Abstract. We propose an effective and reproducible framework to assess the informative content of teleconnections for representing and modeling the frequency regime of rainfall extremes at regional scale. Our dataset consists of 680 annual maximum series of rainfall depth, with 1 and 24 hours durations, located in northern Italy. We compute at-site time series of L-moments through sliding time windows; then we discretize the study region into tiles, where L-moments time series are averaged. We observe that the Western Mediterranean Oscillation index (WeMOI) shows strong spatial correlation patterns with gridded L-moments. Finally, in a preliminary application of climate-informed regional frequency analysis, the L-moments are modelled as functions of WeMOI. We observe high variability of WeMOI-driven rainfall percentiles predictions, and an increase in overall goodness-of-fit of the regional model relative to the stationary framework. Overall, our research suggests promising pathways for climate-informed local and regional frequency analysis of rainfall extremes, and describes general methods, that can be adapted to different environmental variables.

1 Introduction

There is strong evidence that large-scale climate oscillations, also called teleconnections, have a significant influence on a region's climate (e.g., Bardossy and Plate, 1992; Bonsal and Shabbar, 2008; Rasouli et al., 2020). Several authors have investigated the link between teleconnections and the seasonal regime of precipitation, and found strong influence for monthly (e.g., Das et al., 2020; Romano et al., 2022) or 3-month (i.e., seasonal, e.g., Belkhiri and Krakauer, 2023; González-Pérez et al., 2022) cumulate rainfall and number of wet days (e.g., Ouachani et al., 2013; Ríos-Cornejo et al., 2015). Other authors focused on rainfall extremes, and showed how to exploit teleconnections to model the non-stationarity of the frequency regime of annual maxima (Cheng and AghaKouchak, 2014; Fauer and Rust, 2023; Ouarda et al., 2019; Ragno et al., 2018). Not only the parameters of the frequency distribution can be represented as a function of teleconnections (e.g., El Adlouni and Ouarda, 2009), but also the distribution itself may change (Ouarda et al., 2019). Investigations on the balance between increased complexity and better reliability from non-stationary frequency analysis of rainfall extremes point out that the improvement is

worth the effort (Ouarda et al., 2020). Overall, the last findings appear to suggest the need for non-stationary frequency analysis of rainfall extremes, depending on teleconnections (see Nerantzaki and Papalexioiu, 2022). Most of the studies about this topic show applications with a limited number of stations, where observations are abundant enough for fitting non-stationary local frequency analysis models. However, the dependence of the extreme rainfall regime on teleconnections may have regional patterns, instead of being specific for some isolated sites. In case this dependence could be described as a function of space, this would lead to non-stationary models for regional frequency analysis, similarly as in the case of local frequency analysis. The presence of regional structures in the dependence between teleconnections and rainfall has been investigated by several authors, focusing on monthly/seasonal or annual totals (Caroletti et al., 2021; Das et al., 2020; Ríos-Cornejo et al., 2015) or droughts (Romano et al., 2022). Differently, this field remains highly unexplored for rainfall extremes. This is a complex problem, as rainfall extremes have higher statistical and spatial complexity than seasonal/monthly rainfall totals or number of wet days. Thus, the correlation between teleconnections and extreme rainfall can vary significantly in sign, strength and significance within space (see e.g., Jayaweera et al., 2023). In fact, climate may have strong local variations due to orography (Marra et al., 2021), which makes it difficult to understand which teleconnections are more relevant to a specific region. Moreover, the length and quality of the observed timeseries play an important role in the reliability of the obtained results (Martins and Stedinger, 2000; Nerantzaki and Papalexioiu, 2022; Ouarda et al., 2020).

In this study, we propose a framework for assessing the informativeness of teleconnections in frequency analysis of hourly and daily rainfall extremes. In particular, we want to investigate (1) whether it is possible to delineate robust regional zonation of the correlation with teleconnections, and (2) what is the effect and suitability of non-stationary frequency analysis in significantly correlated areas. Accordingly, the study and proposed framework are structured in two parts, a correlation analysis and a regional frequency analysis, respectively. Our study area is northern-central Italy, where 680 timeseries with at least 30 years of records are available. We focus on annual maxima of precipitation with duration of 1 and 24 hours. In the first part of the research, we consider six teleconnection patterns with proven influence on the rainfall regime in the study area (Caroletti et al., 2021; Criado-Aldeanueva and Soto-Navarro, 2020; Krichak et al., 2014): North Atlantic Oscillation (NAO), Pacific Decadal Oscillation (PDO), East Atlantic – West Russia pattern (EA-WR), El Niño Southern Oscillation (ENSO), Mediterranean Oscillation Index (MOI), and Western Mediterranean Oscillation Index (WeMOI).

Differently from other studies, we do not perform our correlation analysis on the raw timeseries of the teleconnections and annual maxima. Here, two strategies are simultaneously adopted, to conveniently aggregate the data temporally and spatially. First, we consider sliding time windows, which allows us to (a) account only for long-term variability components, and (b) consider the variation of the timeseries' statistics during the recorded period. In particular, we consider two linear moments (or L-moments, see Hosking and Wallis, 1997): the mean and L-coefficient of variation (L-CV) for each station. Second, we divide the study region into tiles: within each tile, we average the at-site estimation of the L-moments, in order to obtain timeseries of robust regional L-moments estimates. Finally, we compute tile-wise the correlation between the timeseries of the L-moments and the rolling mean of the teleconnections and we define raster maps of the correlation with the mean and L-CV.

In the second part, we focus on areas (tiles) where significant correlations are present, and we fit a tile-wise polynomial relationship between the L-moments and the most influent teleconnection. By using a hierarchical approach (see e.g. Gabriele and

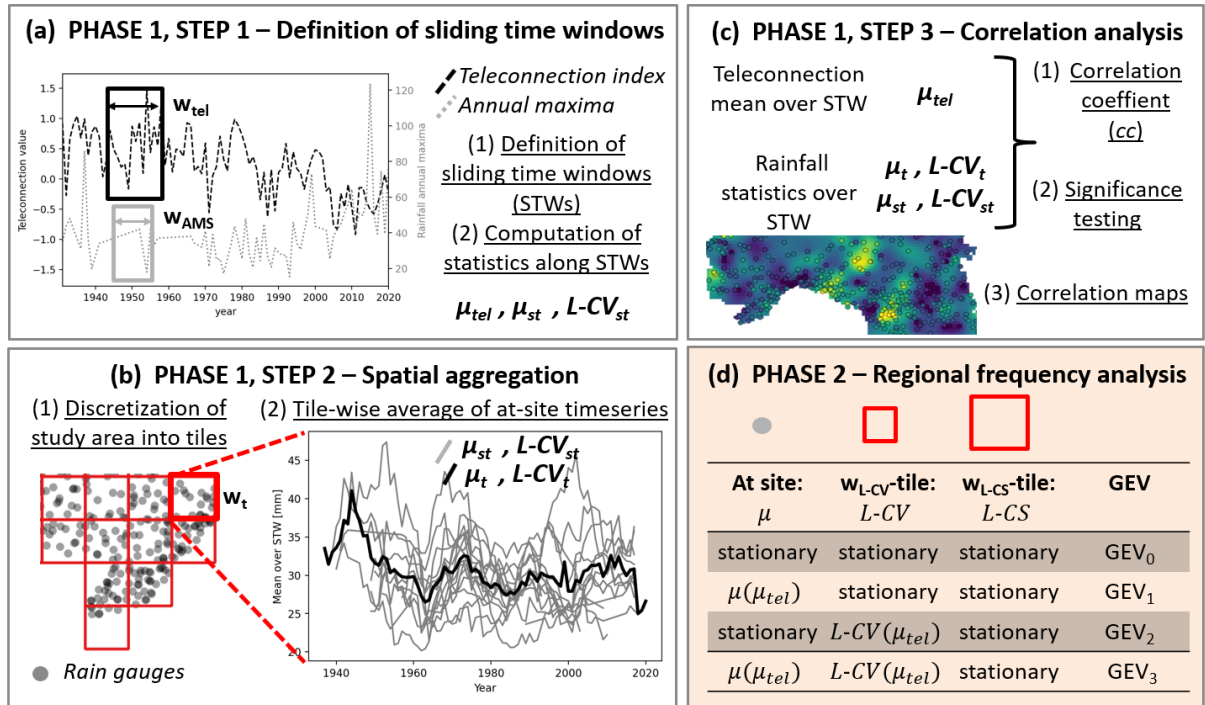

Figure 1. General methodological framework of the present study: first phase (white background, panels (a), (b) and (c)) and second phase (coloured background, panel (d)). Vectors are highlighted with bold, italic font, substeps are numbered and underlined.

