale of (a), (b) and (d) only data from MRI-ESM2-0 is plotted, because other models only provided monthly data. Regions, where less than three out of four models agree on a sign of anomaly are dotted.

The upward shortwave flux in Fig. A3b reflects the distribution of the initial forcing, but locally adapted according to surface or cloud albedo. Especially Antarctica and the region of the westerlies with usually high cloud cover show the strongest reduction in upward shortwave flux. Similar to several other aforementioned climate variables, the uncertainty is high for the following 30 days. Only the reduction of upward shortwave flux in Antarctica remains relatively constant during the first month, due to the unchanged snow albedo. In contrast to that, South America shows an increased reduction in upward shortwave flux compared to the surrounding regions and the first time scale. Since surface albedo remains relatively constant over the first

month, this effect can be attributed to changes in cloud properties in reaction to an overall drying and reduced ascent over tropical land areas. Hence, cloud liquid and ice water paths are decreased over South America, coinciding with an overall decrease in specific humidity and total cloud fraction. This leads to less scattering of downward shortwave flux and hence, more absorption by the surface. Because of its comparably low albedo (mostly green vegetation), the upward shortwave flux is reduced and hence, the planetary albedo is decreased. The opposite effect can be seen in the Indian Ocean, where liquid and ice water paths as well as total cloud fraction are increased, thereby increasing planetary albedo. During the first year, the overall negative trend of upward shortwave flux continues, with only local positive anomalies, where surface albedo or cloud properties are changed. On longer time scales, the cooling of the surface leads to sea ice spreading further to lower latitudes, which strongly increases surface albedo in the respective areas, leading to positive anomalies in upward shortwave flux. Similar surface albedo effects are visible on land, where snow cover is increased, especially in mountain areas. In contrast to that, increased upward shortwave flux over ocean is linked to an increase in cloud fraction, liquid and ice water path. Depending on whether the increase due to increased surface albedo or cloud cover, or the overall decrease due to the reduction of incoming shortwave radiation is stronger, the sign of the global mean upward shortwave flux anomalies differs between different models.

Figure A3c shows the anomaly of upward longwave radiative flux. Overall decreasing atmospheric and surface temperature lead to a decrease of outgoing longwave radiation with time. However, this effect is partly compensated by the reduction in water vapour. This process is especially effective in the tropics, where colder temperatures lead to a reduced amount of water vapour. This reduces the water vapour greenhouse effect and thereby optical depth of the atmosphere, which then in turn can result in a more effective radiative cooling. This can lead to slightly positive signals in outgoing longwave radiation over tropical land areas. Cloud property changes further amplify these effects. During the first two time steps anomalies are small and the uncertainty is high. The few stronger signals coincide with the beforehand described upward shortwave signals due to cloud property changes. The longwave effects often partially counteract the shortwave effects, because an increase in cloud liquid and ice water path will lead to more reflection of shortwave radiation, but at the same time, more upward longwave flux is absorbed, thereby decreasing TOA upward longwave flux. Over the first year upward longwave radiation further decreases due to the reduction of surface temperature, the so-called Planck effect. It becomes the dominant effect on longer time scales, clearly showing the effect of Arctic Amplification as a stronger cooling in Arctic latitudes. The only exception is an increase in upward longwave radiation northeast of Oceania, where cloud liquid and ice water path are reduced significantly, counteracting surface cooling effects.

Figure A3d displays the global distribution of the effective flux anomaly at TOA. During the first 100 hours, the reduced downward shortwave flux is the dominating influence on the TOA effective flux and the distribution of the shortwave forcing is clearly visible. Short-term adjustments reduce the overall loss of energy at TOA only locally, e.g. where precipitation is increased in the tropics, which coincides with changes in cloud properties. During the first month, the pattern remains relatively unchanged. Only the strong changes in surface temperature in high northern latitudes, due to the aforementioned disruption of the polar vortex, lead to a reduction in upward longwave radiation lost to space. Since the region is not directly influenced by

24

the reduced solar constant, this longwave effect leads to a slight increase of the effective flux at TOA in high northern latitudes.

Over the first year, the TOA effective flux anomaly is still dominated by the reduced solar constant. Local effects due to changes in cloud properties do not have significant effects on the effective flux at TOA, because shortwave and longwave effects compensate each other.

On longer time scales, the TOA effective flux anomaly reaches a new balance and the global mean anomaly approaches zero. However, the global distribution of TOA effective flux anomaly shows a significant pattern over different latitudes, depending on the strength of local short- and longwave effects. The Planck effect generally acts against the radiative shortwave forcing by reducing the upward longwave radiation. Hence, the TOA effective flux anomaly is positive, where either the reduction in upward longwave radiation is stronger than the forcing or where also the upward shortwave flux anomaly is negative, counteracting the initial forcing.

3.3.3 Effects on the cloud radiative effect at TOA

Figure 5 shows the temporal evolution of the global mean cloud radiative effect anomaly at TOA ($\Delta\mathrm{CRE_{TOA}}$) and its short- and longwave component ($\Delta\mathrm{CRE_{TOA,sw}}$ and $\Delta\mathrm{CRE_{TOA,lw}}$). As described before, only MRI-ESM2-0 provided daily data, which is plotted for the first two time scales.

Global mean of TOA cloud radiative effect anomaly ($\Delta\mathrm{CRE_{TOA}}$, red) in $\mathrm{W\,m^{-2}}$ for four different time scales after onset of forcing (100 hours, 30 days, 12 month, 150 years). Additionally, shortwave and longwave TOA cloud radiative effect anomalies ($\Delta\mathrm{CRE_{TOA,sw}}$ and $\Delta\mathrm{CRE_{TOA,sw}}$) are shown in brown and orange. Their respective intermodel standard deviation is shown as shading around inter-model means.

The global multi-model mean (red) is positive for all time scales, indicating a decrease of the generally cooling effect of clouds, partially counteracting the negative forcing. However, since this positive anomaly is apparent from the first time step, the initial value is not attributable to changes in cloud properties. It rather is a result of clouds masking changes in the clear-sky budget. After five days $\Delta\mathrm{CRE_{TOA}}$ starts to deviate from its initial value and varies with no clear pattern during the first month. During this time period it follows the same shape as the total TOA budget anomaly, hence, changes in cloud properties seem to be the dominant source of variability of the effective flux anomaly at TOA during the first months. This is supported by the fact, that global mean clear sky fluxes show near to no variability during the first five months. However, the peak of $\Delta\mathrm{CRE_{TOA}}$ around six month coincides with a slight change in downward shortwave flux due to the Earth's elliptical orbit, which also results in a drop in clear-sky upward shortwave flux. Therefore, this is more likely to be a masking effect, rather than purely attributable to changes in clouds, although some small changes are also recognisable in liquid and cloud water path. Moreover, after six month, the initial forcing moves from the southern high latitudes to the northern high latitudes. Due to differing surface albedo and therefore changes in the clear-sky budget, cloud masking is expected to change at this point.

