Abstract. Lightning-produced nitrogen oxides (LNO<sub>x</sub>=LNO+LNO<sub>2</sub>) are an important source of upper tropospheric ozone. Typical parameterizations of LNO<sub>x</sub> in climate-chemistry models introduce a constant amount of NO<sub>x</sub> per flash or per flash type. However, recent satellite-based NO<sub>2</sub> measurements suggest that the production of LNO<sub>x</sub> per flash depends on the lightning flash frequency. In this study, we implement a new parameterization of LNO<sub>x</sub> production per flash based on the lightning flash frequency into a climate-chemistry model to investigate the upper limit implications for the chemical composition of the atmosphere. We find that a larger injection production of LNO<sub>x</sub> in weak thunderstorms leads to a larger mixing ratio of NO<sub>x</sub> in the lower and the middle troposphere, and to a lower mixing ratio of NO<sub>x</sub> in the upper troposphere. The mixing ratios of O<sub>3</sub>, CO, HO<sub>x</sub>, HNO<sub>3</sub> and HNO<sub>4</sub> in the troposphere are influenced by the simulated changes of LNO<sub>x</sub>. Our findings indicate a larger release of nitrogen oxides from lightning in the lower and the middle atmosphere, producing a slightly better agreement with the measurements of tropospheric ozone at a global scale. In turn, we obtain a small decrease of the lifetime of methane and of carbon monoxide, ranging between 0.7% and 3.4%.

#### 1 Introduction

Nitrogen oxides ( $NO_x = NO + NO_2$ ) produced by lightning in the upper troposphere (Zeldovich et al., 1947) is about 6 times more efficient in driving ozone production than anthropogenic  $NO_x$  emissions, producing about 100 molecules of ozone per molecule of lightning-produced  $NO_x$  ( $LNO_x$ ) (Schumann and Huntrieser, 2007). Thus,  $LNO_x$  affects the oxidizing capacity of the atmosphere and the tropospheric budget of carbon monoxide and methane (Wu et al., 2007; Murray et al., 2012; Gordillo-Vázquez et al., 2019).

The global production of  $LNO_x$  is between 2 and 8 Tg N per year, which accounts for approximately 10% of the global  $NO_x$  sources. In the tropics,  $LNO_x$  is responsible for around 20% of the total  $NO_x$  production (Schumann and Huntrieser, 2007, and references therein). Moreover, the  $LNO_x$  Production Efficiency (PE) per lightning flash shows a large variability

between different regions and thunderstorms [e. g., Pickering et al. (2016); Bucsela et al. (2019); Allen et al. (2019, 2021); Zhang et al. (2022); Pérez-Invernón et al. (2022a)]. In particular, systematic retrievals of LNO<sub>x</sub> from the Ozone Monitoring Instrument (OMI) by bucsela2019midlatitude, allen2019lightning Bucsela et al. (2019); Allen et al. (2019) and the Sentinel-5P TROPOspheric Monitoring Instrument (TROPOMI) by Allen et al. (2021) reported an inverse relationship between flash rates and LNO<sub>x</sub> PE per flash. Bucsela2021/AGU Bucsela et al. (2021) reported a new evaluation of TROPOMI-based LNO<sub>T</sub> PE estimations by using GLM lightning measurements and a new set of atmospheric chemistry simulations to estimate the effect of the background-NO<sub>x</sub> in the computations. According to Bucsela 2021/AGUBucsela et al. (2021), the relationship between the production of LNO<sub>x</sub> PE and the lightning flash frequency could be weaker than the relationship previously reported by bucsela2019midlatitude Bucsela et al. (2019) for weak and medium active thunderstorms (thunderstorms with less than 3,000 flashes per hour and degree). Studies based on airborne measurements found a proportional relationship between flash length and LNO<sub>x</sub> PE per flash (Wang et al., 1998; Stith et al., 1999; Schumann and Huntrieser, 2007; Huntrieser et al., 2008). The inverse relationship between the length of lightning channels and the frequency of lightning occurrence in storms can reconcile these measurements (Bruning and MacGorman, 2013). Recently, Pérez-Invernón et al. (2023b) and Pickering et al. (2024) estimated LNO<sub>x</sub> PE per flash by combining Lightning Mapping Arrays (LMA) with satellite- and aircraft-based NO<sub>x</sub> measurements, respectively. They found that thunderstorms with larger lightning rate rates produce shorter flash channel lengths and lower LNO $_x$  PE per flash, confirming previous results.