Arnell, 1991; Castellarin et al., 2001), we define regional Generalized Extreme Value distributions (GEV, see Jenkinson, 1955) in a stationary and non-stationary framework. Finally, the research is enriched by a critical discussion on the generality and reproducibility of the proposed methodology. It is showed that beside the choice of the study area, our methods are innovative and universally applicable.

2 Methodological framework

We propose an innovative and structured methodological framework for assessing the effectiveness of teleconnections-informed frequency analysis of rainfall extremes. The general methodology is structured into two phases. Some elements of the procedure, which include numerical parameters and specific functions, need to be adjusted according to the specific study case; for the sake of brevity, all these elements will be referred to as “parameters”. The general methodology is represented in Figure 1 and described in this Section, while the parametrization adopted for this study is detailed in Section 4.1.

2.1 Phase 1: correlation analysis

The first part aims at (1) evaluating the relation between teleconnection indexes and the local climate indexes (i.e., the statistics of the rainfall regime), (2) investigating the spatial structure of the correlation, and (3) producing maps of the correlation structure over the study area. These objectives are obtained through three fundamental steps which we describe below. The first step is the definition of two sliding time windows (STWs). One STW is used for the teleconnections, with width w_{tel} years. Over this STW, the mean of the teleconnection μ_{tel} is computed.

Another STW is used for the Annual Maximum Series (AMS), with width of w_{AMS} years. Over this STW, the at-site mean (μ) and L-coefficient of variation (L-CV, see Hosking and Wallis, 1997) of the AMS of rainfall depths are computed (see Figure 1.a). Thus, for each gauging station (st) the time series of the mean (μ_{st}) and L-CV ($L-CV_{st}$) are obtained; these have length $n - w_{AMS} + 1$, where n is the number of years of observations for the considered site:

$$\mu_{st} = \{\mu_{1,st}, \mu_{2,st}, \dots, \mu_{n-w_{AMS}+1,st}\} \quad (1)$$

$$L-CV_{st} = \{L-CV_{1,st}, L-CV_{2,st}, \dots, L-CV_{n-w_{AMS}+1,st}\} \quad (2)$$

where $\mu_{1,st}$, $\mu_{2,st}$ and $\mu_{n-w_{AMS}+1,st}$ represent the mean computed over the first, second and last time-steps defined by the STW at site st ; the same notation is used for the L-CV. Notably, at each time-step of the STW, the computed value (i.e., mean or L-CV) is attributed to the last year included in that interval. Thus, each year is represented by a statistical moment (or L-moment) that describes the w_{AMS} previous years, including itself.

The second step is the discretization of the spatial domain into single tiles (or cells, or pixels) that do not overlap with each other. The spatial resolution is w_t . For each single tile (t), the timeseries μ_{st} and $L-CV_{st}$ of the gauged sites within the tile are averaged yearly (see Figure 1.b). Thus, regional timeseries (μ_t and $L-CV_t$) for each tile are obtained:

$$\mu_t = \left\{ \frac{\sum_{i=1}^{n_1} \mu_{1,i}}{n_1}, \frac{\sum_{i=1}^{n_2} \mu_{2,i}}{n_2}, \dots, \frac{\sum_{i=1}^{n_{n-w_{AMS}+1}} \mu_{n-w_{AMS}+1,i}}{n_{n-w_{AMS}+1}} \right\} \quad (3)$$

$$L-CV_t = \left\{ \frac{\sum_{i=1}^{n_1} L-CV_{1,i}}{n_1}, \frac{\sum_{i=1}^{n_2} L-CV_{2,i}}{n_2}, \dots, \frac{\sum_{i=1}^{n_{n-w_{AMS}+1}} L-CV_{n-w_{AMS}+1,i}}{n_{n-w_{AMS}+1}} \right\} \quad (4)$$

where $n_1, n_2, \dots, n_{n-w_{AMS}+1}$, are the numbers of stations with available rainfall statistics at steps 1, 2, ..., $n - w_{AMS} + 1$ of the STW.

The third step is the correlation analysis (see Figure 1.c). The correlation coefficient (cc) is computed for each tile between the averaged timeseries (μ_t and $L-CV_t$) and the rolling mean of the considered teleconnection (μ_{tel}), and the significance of the resulting correlation is tested (with significance 5%). We propose to adopt the Spearman coefficient, as it accounts also

for non-linear correlations, yet preliminary experiments showed very similar results with the Pearson correlation coefficient.
95 Only stations with $p\text{-value} \leq 0.05$ are considered as significantly correlated. Only the teleconnections showing high numbers of significantly correlated pixels are considered for the further steps.

Finally, an additional analysis of the correlation coefficients is needed to delineate eventual spatial structures. Since the definition of the parameters described above (i.e., w_{tel} , w_{AMS} , w_t) is necessarily affected by subjectivity and uncertainty, the robustness, or reliability, of the detected correlation should be assessed: the method adopted for this assessment is detailed in
100 Section 4.1. Then, a map of the correlation field over the study area can be created.

2.2 Phase 2: regional frequency analysis

The second part of the present study aims at assessing (1) the effect of teleconnections on frequency analysis of extreme rainfall, and (2) the benefit of considering teleconnections as covariates for non-stationary frequency analysis.

For the sake of generality, the Generalized Extreme Value distribution (GEV, see Jenkinson, 1955) is considered, given its
105 flexibility and representativeness of the frequency regime of hydrological extremes (e.g., Papalexiou and Koutsoyiannis, 2013; Salinas et al., 2014). Nevertheless, the proposed framework is not limited to the selection of a given frequency distribution; on the contrary, it could be easily extended and adapted to the case in which alternative theoretical frequency distributions are tested against each other. The cumulate probability distribution of the GEV, $F_{GEV}(x)$, depending on the location, scale and shape parameters (ξ, α, k) , is defined as follows:

$$110 \quad F_{GEV}(x) = e^{-e^{-y}}, \text{ where } y = \begin{cases} -k^{-1} \log_e [1 - k(x - \xi)/\alpha], & k \neq 0 \\ (x - \xi)/\alpha, & k = 0 \end{cases} \quad (5)$$

The hierarchical method for regional frequency analysis is adopted (see Gabriele and Arnell, 1991). Accordingly, for a given gauged site, the mean is computed from the at-site records, the L-CV exploits all the time series within a tile with resolution w_{L-CV} where the target site is included, and the L-CS exploits all the time series within a tile with resolution w_{L-CS} (where $w_{L-CV} \leq w_{L-CS}$). The values adopted in the present study for w_{L-CV} and w_{L-CS} are detailed in Section 4.1.

115 First, a stationary GEV is fit (GEV_0), where the mean over the whole time series is computed at-site, and the regional L-CV and L-CS are obtained as described in Hosking and Wallis (1997) as a weighted average over their respective tiles by referring to the complete sequences of annual maxima.