After about 10 years $\Delta\mathrm{CRE_{TOA}}$ remains relatively constant at $4\,\mathrm{W\,m^{-2}}$. A slight decreasing trend is visible in the multi-model mean, even though three out of for models simulate a constant $\Delta\mathrm{CRE_{TOA}}$ for longer time scales. This is due to the continuous decrease of $\Delta\mathrm{CRE_{TOA,lw}}$, simulated by the CanESM5 model, which is not visible in any other model.

If cloud properties were to stay constant, the pure cloud masking effect would lead to a negative $\Delta\text{CRE}_{\text{TOA,lw}}$, because clouds would dampen the Planck effect, which is the main process counteracting the negative forcing. This dampening effect would be stronger, the stronger the surface temperature reduction was. Changes in cloud properties can either increase the dampening (e.g. due to an increase of liquid or ice water path) or counteract the dampening, if absorption of upward longwave radiation by clouds is reduced. Hence, the sign of $\Delta\text{CRE}_{\text{TOA,lw}}$ depends on whether changes in cloud properties can compensate the cloud masking effect of the Planck effect or not. Only in case of the CanESM5 model, the masking effect is much stronger than the effects of cloud property changes. Hence, it simulates a negative long-term trend for $\Delta\text{CRE}_{\text{TOA,lw}}$.

Figure A4 shows the global distribution of the total $\Delta\text{CRE}_{\text{TOA}}$ (Fig. A4c), as well as its shortwave and longwave components, $\Delta\text{CRE}_{\text{TOA,sw}}$ and $\Delta\text{CRE}_{\text{TOA,lw}}$ (Fig. A4a and A4b).

Same as Fig. A3 but for (a) shortwave and (b) longwave and (c) total TOA cloud radiative effect anomaly ($\Delta\text{CRE}_{\text{TOA,sw}}$, $\Delta\text{CRE}_{\text{TOA,lw}}$ and $\Delta\text{CRE}_{\text{TOA}}$) in W m^{-2}.

During the first 100 hours, $\Delta\text{CRE}_{\text{TOA,sw}}$ is strongest on the southern hemisphere, where the shortwave forcing is strong and cloud cover is high. Hence, the increased $\Delta\text{CRE}_{\text{TOA,sw}}$ is mostly an effect of cloud masking, rather than caused by changes in cloud properties. The only exception is Antarctica, where the high snow albedo suppresses any possible shortwave cloud radiative effects. In contrast to that, $\Delta\text{CRE}_{\text{TOA,lw}}$ remains relatively unchanged and only in the tropics some stronger signals appear, roughly coinciding with areas of increased precipitation, indicating increased condensation and bigger droplets that absorb more longwave radiation and lead to a positive $\Delta\text{CRE}_{\text{TOA,lw}}$. Vice versa, areas of decreased total cloud fraction over central Africa, Peru and northern Australia lead to negative $\Delta\text{CRE}_{\text{TOA,lw}}$.

During the first month, $\Delta\text{CRE}_{\text{TOA,sw}}$ further strengthens and the beforehand mentioned decrease in cloud liquid and ice water path over South America as well as the opposite effect on the Indian ocean are visible as areas of increased and decreased $\Delta\text{CRE}_{\text{TOA,sw}}$, respectively. The same regions show up in the $\Delta\text{CRE}_{\text{TOA,lw}}$ as regions of stronger signal, but of opposite sign due to the aforementioned compensation of short- and longwave effects. Moreover, a region of increased cloud ice water path and cloud fraction on the west coast of Africa produces a clear signal of decreasing $\Delta\text{CRE}_{\text{TOA,sw}}$ and increasing $\Delta\text{CRE}_{\text{TOA,lw}}$, since less shortwave radiation is scattered and more longwave radiation is transmitted to space.

Over the first year $\Delta\text{CRE}_{\text{TOA,sw}}$ remains overall positive, with a more homogeneous distribution over the globe, due to the more homogeneous distribution of the forcing after a complete seasonal cycle. Only Oceania shows a distinct decrease of $\Delta\text{CRE}_{\text{TOA,sw}}$ and increase of $\Delta\text{CRE}_{\text{TOA,lw}}$, where all cloud properties, analysed in this study, show a distinct reduction. However, as described before, short- and longwave effects compensate each other in a way, that the changes in cloud properties, mentioned above, are not visible in the total $\Delta\text{CRE}_{\text{TOA}}$.

On long-term time scales, $\Delta\text{CRE}_{\text{TOA,sw}}$ shows a clear correlation with increased surface albedo at high latitudes, leading to a strong positive masking effect. Moreover, decreased cloud liquid water path, e.g. over high latitudes and the equatorial Pacific lead to increase of $\Delta\text{CRE}_{\text{TOA,sw}}$ in these regions, while an increasing cloud liquid water path over tropical oceans has the opposite effect. In contrast to that, $\Delta\text{CRE}_{\text{TOA,lw}}$ shows stronger correlation with the cloud ice water path anomaly, since ice clouds have a generally stronger longwave effect than liquid clouds. In total, shortwave effects are overall stronger and thus, dominate $\Delta\text{CRE}_{\text{TOA}}$, while longwave effects only appear at certain locations of strong longwave anomalies. Hence,

4 Discussion

The aim of this study ~~is~~ was to understand and analyse atmospheric processes that take place on time scales of hours, days and months after the onset of a negative solar forcing. We did so using the output of four different climate models that participated
705 in the abrupt-solm4p experiment of CFMIP of CMIP6. These fully coupled simulations provide the opportunity to get a more realistic ~~few~~ view on rapid adjustments in the climate system, as all components of the climate system are allowed to react to the forcing at the same time, rather than fixing (sea) surface temperatures. This allows for a more realistic interplay between the different components, although a ~~+4% solar~~ −4% solar constant forcing still needs to be considered a highly idealized forcing compared to e.g. transient climate change.
710   Our approach is based on the assumption ~~,~~ that the short timescales of hours, days and months are dominated by rapid adjustments rather than by surface temperature mediated changes. We showed in Fig. 4 that for these three time scales, the simulated change in surface temperature cannot explain the simulated change in TOA fluxes. Only when adjusting it by the rapid adjustments found in the linear regression plots of Sect. 3.1, temperature ~~mediate~~ mediated TOA flux change and simulated TOA flux change start to coincide after around 4 years in model mean. This corresponds to the time, the linear regression
715 plots show non-linearities and is likely connected to adjustments of system with high inertia, like cryosphere and vegetation, that happen on longer time scales or a delay in the response of the deeper ocean compared to the surface ~~.~~ (SST-pattern effect, e.g. Andrews et al. (2015)). Since our study concentrates on adjustments during the first year, these ~~kind of adjustment~~ kinds of adjustments are not considered here.
     Having the atmosphere, surface and deep ocean react to the forcing at the same time, poses the challenge of a possible
720 overlap of adjustments to the forcing and temperature mediated processes. Nevertheless, our findings do agree in many points with findings of other studies that applied a variety of different methods, often more restrictive compared to our approach, which we discuss in the following.
     Smith et al. (2018) analysed adjustments to five different forcing agents, among them a $+2\%$ solar forcing, using 11 GCMs with fixed SST in combination with radiative kernels. Similar to our results, they found that in case of solar forcing, rapid
725 adjustments ~~overall~~ reduce ERF. However, the adjustments we found using the linear regression method were overall stronger ($\sim 35\% \pm 5\%$ of IRF) in relation to the original forcing than they were in case of Smith et al. (2018) ($\sim 10\% \pm 5\%$). According to their findings, the change in surface, tropospheric and stratospheric temperature adjustment contribute the most to counteracting the forcing. Our method does not allow a quantification of the different effects in the same way, but we also see a decrease in temperature for surface as well as atmospheric temperatures in global mean, which will ~~reduces~~ reduce the TOA
730 forcing. The ~~overall~~ atmospheric cooling leads to a reduction of specific humidity in the whole atmosphere, which reduces the warming ~~properties~~ effect of water vapour in the atmosphere and is hence expected to increase TOA forcing, which is

also shown in Smith et al. (2018). We find a very similar pattern of cloud fraction change to that reported by Smith et al. (2018), though of opposite sign, since this study was based on a reduction of the solar constant. We calculated the anomaly of cloud radiative effect in order to estimate the influence of cloud adjustments on the ERF. However, the cloud radiative effect anomaly contains masking effects ~~which hampers~~, which hamper the comparability with studies ~~,~~ that specifically quantified cloud adjustments. Nevertheless, when assuming ~~,~~ that all initial signals in $\Delta\mathrm{CRE}_{\mathrm{TOA}}$ can be attributed to masking, rather than changes in cloud properties, this initial signal can be subtracted, leaving a more variable, but positive cloud adjustment, like it was found by Smith et al. (2018).

Russotto and Ackerman (2018) conducted a study using G1 data from the geoengineering MIP (GeoMIP) of CMIP6, where a fourfold CO_2 increase is balanced by a matching decrease in solar constant. The decrease is between -3.2% to -5%, ~~hence~~ thus of similar magnitude as was used in the abrupt-solm4p experiment. That experimental setup avoids a long term change in surface temperature. Hence, all signals are a mix of adjustments to the two different forcing agents. They find a significant cooling of the higher troposphere, as was shown in our results and a warming of the polar regions, which we also detected. However, in their case it is probably linked to the so-called "residual polar amplification", which can be seen in only CO_2 forcing experiments and is of higher magnitude and higher SNR than the signal, found in this study. A significant difference in the atmospheric temperature change is the stratospheric cooling, which is much stronger in the results of Russotto and Ackerman (2018) due to adjustments to 4xCO2 because of the increased LW radiation to space (Manabe and Wetherald, 1975). This effect is much stronger than the stratospheric cooling in response to solar forcing, which we see in our results. Although of similar magnitude, cloud fraction changes in the G1 experiment seem to be dominated by adjustments to CO_2, since Russotto and Ackerman (2018) find opposite signals to what we found. This is supported by the findings of Smith et al. (2018), who estimate cloud adjustments to CO_2 forcing to be twice as large as to a positive solar forcing with twice as strong IRF. However, Smith et al. (2018) quantified a positive solar forcing and Aerenson et al., 2024 show ~~,~~ that responses to positive and negative solar forcing can differ, not only in sign, but also in strength and pattern.

Furthermore, for their solp4p experiment Aerenson et al. (2024) find an increasing cloud cover over tropical land regions, decreasing cloud cover in higher latitudes over land and an overall reduction in cloud cover over ocean. We find similar patterns, though of opposite sign, as expected for a reduction of solar constant. The same is true for the CRE components they calculated for a solp2p experiment. However, when applying their newly developed method, Aerenson et al. (2024) ~~found~~ find an overall positive cloud radiative adjustment to a ~~positive solar radiative forcing of~~ +4% ~~of solar constant~~ solar constant forcing, meaning that clouds further increase the initial solar forcing rather than reducing it, mostly via their shortwave effects due to changes in cloud fraction. This is the opposite effect compared to what was found by e.g. Smith et al. (2018) or Virgin and Fletcher (2022) and what our results indicate. Aerenson et al. (2024) show that there can be substantial differences in adjustments to positive and negative solar forcing and linearity cannot be assumed. Nevertheless, they also find the opposite sign to Smith et al. (2018), who also analysed positive solar forcing simulations. All studies ~~found~~ report high uncertainty for cloud adjustments and, similar to our study, Aerenson et al. (2024) only had data from four climate models they could base their analysis on. In their case one model predicts negative cloud adjustments and only two models show significantly positive adjustments. Moreover, their method combines fixed SST with fully coupled model runs in order to quantify adjustments to solar forcing. Several studies

have shown ~~,~~ that the two approaches, although showing similar results, can also show deviations due to differences in e.g. dynamical adjustments of land-sea-circulation. The approach of Aerenson et al. (2024) may mistakenly interpret CO_2 forcing offsets caused by the fixed SST method as adjustments to solar forcing.

All in all this disagreement shows how challenging a proper quantification of cloud adjustments is and that they remain a source of high uncertainty in climate models.

Salvi et al. (2021) conducted a study on adjustments, using idealized atmospheric heating experiments, which were then fitted to the diagnosed heating curve of different forcing agents. This way, they found that the vertical center of mass, what they call the "characteristic altitude" determines the cloud adjustments. Like Smith et al. (2018) and our study they found negative cloud adjustments to in their case a $+3\%$ solar forcing. In their observed and fitted data they found a decrease in relative humidity and cloud fraction at around 300 and $800\,\mathrm{hPa}$, which corresponds well with the increased cloud fraction we find in these altitudes. There is some deviation in the UTLS region, where we find a significant reduction in cloud fraction and relative humidity, while Salvi et al. (2021) only diagnosed minor changes in cloud fraction and the fitted algorithm predicted a decrease. This again could either be an effect of different methods, as Salvi et al. (2021) themselves attribute the deviation to insufficient resolution of the vertically heating curves in these high altitudes. Nevertheless, some differences in response to positive and negative solar forcing can take place, like Aerenson et al. (2024) found, especially when considering non-linear processes like phase changes in clouds.

Moreover, our study supports the findings of other studies like Kamae et al. (2019) ~~,~~ that adjustments can also depend on the season of initialization. The strong response in Arctic surface temperatures, which we attribute to a disruption of the polar vortex, is an effect of initializing the forcing in January.