Second, three types of non-stationary GEV are set up. The first type, GEV_1 , adopts the same L-CV and L-CS as the GEV_0 , whereas the mean varies as a function of the best teleconnection index (selected in phase 1). This function is fitted at-site,
120 according to the hierarchical regionalization framework. The choice for its shape, $f(x)$, is detailed in Section 4.1. The second type GEV, GEV_2 , adopts the same mean and L-CS as the GEV_0 , while the L-CV varies as a function $f(x)$ of the best index. This is fitted on the w_{L-CV} -averaged timeseries ($L-CV_t$), according to the hierarchical regionalization framework. The third type GEV, GEV_3 , adopts the same L-CS as the GEV_0 , while the mean and L-CV are obtained with the same methods as for the GEV_0 and GEV_2 , respectively. Finally, the four models are compared by means of three commonly used metrics: the ratio of

125 maximized likelihood (RML), the Anderson-Darling statistic (AD), and the modified Shapiro-Wilk statistic (TN.SW). These
 three metrics, or discrimination statistics, as they are frequently defined, are selected based on the results of other authors.
 Ashkar and Aucoin (2012) and Ashkar and Ba (2017) found that the discrimination power of these three metrics is higher than
 other metrics after multiple and extensive testing. In particular, Laio et al. (2009) found that the Anderson-Darling statistic had
 better discrimination power than other considered metrics when the parent distribution is a GEV. The RML is defined as in
 130 Ashkar and Ba (2017):

$$RML = \log_e \left(\frac{LH_{non-stationary}}{LH_{GEV_0}} \right) \quad (6)$$

The AD statistic is defined as in Laio et al. (2009) and Laio (2004). For an ordered series of annual maxima, $\mathbf{x} = \{x_1 < x_2 < \dots < x_i < \dots < x_n\}$, the AD depends on the originally version proposed by Anderson and Darling (1952):

$$AD_{1952} = -n - \frac{1}{n} \sum_{i=1}^n [(2i-1) \cdot \log_e(F(x_i)) + (2(n-i)+1) \cdot \log_e(1-F(x_i))] \quad (7)$$

$$135 \quad AD = \begin{cases} 0.0403 + 0.116 \left(\frac{AD_{1952} - \xi}{\beta} \right)^{\eta/0.861}, & 1.2\xi \leq AD_{1952} \\ \left[0.0403 + 0.116 \left(\frac{0.2\xi}{\beta} \right)^{\eta/0.861} \right] \cdot \frac{AD_{1952} - 0.2\xi}{\beta}, & 1.2\xi > AD_{1952} \end{cases} \quad (8)$$

where $F(x)$ is the cumulative density function of the probability distribution under exam, AD_{1952} is the original Anderson-Darling statistic (see also Das, 2022), and ξ , β and η are distribution-dependent coefficients that are tabled by Laio (2004) (Tables 3 and 5).

The TN.SW statistic, generated by the modified Shapiro-Wilk test (see the original test by Shapiro and Wilk (1965)), is
 140 performed as in Ashkar and Ba (2017). First, the series of annual maxima is transformed into a standard normal sample by
 applying the cumulative density function of the distribution under exam, $F(x)$, and the percentile function of the standard
 normal distribution, $\Phi^{-1}(x)$:

$$z_i = \Phi^{-1}(F(x_i)) \quad (9)$$

Then, the TN.SW is computed:

$$145 \quad TN.SW = \left(\sum_{i=1}^n v_i z_i \right)^2 / \sum_{i=1}^n (z_i - \mu_z)^2 \quad (10)$$

where the coefficients v_i are computed as in the approximation described by Royston (1992), and μ_z is the mean of the standardized vector \mathbf{z} .

These three metrics are computed for the four types of GEV at all the locations where the correlation is significant (i.e., p-value $\leq 5\%$) and strong (i.e., Spearman coefficient ≤ -0.5 or ≥ 0.5). While the RML represents the comparison between the LH
 150 of two distribution probabilities, the AD and TN.SW measure the goodness-of-fit of a single distribution to the data (i.e., larger values represent better fit). In order to compare the stationary with the non-stationary distributions, we consider the differences

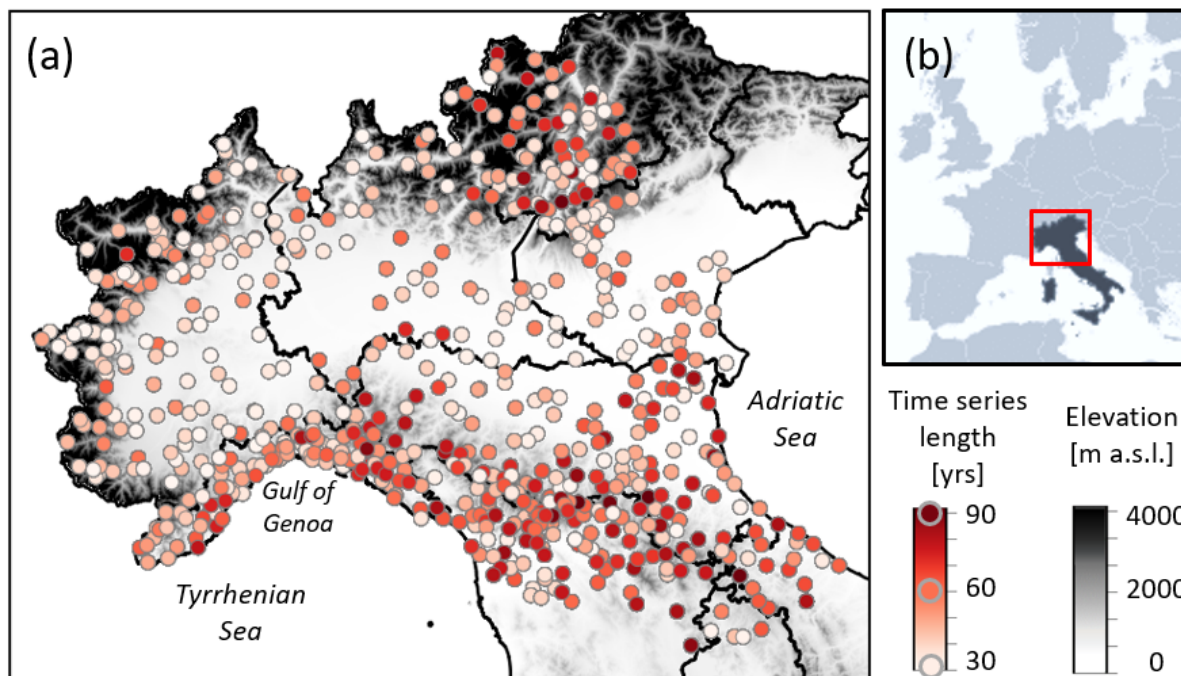

Figure 2. Elevation (a, in grey color scale) and location (b) of the study area. Length of the timeseries of sub-daily annual maximum rainfall depths (a, red color scale). In black: Italian administrative regions.

$\Delta_{AD} = AD_{non-stationary} - AD_{GEV_0}$ and $\Delta_{TN.SW} = TN.SW_{non-stationary} - TN.SW_{GEV_0}$ (Ashkar and Ba, 2017; Das, 2022). Thus, either for RML, Δ_{DA} and $\Delta_{TN.SW}$, positive values indicate that the considered non-stationary model provides a higher goodness-of-fit to the observed annual maxima relative to the stationary model.

155 3 Dataset

The study area includes most of northern and part of central Italy, a region characterized by great climate variability (see Figure 2.a). Two main mountain ranges are present: the Alps in the north, with a maximum elevation of 4000 m a.s.l., and the Apennines, crossing all along continental Italy, with a maximum elevation of ~ 2100 m a.s.l. in the study area. The largest Italian plain, the Po plain, is located at the southern border of the Alps, following the course of the Po River from the northwest to the northeast, where low coasts are located.

We select 680 gauged stations (Figure 2.a) from the I2-RED dataset (Mazzoglio et al., 2020), filtering by a minimum of 30 years of data. Thus, all the selected timeseries should be long enough to show variations of the statistical regime during time, if these are present (see also Renard et al., 2008; Ouarda et al., 2019). For each station, we consider time series annual maximum cumulative rainfall over 1 and 24 consecutive hours, which represent distinct events: mainly convective and mainly synoptic, respectively. Data have been recorded between 1928 and 2020.

In the study, six teleconnections are considered; a detailed description of their nature is not reported here, since an interested reader can refer to the extensive literature cited in the text. Namely, these are the North Atlantic Oscillation (NAO, see Jones et al., 1997), the East Atlantic-West Russia (EA-WR) pattern (see Barnston and Livezey, 1987), the Pacific Decadal Oscillation (PDO, see Zhang et al., 1997), El Nino Southern Oscillation (ENSO, see Chen et al., 2019), Mediterranean Oscillation Index (MOI, see Conte et al., 1991), and Western Mediterranean Oscillation Index (WeMOI, see Martin-Vide and Lopez-Bustins, 2006). All these climate indexes have significant influences on several locations in Europe and the Mediterranean (e.g., Caroletti et al., 2021; Krichak et al., 2014, 2002; Krichak and Alpert, 2005). The NAO, EA-WR, PDO and ENSO are freely accessible from the NOAA Physical Sciences Laboratory data base available at <https://psl.noaa.gov/data/climateindices/list/>. The MOI and WeMOI can be retrieved from the University of East Anglia's Climate Research Unit (CRU; <https://crudata.uea.ac.uk/cru/data/moi/>).

4 Results

4.1 Parametrization of the procedure for the study area

Based on several preliminary experiments conducted, the parametrization of the general methodology to the study area is the following.

The first part of the study requires the definition of w_{tel} , w_{AMS} , w_t , and the methodology for the robustness analysis. First, w_{tel} is assumed as 30 years. Preliminary experiments with smaller w_{tel} provided similar results, yet not exactly the same. The final choice accounts to 30 years in order to smooth short interannual oscillations, considering instead a pluridecadal climate window. Shorter oscillations (i.e., <30 years) would not be of interest for the design of hydraulic structures, while longer ones (i.e., >30 years) would be highly uncertain to detect, due to limited length of the timeseries.

Second, the w_{AMS} parameter is assumed as 10yrs. This choice is also due to a balance between a minimum width for the computation of the L-CV and a minimum length of the timeseries of the rainfall statistics (i.e., μ_{st} and $L-CV_{st}$). In fact, on the one hand $w_{AMS} < 10$ would lead to unacceptable inaccuracy for the definition of the L-CV. On the other hand, the μ_{st} and $L-CV_{st}$ timeseries originated from an n -long annual maxima timeseries have length of $n - (w_{AMS} - 1)$. This means that the longer w_{AMS} would lead to shorter μ_{st} and $L-CV_{st}$, which in turn would lead to a smaller number of stations where the correlation between teleconnections and rainfall statistics can be reliable. Indeed, to the aim of defining a zonation of the teleconnection-statistics correlation field, as in the present study, the number of sufficiently long timeseries needs to be as high as possible.

According to the adopted parametrization, equations 1 to 4 become the following:

$$\mu_{st} = \{\mu_{1,st}, \mu_{2,st}, \dots, \mu_{n-10+1,st}\} \quad (11)$$

$$L-CV_{st} = \{L-CV_{1,st}, L-CV_{2,st}, \dots, L-CV_{n-10+1,st}\} \quad (12)$$

$$\boldsymbol{\mu}_t = \left\{ \frac{\sum_{i=1}^{n_1} \mu_{1,i}}{n_1}, \frac{\sum_{i=1}^{n_2} \mu_{2,i}}{n_2}, \dots, \frac{\sum_{i=1}^{n_{n-10+1}} \mu_{n-10+1,i}}{n_{n-10+1}} \right\} \quad (13)$$

$$\mathbf{L-CV}_t = \left\{ \frac{\sum_{i=1}^{n_1} L - CV_{1,i}}{n_1}, \frac{\sum_{i=1}^{n_2} L - CV_{2,i}}{n_2}, \dots, \frac{\sum_{i=1}^{n_{n-10+1}} L - CV_{n-10+1,i}}{n_{n-10+1}} \right\} \quad (14)$$

For the spatial resolution of the tile size, w_t , we adopt four values: 0km (i.e., considering the single gauged stations, with no spatial discretization), 15km, 30km and 50km. This multiple choice comes from a balance. On the one hand, L-CV computed over a 10yrs STW may have low robustness, which can be addressed by averaging L-CVs from several stations within large tiles. On the other hand, larger tiles may be less statistically homogeneous. Moreover, averaging L-statistics over large tiles may smooth the variability of the rainfall regime, hiding local patterns where the morphology is complex. Since there is no universal rule for solving this balance, we decide to consider four different values for w_t . The suitability of these values is tested by means of the heterogeneity test described by Hosking and Wallis (1997) for the L-CV. The results show that most of the tiles are homogenous for all the resolutions. These analyses are not reported here for the sake of brevity. Regarding the robustness of the correlation signal is defined through a reliability index. At each station st , it is defined as ri_{st} :

$$ri_{st} = \text{sign}(cc_{0km,st}) + \text{sign}(cc_{15km,st}) + \text{sign}(cc_{30km,st}) + \text{sign}(cc_{50km,st}) \quad (15)$$

Where $cc_{0km,st}$ is the correlation computed at station st , while $cc_{15km,st}$, $cc_{30km,st}$ and $cc_{50km,st}$ are the correlation coefficients relative to the tiles (with w_t 15km, 30km and 50km) where st is inserted. Non-significant correlations are considered as 0.

This is considered to be a measure of the spatial coherence of the correlation signal, which varies between -4 and 4. The absolute value is the coherence of the correlations at different tiles. The sign represents the sign of the prevailing correlation. For instance, considering a gauged station where the absolute value of ri is 4, the correlation is significant and with the same sign both when calculated at-site, and when it derives from a 15km aggregation, and at 30km, and at 50km. On the opposite, 0 represents areas with no significant correlation or where positive and negative correlations compensate with each other (e.g. positive correlation at-site and at a 15km tile, and negative correlation at 30km and 50km). In general, the ri can be rescaled between -1 and 1, in order to be more similar to a correlation coefficient. In this study, the original scale is kept, as it is more easily interpretable.

Finally, the reliability index is interpolated by ordinary kriging (Hengl, 2007) to produce a robust map of the correlation field. Regarding the second part of the study, three parameters need to be adjusted: w_{L-CV} , w_{L-CS} and $f(x)$. The selected resolution w_{L-CV} is 30km, as it is a good balance between robustness (i.e., aggregating at least two L-CV at-site timeseries) and representing regional patterns and local variability. The selected resolution w_{L-CS} is 100km, based on low spatial variability of the skewness parameter (e.g., Gabriele and Arnell, Claps et al 2022) and improved robustness (see above).

The function $f(x)$ between teleconnections and L-statistics is shaped as a second-order polynomial function. This form has

225 been selected because of its simplicity (i.e., only two parameters are needed) and yet adaptability to the data, while the dependence observed of extreme rainfall statistics on teleconnections is clearly non-linear. Other choices are clearly possible. However, it should be underlined that the aims of the present study are mainly demonstrative of the potential of the proposed approach. Thus, the nature and selection of the best function is not discussed in detail.

4.2 Results of phase 1: correlation analysis

230 First, it is observed that the WeMOI shows a remarkably higher number of significant correlations in the study area than any other teleconnection considered in the study. When considering single stations, we found 387 significant correlations for hourly rainfall for WeMOI, while for the other indexes they range from 0 (ENSO) to 78 (PDO). Due to this huge difference, only the results obtained for WeMOI are presented below.

Figure 2 reports significant Spearman correlation coefficients with WeMOI at different resolutions for spatial aggregation for 235 the mean (panels (a)-(h)) and L-CV (panels (i)-(p)), respectively. Several stations present statistically significant correlation values with this index, with signs and amplitude changing depending on the site considered (panels (a) and (e) for mean, (i) and (m) for L-CV, Figure 3). Aggregating stations into tiles reduces spatial heterogeneity, and allows to describe the geographical pattern of the correlation field (see other panels).