A challenge our study faced was the sparse dataset it is based on. Only four models participated in the solm4p experiment, each providing one run. A higher number of models and ensembles would increase the reliability of our findings. However, due to the strong nature of the forcing and since every model initialized the experiment from a different point in their piControl runs, we do expect ~~,~~ that the four models cover different climate variability modes. Hence, an agreement of several models on the sign of an adjustment effect and overall high model-mean anomalies indicate a signal that exceeds possible climate variability. For all analysed climate variables, the first month is the time scale with lowest agreement of the models on the sign of the signal. This is to be expected, since responses will strongly depend on the position of e.g. pressure systems at the moment of onset of forcing. For example, this becomes apparent in the Arctic surface temperature anomaly during the first month, ~~were~~ where all models simulated strong changes in surface temperature. We attribute those to a disruption of the polar vortex, but the actual pattern differs between the models, since it will be influenced by the original state of the atmosphere. Nevertheless, Fig. 6 shows strong signals for several high latitude regions, ~~were~~ where at least 3 out of 4 models agree on the sign. Therefore, we interpret it as a rapid adjustment rather than a random signal due to climate variability and expect to find similar signals for more realistic forcing scenarios like volcanic eruptions.

One surprising aspect of this study was the disagreement of the long term development of the models, especially when examining cloud related variables. While the models agree well on the TOA budget anomaly, they differ in how the long- and shortwave components contribute to this and how the fluxes interact with changes in cloud properties. In a number of

cloud variables and hence, in the cloud radiative effect anomalies, high latitudes and tropics show an opposite response and the global mean signal is determined by the dominating ~~effect~~region, which differs between the models. Further investigation into the single models and parametrization as well as possible tuning ~~,~~would be necessary to understand the different outputs. Though this was out of the scope of this study, it shows ~~,~~how even climate models of the newest generation still struggle to simulate short and long term change of cloud properties and further research on the topic is necessary.

5 Conclusion

This study offers insights into the dynamics of short-term adjustments within the climate system in response to an instantaneous radiative forcing. This was done through the analysis of the abrupt-solm4p experiment of CMIP6. By simulating a $4\,\%$ reduction in the solar constant, the experiment provides a valuable framework for understanding how the Earth climate system reacts to changes in solar energy input, especially on shorter time scales of days to month.

Following the linear regression method developed by Gregory et al. (2004), we find rapid adjustments of $3.6\,\mathrm{W\,m^{-2}}$ in response to an instantaneous negative solar forcing of $-10\,\mathrm{W\,m^{-2}}$. Other studies like Smith et al. (2018) also found that RA counteracted an initial solar forcing but of smaller magnitude ($\sim 10\%$). However, the amount of reduction differs, based on the method and number of participating models.

For this study, data from fully coupled climate models was used, leading to a possible overlap of adjustment and feedback mechanisms. However, it was shown that surface temperature change cannot explain the variability of the TOA radiative budget over the course of the first hours, days and months. Instead, the cloud radiative effect anomaly was found to closely match the TOA budget variability, indicating cloud property changes to be a major contribution to overall atmospheric adjustments. However, the method applied in this study did not allow for a quantification of cloud adjustments at TOA. Instead, global distribution patterns of a number of climate variables were analysed in order to find characteristic patterns (fingerprints) of atmospheric adjustments that could help explain the underlying mechanisms.

The analysis reveals significant alterations in various climate variables, including surface and atmospheric temperatures, relative humidity and vertical velocity as well as a number of cloud properties. All models simulate decreasing atmospheric and surface temperatures, beginning immediately after the onset of forcing in January. One exception was an increase of Arctic surface temperature, which we attribute to a weakened polar night jet and thereby disruption of the polar vortex leading to warm air intrusions. Significant differences were found between the response of relative humidity over land and over ocean. Over ocean, decreased vertical stability, due to a quicker cooling of the lower troposphere compared to the ocean surface, leads to increased convection and thereby drying of the boundary layer, which is then compensated by an increased latent heat flux leading to an increase in relative humidity and mid-level cloud cover. Over land in the tropics, convection is reduced and moisture effectively trapped in the boundary layer, which leads to an increase of relative humidity in surface-near layers and a decrease in relative humidity and cloud cover in the higher troposphere. This highlights the complex interactions and differences between land and sea response. On time scales of months, overall lower temperatures lead to drying of the troposphere and the decrease in solar energy in the tropics leads to a reduction of ascend, less convection and a descending high cloud layer.

835 ~~Inter-model agreement of cloud variables was overall low. Generally, clouds are a major source of uncertainty in climate models due to complex interactions of a huge number of variables and non-linear processes. This was especially obvious, when analysing the total cloud radiative effect anomaly. While the single short- and longwave components showed characteristic correlation with a number of cloud variables like cloud liquid and ice water path, the total cloud radiative effect anomaly is dominated by cloud masking effects. Characteristic regions of changing cloud properties over South America and the~~

840 ~~Indian ocean were less discernible in the total cloud radiative effect anomaly, because short- and longwave effects partially compensated each other . Therefore, a separate analysis of short- and longwave effects can support process understanding. A higher number of models participating in the experiment would be beneficial, in order to further reduce uncertainty. Nevertheless, significant signals were found for e.g. for atmospherical cloud fraction and our findings where in good agreement with other studies on the topic.~~

845 ~~The TOA rapid adjustments was quantified via linear regression and RA of 3.6 W m^{-2} were found, reducing the initial radiative forcing of 10 W m^{-2} by 36 %. Other studies like Smith et al. (2018) also found that RA were counteracting an initial solar forcing. However, the amount of reduction differs, based on the method and number of participating models.~~

~~While other~~ While other experiments of CMIP6 are designed in a way ~~,~~ that influence of seasonal and climate variability are reduced by using a number of different initialization dates, the abrupt-solm4p simulations use only one date (1 January).

850 This could be viewed as a limitation of this study. Nevertheless, if the scientific community strives for a validation of new discoveries about rapid adjustments in climate models with e.g. satellite measurements, more realistic simulations are crucial in order to further improve state of the art climate models. This study showed that the positioning of the forcing can have significant influence on the resulting short-term adjustments, in this case, the disruption of the polar vortex and consequently warming of the higher northern latitudes.

855 Moreover, the described adjustments to a reduced solar constant may resemble adjustments to more realistic forcing scenarios. After large volcanic eruptions a global stratospheric aerosol scattering layer can form a few months after the eruption. This aerosol layer reduces the amount of shortwave radiation that reaches the surface, which could lead to similar adjustment effects as simulated for a reduced solar constant. However, in case of the abrupt-solm4p experiment, the forcing is instantaneous and constant, which makes it easier to differentiate between instantaneous forcing, short-term adjustments and long-term feedbacks.

860 Therefore, it is a useful tool on the way to a more in depth understanding of realistic forcing agents of more transient nature. By elucidating the short-term adjustments that occur in response to reduced solar radiation, essential insights can be provided that can inform risk assessments associated with solar radiation management methods. Understanding these adjustments is vital for anticipating potential local impacts, such as droughts or floods, which can have significant consequences for communities and ecosystems.

865 In conclusion, this study identifies several characteristic adjustment processes as well as a number of challenges related to the current approaches in quantifying adjustments. By integrating short-term adjustment processes into climate modelling efforts, the scientific community can improve the accuracy of long-term climate predictions and develop more effective strategies for addressing the challenges posed by climate change.

870

Author contributions. CL and JQ designed the study. CL analysed the CFMIP abrupt-solm4p experiment data, produced the figures, and drafted the initial manuscript. Both authors contributed to the writing, editing and review of the paper.

Competing interests. JQ is a member of the editorial board of Atmospheric Chemistry and Physics

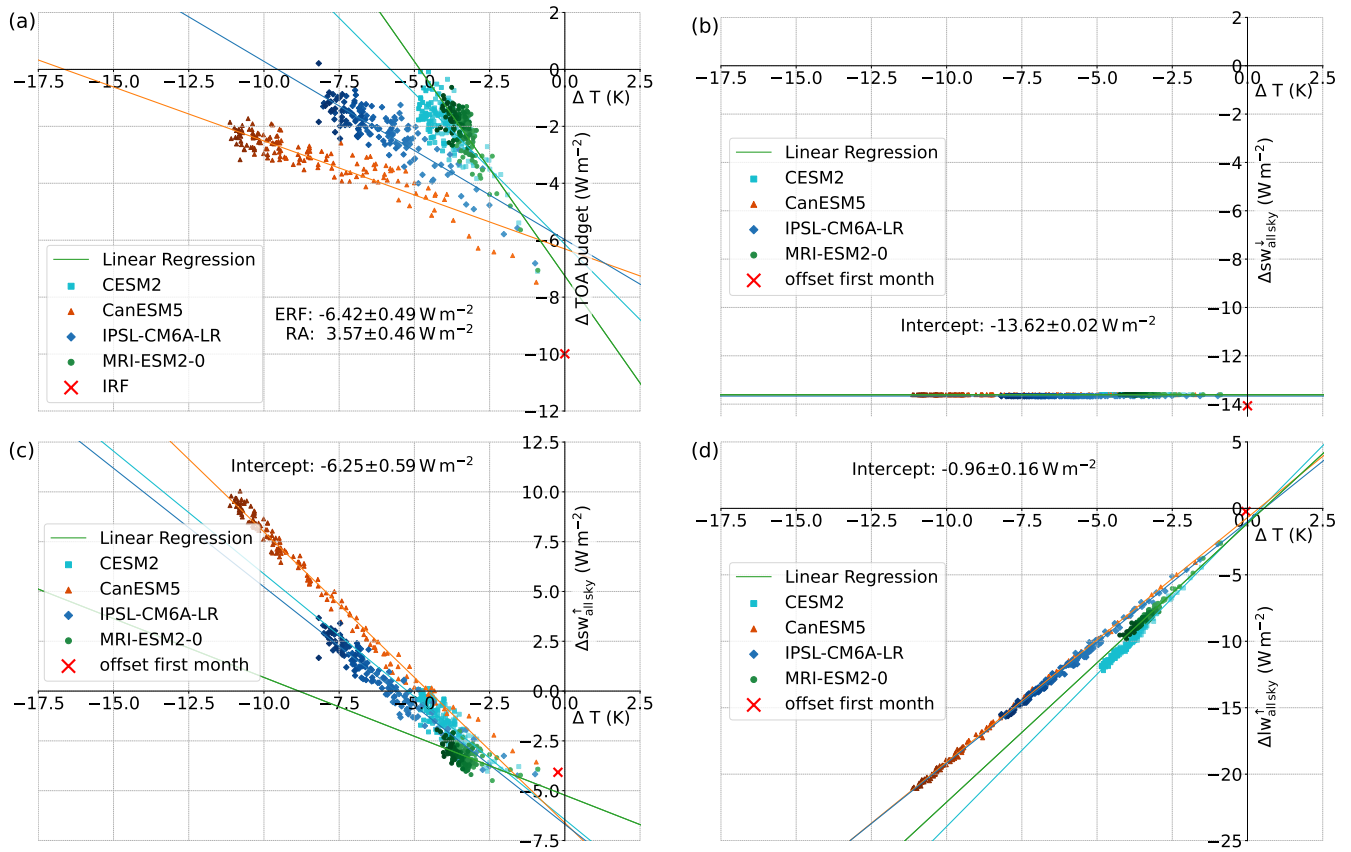

Figure A1. Linear regression plots for yearly global mean TOA radiative flux anomalies in $\mathrm{W\,m^{-2}}$ vs. change in yearly global mean surface temperature (ΔT). Plotted are (a) the TOA radiative budget, (b) the downward shortwave flux at TOA, (c) the upward shortwave flux at TOA and (d) the upward longwave flux at TOA. The respective initial offsets after one month are marked as a red cross. Deepening colours indicate temporal development.