Both for the mean and L-CV, the correlation fields of extreme rainfall with 1h duration present complex spatial patterns, with 240 small areas characterized by homogeneous values.

The reliability index (ri , see Equation 15) is showed for the mean and L-CV in Figure 4. As observed above, stable geographical structures in the correlation are larger (1) for the 24h duration than for the 1h (compare panels (a) and (b) with panels (c) and (d) in Figure 4), and (b) for the mean than for L-CV (compare panels (a) and (c) with panels (b) and (d) in Figure 4). Concerning the mean of the AMS series, two major patterns of robust negative correlation are present in the Western coast of 245 the Tyrrhenian Sea (Gulf of Genoa) and in the north-eastern Alps. Less intense but significant positive correlation values are present along the northern flank of the northern Apennines. For the L-CV, the pattern in the Gulf of Genoa is still present, but less evident and less extended, while some positively correlated hotspots are present, mostly located in the Southern portion of the study area.

4.3 Results of phase 2: Frequency analysis

250 Following the adopted framework (see Section 3.2), regional frequency analysis is applied to all the locations where significant correlation is observed (i.e., $p\text{-value} \leq 5\%$). Figure 4 illustrates the results obtained for a station (see panel (a) for its location) where the three non-stationary GEV can be fitted (i.e., GEV_1 in panel (c), GEV_2 in panel (d), and GEV_3 , in panel (e)).

It is evident from the example provided in Figure 5 that the variation of the expected percentiles due to the dependence of the GEV parameters on the teleconnections may be very significant. The prediction of the 100-year 24-hour rainfall depth in 255 the selected location is equal to 370mm according to the stationary model (GEV_0), but may vary between 340 and 375 if the empirical relationship between WeMOI and L-CV is explicitly modelled (GEV_2), between 300 and 460 if the mean 24-hour annual maximum rainfall depth becomes a function of WeMOI (GEV_1), and may be as low as 275 and as high as 470 if both

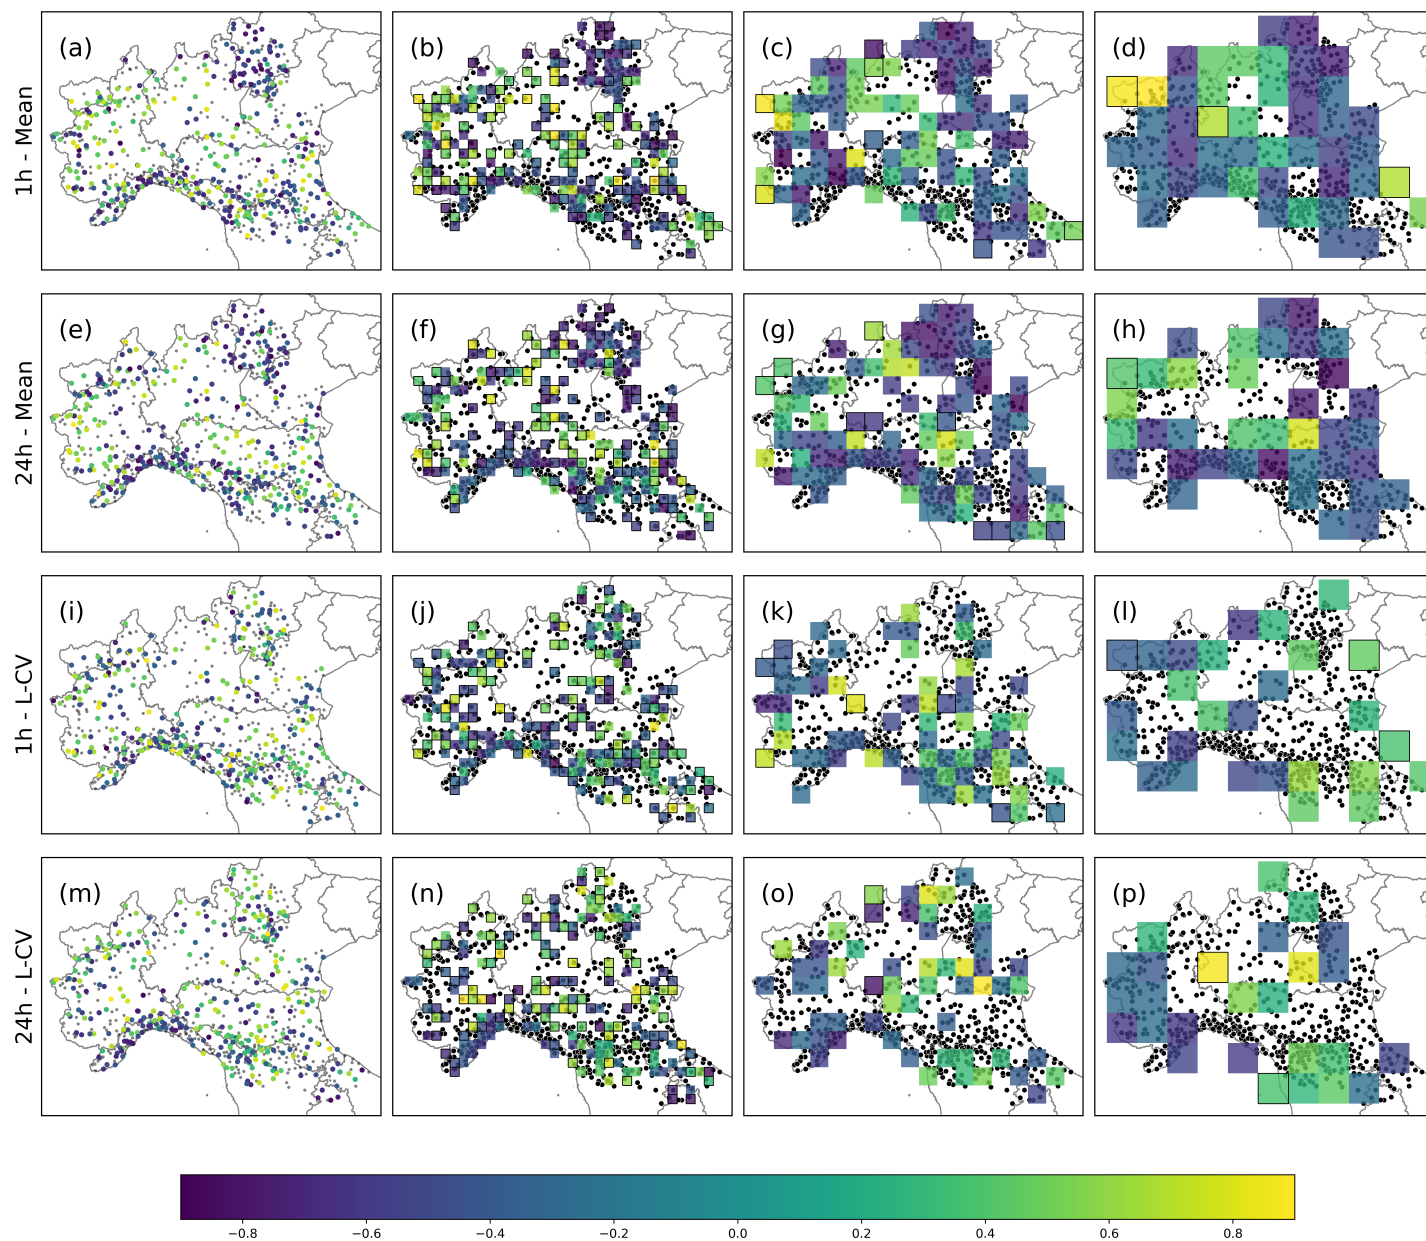

Figure 3. Correlation coefficient for the mean [L-CV] for AMS of rainfall depths with duration of 1h and 24h: at-site ((a)/(i) and (e)/(m)) and for tiles of size 15km ((b)/(j) and (f)/(n)), 30km ((c)/(k) and (g)/(o)), and 50km ((d)/(l) and (h)/(p)). Only statistically significant (at 5%) correlation coefficients are illustrated using a purple-green-yellow color scale. Black outlines highlight tiles where only one station is present

mean and L-CV are expressed as functions of WeMOI (GEV_3).

Figure 6 represents the RML, Δ_{AD} , and $\Delta_{TN.SW}$ (panels (a), (b) and (c), in this order). These measure the increase in

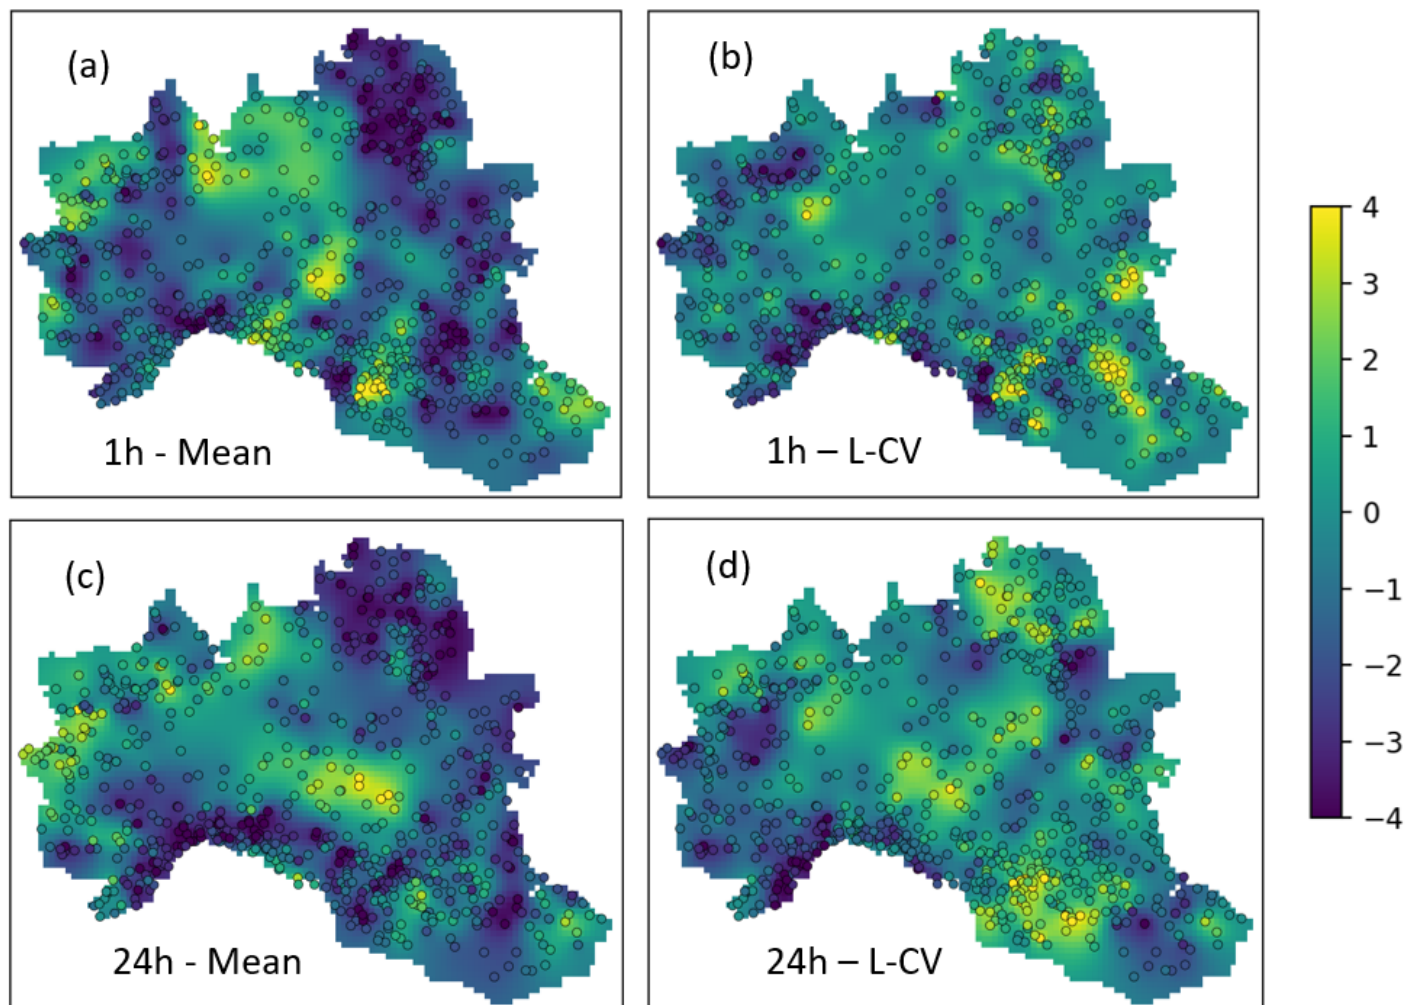

Figure 4. Raster maps of reliability index (r_i) of the correlation between WeMOI and mean/L-CV of AMS of rainfall depths with duration of 1h (a/b) and 24h (c/d)

260 goodness-of-fit due to the non-stationary regional GEV models with respect to the stationary ones. They are computed for all locations in which statistically significant correlation between AMS statistics and WeMOI was detected (see Sections 2.1 and 2.2).

Values of RML (Figure 6.a) and Δ_{AD} are mainly positive for GEV_1 and GEV_3 (i.e., non-stationary models show a better representation relative to the stationary one), where negative values are present in less than 25% of the cases. For GEV_2 , in
265 nearly half of the stations examined the precipitation regime is better represented by a stationary framework. Differently, values of $\Delta_{TN.SW}$ are almost equally divided into positive and negative for both the 1h and 24h durations and all the non-stationary models.