Appendix A: Supplements

A1 Linear regression plots for components of TOA radiative budget

Analogous to the total TOA radiative budget, also the yearly mean of the components of the TOA budget, i.e. downward shortwave flux change $\Delta\mathrm{sw}^{\downarrow}_{\mathrm{all\,sky}}$, upward shortwave flux change $\Delta\mathrm{sw}^{\uparrow}_{\mathrm{all\,sky}}$ and upward longwave flux $\Delta\mathrm{lw}^{\uparrow}_{\mathrm{all\,sky}}$, were plotted against the surface temperature change and linear regressions were applied in Figures A1b, A1c and A1d. Offsets after one month of simulation were marked as red crosses to provide insight into the contribution to overall RA of the single radiative components. The multi-model mean intercepts of the linear regression with the radiative flux axis are shown in the respective figures as well as in Table 2 of the main paper. As determined by the experiment conditions, $\Delta\mathrm{sw}^{\downarrow}$ (Fig. A1b) is held constant over the whole experiment time. However, a seasonal variation occurs due the elliptical orbit of the Earth and produces a small
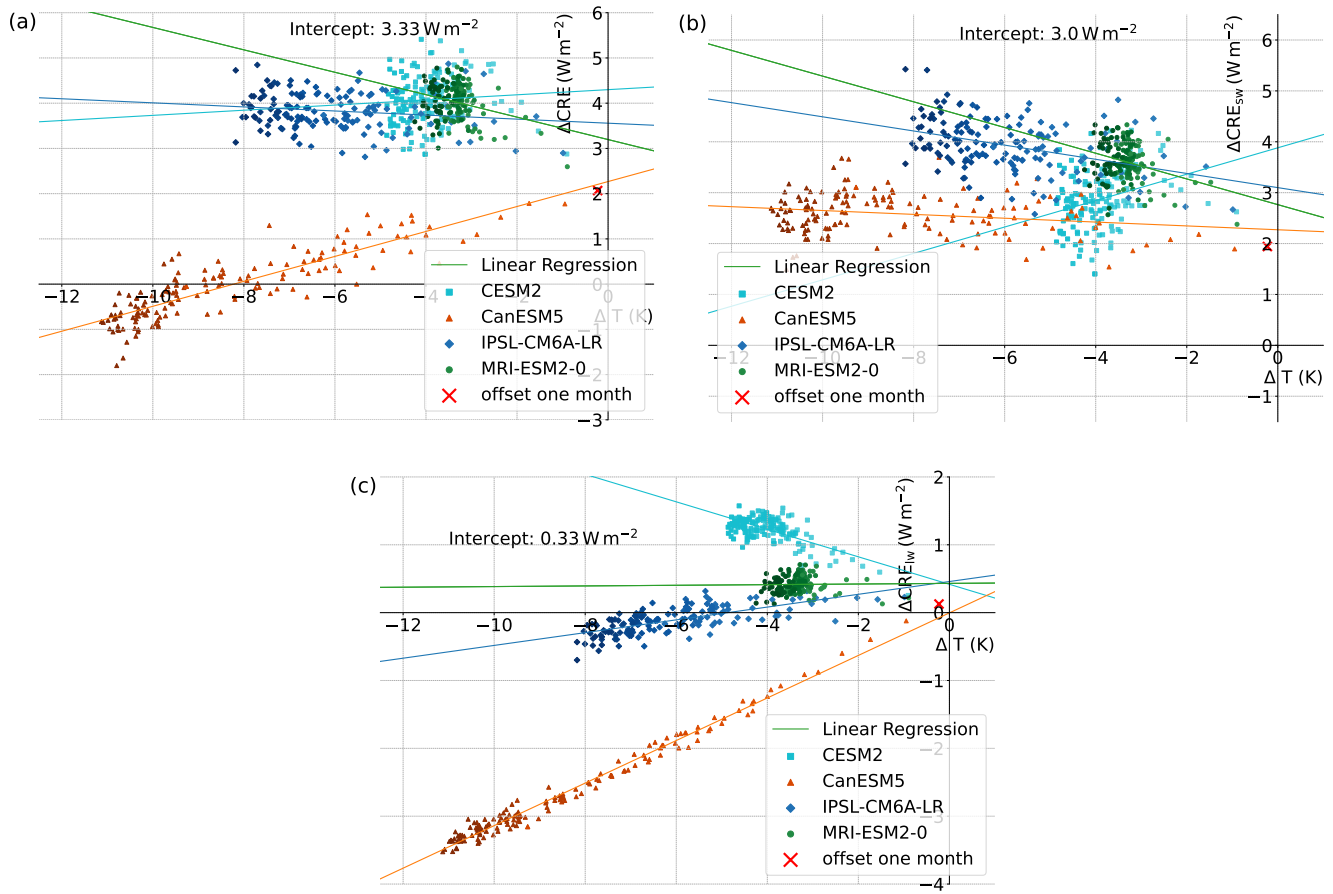

37

Figure A2. Same as Fig. A1 but for Linear regression plots for yearly global mean $\Delta\mathrm{CRE}_{\mathrm{TOA}}$ (a) and its long- and shortwave components $\Delta\mathrm{CRE}_{\mathrm{TOA,sw}}$ (b) and $\Delta\mathrm{CRE}_{\mathrm{TOA,lw}}$ (c).

offset between the first month value (January) and the yearly mean values. This offset is considered to be a part of IRF not the RAs.

In contrast, $\Delta\mathrm{sw}^{\uparrow}$ (Fig. A1c) exhibits a clear approximately linear relation to ΔT. All models simulate an instantaneous response of $\Delta\mathrm{sw}^{\uparrow}$ in reaction to the reduction of solar constant (red cross), depending on the planetary albedo.

Figure A1d shows the same linear regression for upward longwave radiation anomaly ($\Delta\mathrm{lw}^{\uparrow}$). All models simulate a clear linear relationship between $\Delta\mathrm{lw}^{\uparrow}$ and ΔT with an intercept of around $-1\,\mathrm{W\,m}^{-2}$, which equals the longwave adjustment as no instantaneous adjustments are expected.

The linear regression method was also applied to the cloud radiative effect anomaly $\Delta\mathrm{CRE}_{\mathrm{TOA}}$ and its short- and longwave components ($\Delta\mathrm{CRE}_{\mathrm{TOA,sw}}$ and $\Delta\mathrm{CRE}_{\mathrm{TOA,lw}}$). The results are shown in Figure A2. Analogous to the TOA radiative flux components contributions to ERF and RA were calculated and provided in Table 2 in the main paper.

38

A2   Geographical distributions of Δ TOA budget and its components

Figures A3a, A3b and A3c show the geographical distributions of the TOA radiative flux anomalies shown in Fig. 2 of the main paper. Since only MRI-ESM2-0 provided daily data, the first time scales does not display a multi-model mean, but only the data of the MRI-ESM2-0 model. For the following 30 days, the January model mean of all four models were averaged.

Figure A3a clearly shows the uneven distribution of downward shortwave flux anomaly due to the chosen starting point of the experiment on 1 January. As the region of maximum sun exposure moves further north during the following month, the averages over the first year and the following 120–150 years then show the expected symmetric distribution after a full seasonal cycle with the strongest forcing in the tropics.

The upward shortwave flux in Fig. A3b reflects the distribution of the initial forcing, but locally adapted according to surface or cloud albedo. Especially Antarctica and the region of the westerlies with usually high cloud cover show the strongest reduction in upward shortwave flux. Similar to several other aforementioned climate variables, the uncertainty is high for the following 30 days. Only the reduction of upward shortwave flux in Antarctica remains relatively constant during the first month, due to the unchanged snow albedo. In contrast to that, South America shows an increased reduction in upward shortwave flux compared to the surrounding regions and the first time scale. Since surface albedo remains relatively constant over the first month, this effect can be attributed to changes in cloud properties in reaction to an overall drying and reduced ascent over tropical land areas. Hence, cloud liquid and ice water paths are decreased over South America, coinciding with an overall decrease in specific humidity and total cloud fraction. This leads to less scattering of downward shortwave flux and hence, more absorption by the surface. Because of its comparably low albedo (mostly green vegetation), the upward shortwave flux is reduced and hence, the planetary albedo is decreased. The opposite effect can be seen in the Indian Ocean, where liquid and ice water paths as well as total cloud fraction are increased, thereby increasing planetary albedo. During the first year, the overall negative trend of upward shortwave flux continues, with only local positive anomalies, where surface albedo or cloud properties are changed. On longer time scales, the cooling of the surface leads to sea ice spreading further to lower latitudes, which strongly increases surface albedo in the respective areas, leading to positive anomalies in upward shortwave flux. Similar surface albedo effects are visible on land, where snow cover is increased, especially in mountain areas. In contrast to that, increased upward shortwave flux over ocean is linked to an increase in cloud fraction, liquid and ice water path. Depending on whether the increase due to increased surface albedo or cloud cover, or the overall decrease due to the reduction of incoming shortwave radiation is stronger, the sign of the global mean upward shortwave flux anomalies differs between different models.