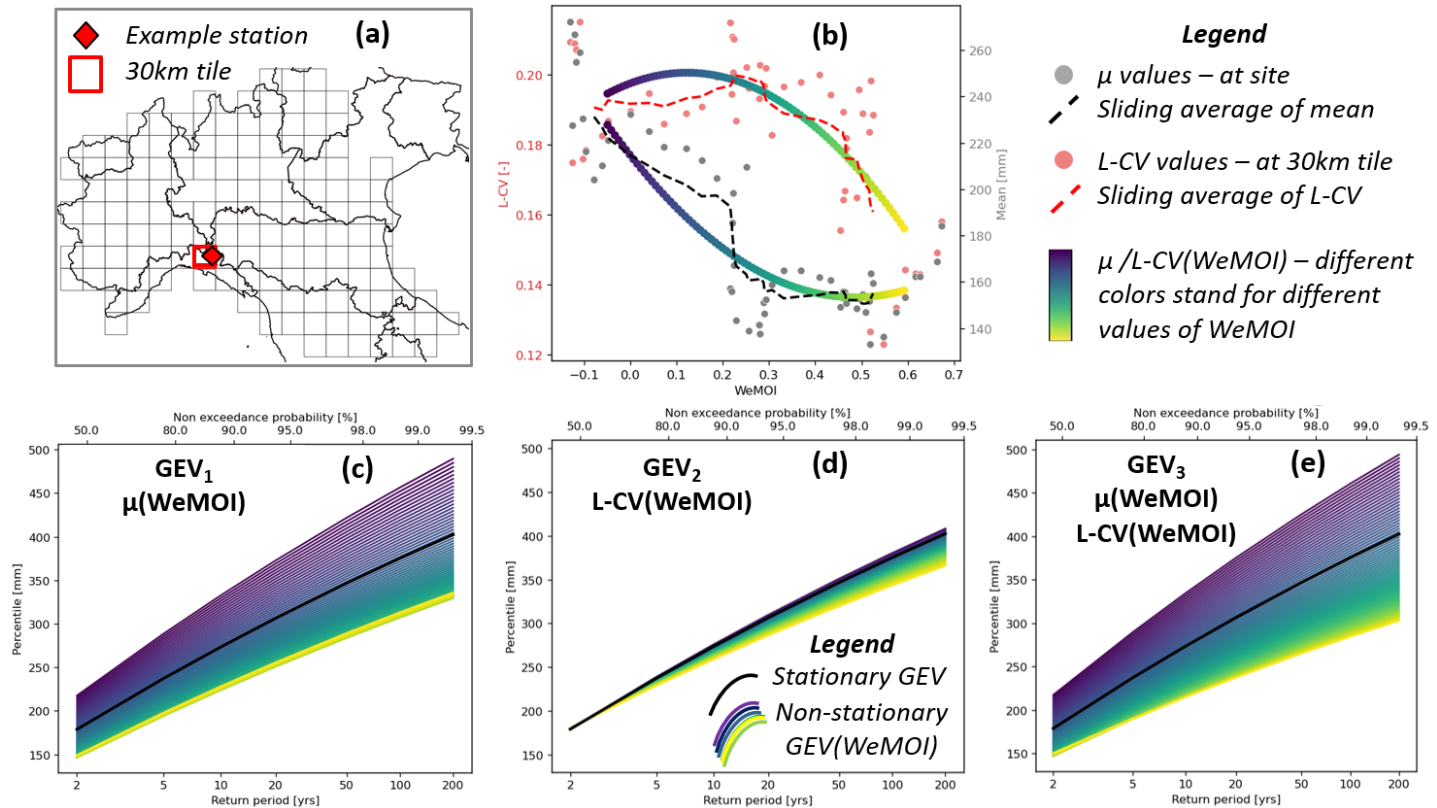

Figure 5. Example of location where regional frequency analysis for 24h duration is performed. Upper panels: location of example station (a), polynomial function of mean (μ) and L-CV depending on WeMOI (b). Lower panels: expected percentiles with given return periods in stationary (black line) and non-stationary framework (colored scale lines) when only the mean depends on the WeMOI (c), only the L-CV depends on the WeMOI (d), or both mean and L-CV depend on the WeMOI (e).

Overall, the GEV_2 model shows the lowest number of cases (which is still above 50%) where it should be preferred to the stationary regime. For all the three metrics, light differences are observed between the results for 1h and 24h.

270 5 Discussion

5.1 Zonation of the correlation

The stronger influence of the WeMOI compared to the other teleconnections was expected. In fact, the WeMOI consists of the normalized difference between Cadiz, in the South of Spain, and Padua, in northern Italy, and thus, it describes the formation of precipitation systems over the Tyrrhenian Sea (Lopez-Bustins et al., 2020; Redolat et al., 2019). Strong significant correlations with the WeMOI were also found in other studies, as for Central Italy by Romano et al., 2021 and for Southern Italy by Caroletti et al., 2021. In particular, the presence of significant intense negative correlation values in the Gulf of Genoa and the

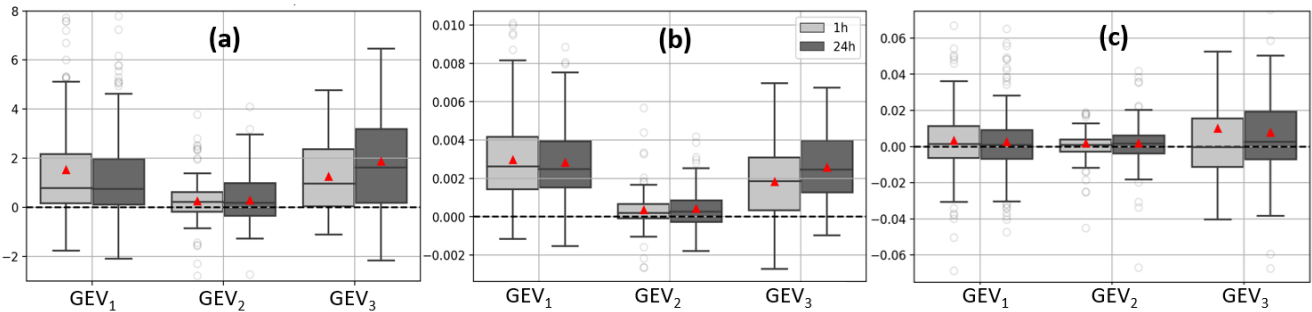

Figure 6. Evaluation metrics for stationary and non-stationary RFA framework for locations where at-site strong and significant correlation $\mu_{WeMOI}-\mu_{st}$ is present (GEV_1), 30km strong and significant correlation $\mu_{WeMOI}-L-CV_t$ is present (GEV_2), and both correlations $\mu_{WeMOI}-\mu_{st}$ and $\mu_{WeMOI}-L-CV_t$ are strong and significant (GEV_3). In particular, RML (a), Δ_{AD} (b), and $\Delta_{TN.SW}$ (c). For all the metrics, results larger than zero represent better performances of non-stationary over stationary framework.

North-East for the mean-WeMOI correlation (Figure 4.a and 4.c) is consistent with the known patterns of precipitation regimes over north-central Italy. In fact, intense daily precipitation values are expected over the Tyrrhenian Coast and north-eastern Alps in the presence of intense southwesterly flows from the Mediterranean, typical during the autumn season and favored by large scale circulation anomalies associated with negative value of the WeMOI. On the other hand, in the presence of positive values of the index, precipitation is expected to be linked to cut-off flows mostly affecting the Adriatic section of the Apennines. In the remaining portion of the study area, precipitation systems are more complex, as influenced by the passage of cut-of flow favoring precipitation over the southern and eastern portion of the Apennines area. In this case, correlation patterns with the WeMOI are expected to be more fragmented (Figure 4.c).

For the 1h rainfall maxima, mostly linked to convective phenomena, which are often characterized by a very limited spatial scale, the correlation with WeMOI presents more complex geographical patterns, even if still present (Figure 4.a).

A physical interpretation of the L-CV-WeMOI dependence is more complex. It is evident that some hotspots of correlation are present (Figure 3.k-l for and 3.o-p): negative correlations are mostly located in the North-West, which partially confirms the results for the mean (compare Figure 3.f-g with 3.n-o). Elsewhere, small and fragmented, mainly positive patterns are visible.

Considering the r_i , the robustness of patterns to spatial aggregation is lower than for the mean, which may be due to higher uncertainty in at-site computation of L-CV within a 10-year time window. For this reason, we believe that for L-CV, a spatial aggregation at 30km should be preferred for RFA.

Based on the results described in Section 4, the methods adopted generally allowed a reliable zonation of the teleconnection-extreme rainfall correlation. This is due to two elements: the temporal and spatial aggregation of the data. First, the temporal aggregation through sliding time windows allow to consider the statistics of the extreme rainfall during time, instead of the rainfall depth themselves. In this way, it is possible to filter out inter-annual variability of the seasonality and magnitude of the annual maxima and focus on the decadal precipitation statistics. Second, the spatial aggregation into tiles allows to obtain more reliable values of the rainfall statistics. This produces a smoothing local effect, that could be due to data fragmentation and

noise and enhance geographical pattern recognition (see Figure 3). The choice of w_t for spatial aggregation should be carefully
300 conducted, as it mainly depends on the morphology of the study area, and the density and location of the rain gauges. Generally,
considering a number of different values for w_t is useful to analyze the reliability of the detected correlation patterns.

A different approach for spatial aggregation could be the one described in Castellarin et al. (2024), where overlapping tiles are
used. However, including each gauged site in multiple tiles could result in excessive smoothing effect of the orographic effect
over the correlation field. Thus, this solution should be preferred only in case of scarce density of gauges network.