Figure A3c shows the anomaly of upward longwave radiative flux. Overall decreasing atmospheric and surface temperature lead to a decrease of outgoing longwave radiation with time. However, this effect is partly compensated by the reduction in water vapour. This process is especially effective in the tropics, where colder temperatures lead to a reduced amount of water vapour. This reduces the water vapour greenhouse effect and thereby optical depth of the atmosphere, which then in turn can result in a more effective radiative cooling. This can lead to slightly positive signals in outgoing longwave radiation over tropical land areas. Cloud property changes further amplify these effects. During the first two time steps anomalies are small
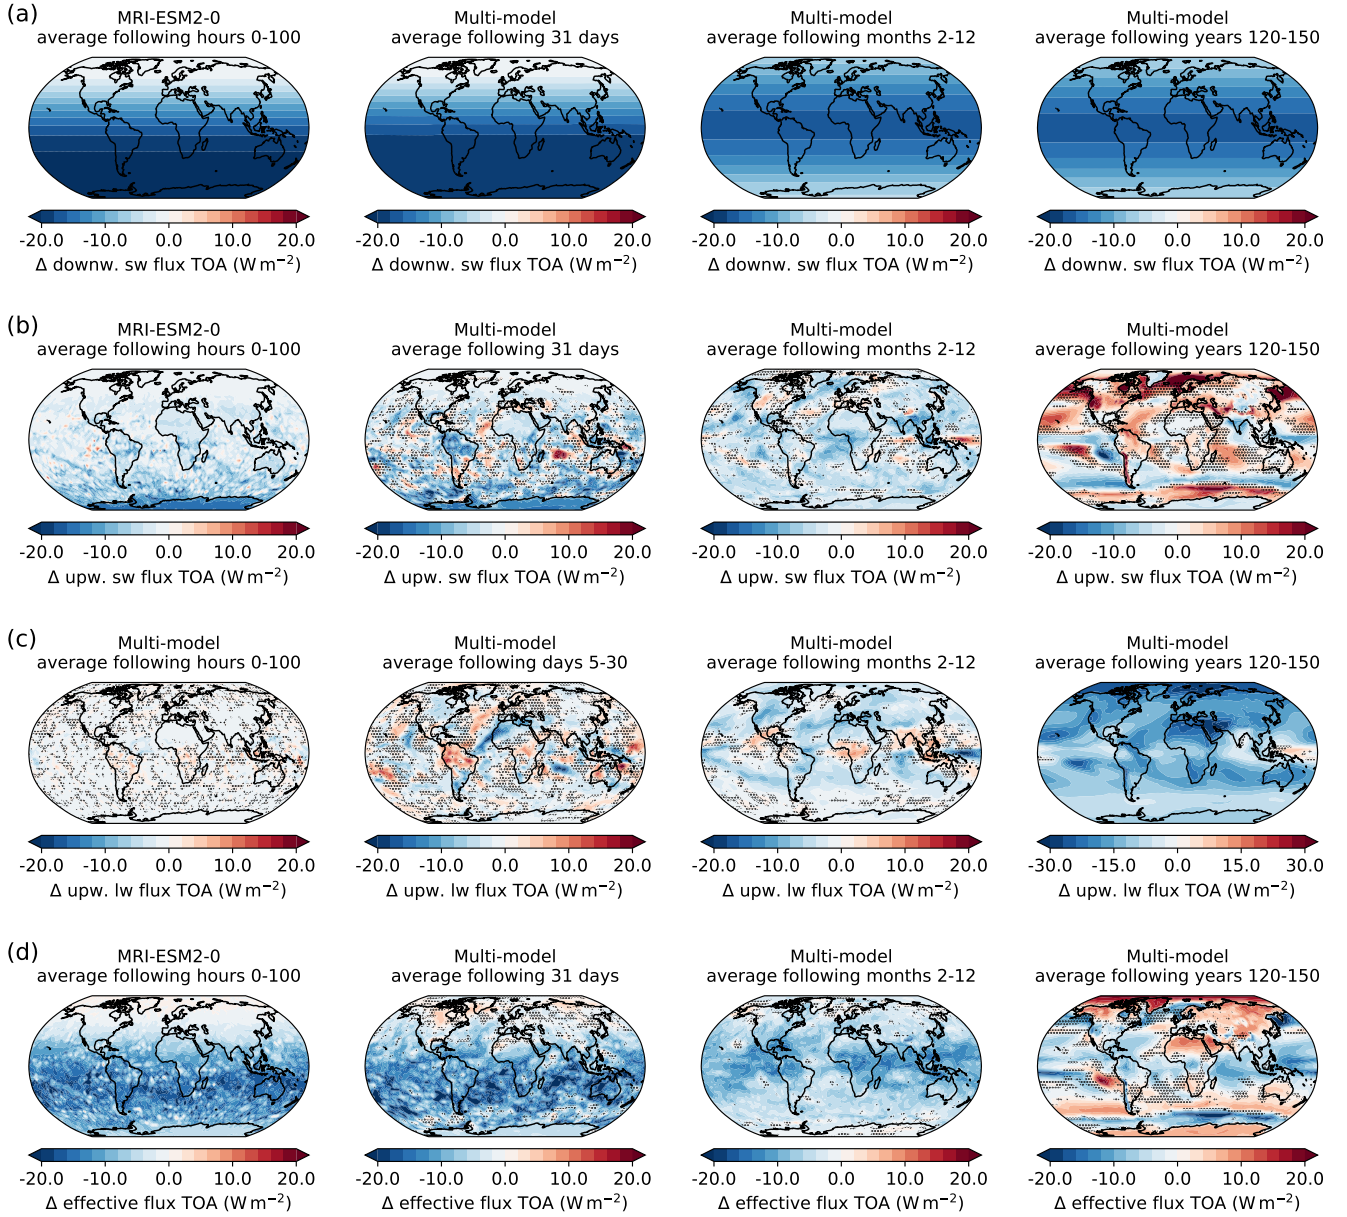