305 A key aspect of the proposed approach is its high adaptability. In fact, the same methodology with an appropriate parametriza-
tion could be used to study the influence of teleconnections on several environmental variables, such as AMS of floods or
temperature or wind. Moreover, raster maps of the correlation field (as the ones in Figure 4) could be used as descriptors of
the drivers of an environmental variable, and adopted as input of predictive raster-based models (e.g., for prediction of flood
susceptibility, as in Magnini et al., 2023).

310 5.2 Non-stationary regional frequency analysis

Looking at the results of the second phase of our study (Figure 5), two main points are of general interest. First, the range of
variability of the expected percentiles with non-stationary models depending on teleconnections is very significant, confirming
what observed locally by other authors. Second, the regional dependency of rainfall statistics on teleconnections can be suc-
cessfully exploited locally for frequency analysis. This is a useful improvement over present literature, as it allows to obtain
315 the μ_{st} and $L - CV_{st}$ even where observations are not locally available. Moreover, the observed variability of the expected
maximum rainfall with given return periods could be used as teleconnection-informed uncertainty range for the design of hy-
draulic structures.

The results in Figure 6 show that an incontrovertible evaluation of which model is the most accurate is impossible. In fact,
each metric, or test, evaluates differently the goodness-of-fit and may provide wrong indication of the best model (e.g., see
320 Laio et al., 2009; Ashkar and Aucoin, 2012; Ashkar and Ba, 2017). In general, it is positive that two metrics out of three (i.e.,
RML and Δ_{AD}) indicate that the non-stationary framework fits the data better for most of the stations analyzed. Nevertheless,
it is not surprising that one of the metrics ($\Delta_{TN,SW}$) suggests to select the stationary approach in half of the cases. In fact,
the framework we adopted for non-stationary RFA is based on the strong assumption that the same type of function (i.e., a
polynomial function) can represent the teleconnection-statistic relationships within all the study area. Indeed, this approxima-
325 tion is sufficiently accurate in some stations, while being not adapt in others. This is probably also the reason why the GEV_1
models perform generally better than the GEV_2 ones. In fact, the polynomial approximation may fit the data better when these
are collected locally (as for the $\mu_{tel}-\mu_{st}$ case) than when they result from tile-wise averaging (as for the $\mu_{tel}-L-CV_{st}$ case).
Accordingly, the GEV_3 models derive their goodness or badness from the sum of the GEV_1 and GEV_2 contributes. This leads
them to be the best models for some stations, and the worst for others (see the extension of the GEV_3 boxplots in Figure 6.a
330 and 6.c), depending on the goodness of the polynomial approximation for μ and L-CV.

To summarize, the metrics showed in Figure 6 can be considered as encouraging, as they detect better goodness-of-fit of
non-stationary RFA models than the stationary ones, despite the low-complexity of the function adopted for modelling the

dependence on teleconnections. It is important to underline that the aim of the present research is to investigate the potential of teleconnections as independent variables in RFA models, and not to propose a specific method for RFA. Indeed, the RFA results depend on a number of parameters, that are the widths of STWs for temporal aggregation of the teleconnection indexes (w_{tel}) and AMS (w_{AMS}), and the resolution for spatial aggregation (w_t). The choice of these parameters can be done by a careful sensitivity analysis for defining the spatial field of the teleconnection-statistic correlation (see Sections 2 and 4.2). The case of setting a framework for RFA is very different and much more complex, as it requires the formalization of a function of extreme rainfall statistics depending on teleconnection indexes. In this case, one should decide not only the shape of this function, but also the way its parameters vary in space and should be estimated. In our study, we adopted a simple framework, as this function has a limited number of parameters and the same shape (i.e., polynomial) in all the spatial domain. We showed a hierarchical RFA approach where the parameters of the polynomial functions are fitted at-site for the μ and at 30km-tiles for the L-CV. Our analyses overall suggest that even with a simple RFA framework, the use of teleconnections as dependent variables to describe the extreme rainfall regime may increase the accuracy in frequency modelling.

However, different approaches are indeed possible. First, the best resolution for spatial aggregation and the shape of the teleconnection-statistic function should be carefully evaluated for each specific case. Second, a more complex teleconnection-statistics function could be defined. A possible approach is the one proposed by Magnini et al. (2024), which leverages neural networks' capabilities to obtain functions whose parameters depend on the location of the considered site and other morphoclimatic descriptors. Indeed, the implementation and discussion of more sophisticated RFA methods to exploit teleconnections' informative content is complex, and should be addressed by future studies.

6 Conclusions

A growing number of recent studies show how large scale climatic indexes (or teleconnections) can be used as covariates to increase reliability of local frequency analysis of rainfall extremes across diverse geographical regions worldwide (e.g., Fauer and Rust, 2023; Ouarda et al., 2020; Ragno et al., 2018). It is theoretically possible to extend these methods to regional frequency analysis (RFA), but the teleconnection-extreme rainfall dependency at a regional scale should be first investigated. Beside its usefulness for correct estimation of the design rainfall for engineering applications, this topic is still not well addressed in the literature.

In the present study, we propose a framework to assess the link between teleconnections and the frequency regime of rainfall extremes at a regional scale, in order to perform climate-informed regional frequency analysis.

The approach is tested for a large and climatically diverse region in northern Italy. Our dataset consists of 680 annual maximum series (AMS) of hourly and daily (i.e., 1 and 24 hours durations) rainfall depth, recorded between 1921 and 2022. We select six global climate indexes, known to have significant correlation with local climate variability over the study area (Caroletti et al., 2021; Criado-Aldeanueva and Soto-Navarro, 2020; Romano et al., 2022): the North Atlantic Oscillation, Pacific Decadal Oscillation (PDO), East Atlantic – West Russia pattern, El Niño Southern Oscillation, Mediterranean Oscillation Index (MOI),

and Western Mediterranean Oscillation Index.

The main steps of the proposed framework can be summarized as follows. First, we define sliding time windows in order to obtain time series of teleconnections and statistics of annual maxima (i.e. L-moments of AMS, which in our case were used characterized the distribution of sub-daily rainfall extremes). Second, we discretize the study area into tiles where the L-moments are averaged into regional predictions. Then, we evaluate the correlation of teleconnections with time series of spatially gridded L-moments. Finally, we show a preliminary application of climate-informed regional frequency analysis of rainfall extremes, where the L-moments are modelled as functions of WeMOI. We selected WeMOI as it shows a notably higher number of significant correlations with the statistics of sub-daily rainfall maxima than the other teleconnection indexes. Application to different regions and hydroclimatic contexts may result in a higher relevance of other teleconnections. More-over, the relationship between WeMOI and L-moments of extreme rainfall shows clear spatial patterns across the study area, whose robustness is confirmed by their limited sensitivity to the chosen grid resolution and the partial agreement with previous studies (Caroletti et al., 2021; Romano et al., 2022). As well, this is coherent with the known spatial variability of precipitation regimes over the region.

The proposed approach is simple and easily reproducible, yet it is new with respect to the existing literature. In fact, while most authors investigated the correlation between the teleconnections and the raw AMS, we consider the L-moments. This, in combination with spatial discretization of the domain, allows us to focus on the relationship between the teleconnections and the extreme rainfall regime, instead of the extreme values themselves, whose seasonality and interannual variability can affect the correlation analysis. Beside the preliminary nature of the RFA application, three commonly used metrics (e.g., Ashkar and Ba, 2017) detect overall an increase in goodness-of-fit with respect to a stationary approach, in line with previous studies (Nerantzaki and Papalexioiu, 2022), shows that teleconnections may be useful covariates in a regional a framework. Overall, our research suggests promising pathways for climate-informed local and regional frequency analysis of rainfall extremes, and our methodology is highly adaptable to different environmental variables, such as floods and temperature.

Data availability. The rainfall data used in the present study are part of the dataset I2-RED (Mazzoglio et al., 2020), available under authorization at the website <https://doi.org/10.5281/zenodo.4269509>. Teleconnections indexes data are available at <https://psl.noaa.gov/data/climateindices/list/> and <https://crudata.uea.ac.uk/cru/data/>.