Figure A3. Multi-model mean global distribution of TOA radiative fluxes in $\mathrm{W\,m^{-2}}$ averaged over four different time scales after onset of forcing (100 hours, 31 days, months 2–12, years 120–150). Plotted are (a) the downward shortwave radiative flux anomaly at TOA, (b) the upward shortwave radiative flux anomaly at TOA, (c) the upward longwave radiative flux anomaly at TOA and (d) the effective radiative flux anomaly at TOA. For the first time scale of (a), (b) and (d) only data from MRI-ESM2-0 is plotted, because other models only provided monthly data. Regions, where less than three out of four models agree on a sign of anomaly are dotted.

and the uncertainty is high. The few stronger signals coincide with the beforehand described upward shortwave signals due to cloud property changes. The longwave effects often partially counteract the shortwave effects, because an increase in cloud liquid and ice water path will lead to more reflection of shortwave radiation, but at the same time, more upward longwave flux is absorbed, thereby decreasing TOA upward longwave flux. Over the first year upward longwave radiation further decreases due to the reduction of surface temperature, the so-called Planck effect. It becomes the dominant effect on longer time scales, clearly showing the effect of Arctic Amplification as a stronger cooling in Arctic latitudes. The only exception is an increase in upward longwave radiation northeast of Oceania, where cloud liquid and ice water path are reduced significantly, counteracting surface cooling effects.

Figure A3d displays the global distribution of the effective flux anomaly at TOA. During the first 100 hours, the reduced downward shortwave flux is the dominating influence on the TOA effective flux and the distribution of the shortwave forcing is clearly visible. Short-term adjustments reduce the overall loss of energy at TOA only locally, e.g. where precipitation is increased in the tropics, which coincides with changes in cloud properties. During the first month, the pattern remains relatively unchanged. Only the strong changes in surface temperature in high northern latitudes, due to the aforementioned disruption of the polar vortex, lead to a reduction in upward longwave radiation lost to space. Since the region is not directly influenced by the reduced solar constant, this longwave effect leads to a slight increase of the effective flux at TOA in high northern latitudes.

Over the first year, the TOA effective flux anomaly is still dominated by the reduced solar constant. Local effects due to changes in cloud properties do not have significant effects on the effective flux at TOA, because shortwave and longwave effects compensate each other.

On longer time scales, the TOA effective flux anomaly reaches a new balance and the global mean anomaly approaches zero. However, the global distribution of TOA effective flux anomaly shows a significant pattern over different latitudes, depending on the strength of local short- and longwave effects. The Planck effect generally acts against the radiative shortwave forcing by reducing the upward longwave radiation. Hence, the TOA effective flux anomaly is positive, where either the reduction in upward longwave radiation is stronger than the forcing or where also the upward shortwave flux anomaly is negative, counteracting the initial forcing.

A3 Geographical distributions of $\Delta\text{CRE}_{\text{TOA}}$ and its components

Figure A4 shows the global distribution of the total $\Delta\text{CRE}_{\text{TOA}}$ (Fig. A4c), as well as its shortwave and longwave components, $\Delta\text{CRE}_{\text{TOA,sw}}$ and $\Delta\text{CRE}_{\text{TOA,lw}}$ (Fig. A4a and A4b).

During the first 100 hours, $\Delta\text{CRE}_{\text{TOA,sw}}$ is strongest on the southern hemisphere, where the shortwave forcing is strong and cloud cover is high. Hence, the increased $\Delta\text{CRE}_{\text{TOA,sw}}$ is mostly an effect of cloud masking, rather than caused by changes in cloud properties. The only exception is Antarctica, where the high snow albedo suppresses any possible shortwave cloud radiative effects. In contrast to that, $\Delta\text{CRE}_{\text{TOA,lw}}$ remains relatively unchanged and only in the tropics some stronger signals appear, roughly coinciding with areas of increased precipitation, indicating increased condensation and bigger droplets that absorb more longwave radiation and lead to a positive $\Delta\text{CRE}_{\text{TOA,lw}}$. Vice versa, areas of decreased total cloud fraction over central Africa, Peru and northern Australia lead to negative $\Delta\text{CRE}_{\text{TOA,lw}}$.
Figure A4. Same as Fig. A3 but for (a) shortwave and (b) longwave and (c) total TOA cloud radiative effect anomaly ($\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$, $\Delta \mathrm{CRE}_{\mathrm{TOA,lw}}$ and $\Delta \mathrm{CRE}_{\mathrm{TOA}}$) in $\mathrm{W\,m^{-2}}$.

During the first month, $\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$ further strengthens and the beforehand mentioned decrease in cloud liquid and ice water path over South America as well as the opposite effect on the Indian ocean are visible as areas of increased and decreased $\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$, respectively. The same regions show up in the $\Delta \mathrm{CRE}_{\mathrm{TOA,lw}}$ as regions of stronger signal, but of opposite sign due to the aforementioned compensation of short- and longwave effects. Moreover, a region of increased cloud ice water path and cloud fraction on the west coast of Africa produces a clear signal of decreasing $\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$ and increasing $\Delta \mathrm{CRE}_{\mathrm{TOA,lw}}$, since less shortwave radiation is scattered and more longwave radiation is transmitted to space.

Over the first year $\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$ remains overall positive, with a more homogeneous distribution over the globe, due to the more homogeneous distribution of the forcing after a complete seasonal cycle. Only Oceania shows a distinct decrease of $\Delta \mathrm{CRE}_{\mathrm{TOA,sw}}$ and increase of $\Delta \mathrm{CRE}_{\mathrm{TOA,lw}}$, where all cloud properties, analysed in this study, show a distinct reduction.

However, as described before, short- and longwave effects compensate each other in a way, that the changes in cloud properties, mentioned above, are not visible in the total $\Delta\mathrm{CRE}_{\mathrm{TOA}}$.

On long-term time scales, $\Delta\mathrm{CRE}_{\mathrm{TOA,sw}}$ shows a clear correlation with increased surface albedo at high latitudes, leading to a strong positive masking effect. Moreover, decreased cloud liquid water path, e.g. over high latitudes and the equatorial Pacific lead to increase of $\Delta\mathrm{CRE}_{\mathrm{TOA,sw}}$ in these regions, while an increasing cloud liquid water path over tropical oceans has the opposite effect. In contrast to that, $\Delta\mathrm{CRE}_{\mathrm{TOA,lw}}$ shows stronger correlation with the cloud ice water path anomaly, since ice clouds have a generally stronger longwave effect than liquid clouds. In total, shortwave effects are overall stronger and thus, dominate $\Delta\mathrm{CRE}_{\mathrm{TOA}}$, while longwave effects only appear at certain locations of strong longwave anomalies. Hence, a separate consideration of short- and longwave effects can help to understand the underlying processes better, compared to only considering the total $\Delta\mathrm{CRE}_{\mathrm{TOA}}$. Nevertheless, masking effects impede a clear detection of cloud adjustments based on the cloud radiative effect.