Lightning parameterizations in climate-chemistry models define the injection-emissions of LNO $_x$  by lightning as a total number of NO $_x$  molecules per flash, sometimes distinguishing between CG (cloud-to-ground) and IC (intra-cloud) lightning strikes by a factor of 10 (Price et al., 1997; Allen and Pickering, 2002; Tost et al., 2007; Murray et al., 2012; Jöckel et al., 2016; Gordillo-Vázquez et al., 2019; Luhar et al., 2021; Pérez-Invernón et al., 2023a) or between tropical and extratropical regions (Murray et al., 2012). The parameterization of lightning and LNO $_x$  production has a substantial impact on the global ozone burden. Specifically, these parameterizations can simultaneously lead to significant overestimates and underestimates of tropospheric ozone mixing ratios in different regions. For instance, Grewe et al. (2001) and Allen and Pickering (2002) noted that commonly used lightning parameterizations based on Cloud Top Height (CTH) can result in an underestimation of tropospheric ozone mixing ratios in the Southern Hemisphere and, conversely, an overestimation in the Northern Hemisphere. Therefore, they developed a new lightning parameterizations that produce a larger lightning flash frequency over the ocean (Tost et al., 2007). More recently, Luhar et al. (2021) proposed a modification of the lightning parameterization based on the CTH by Price et al. (1997) to partially address this disagreement. The new lightning parameterization by Luhar et al. (2021) led to a larger production of LNO $_x$  over the ocean, producing more tropospheric ozone in the Southern Hemisphere, which agrees better with observations. However, their new lightning parameterization produced an enhancement of tropospheric ozone in the Northern Hemisphere, in disagreement with ozone measurements.

Previous studies have proposed various parameterizations for  $LNO_x$  production to introduce a certain level of variability and investigate the sensitivity of tropospheric chemical composition (Koshak et al., 2014; Kang et al., 2019; Wu et al., 2023). However, so far there have been no sensitivity studies of climate-chemistry models to lightning  $NO_x$  production parameterizations based on lightning frequency. In this study, we explore the differences of the chemical composition of the atmosphere

by using a parameterization of  $LNO_x$  production based on lightning frequency (Bucsela et al., 2019, Fig. 11(c)) compared to imposing a constant amount of  $NO_x$  molecules injected emitted per CG lightning strike and a factor of one order of magnitude lower amount for the injection emissions from IC lightning flashes. Bucsela et al. (2019) reported that  $LNO_x$  PE decreases by one order of magnitude, if the flash frequency increases by two orders of magnitude.

# 60 2 Simulation set-ups Models

# 2.1 Lightning $NO_x$ production parameterization

Firstly, the relationship between the LNO<sub>x</sub> production efficiency (PE) and the flash rate, as shown in (Bucsela et al., 2019, Fig. 11(c)), is fitted to the following equation:

$$PE = \exp(-a \times \log(f) + b), \tag{1}$$

where PE is the production efficiency in moles of  $NO_x$  per flash, f is the flash rate in kilo flashes per hour, and a and b are fitting coefficients with values of 0.503 and 8.01, respectively. The goodness of fit for this relationship is characterized by  $R^2 = 0.995$ .

### 2.2 Climate-chemistry model and simulation set-ups

We employ the ECMWF-Hamburg (ECHAM)/Modular Earth Submodel System (MESSy version 2.55) Atmospheric Chemistry (EMAC) model (Jöckel et al., 2016) to perform pairs of five 8-year simulations using three different flash frequency parameterizations, with two different LNO $_x$  schemes each. The simulations are conducted at a T42L90MA resolution, utilizing a quadratic Gaussian grid with box dimensions of approximately  $2.8^{\circ} \times 2.8^{\circ}$  in latitude and longitude. The model setup covers 90 vertical levels that extend up to the 0.01 hPa pressure level, and a time step length of 720 s is employed (Jöckel et al., 2016). The lightning frequency is calculated at every time step and box by using the lightning parameterizations proposed by Price and Rind (1992), Grewe et al. (2001), or Luhar et al. (2021), being the latest a modification of the parameterization based on the CTH by Price and Rind (1992). In turn, we use scaling factors that ensure a global lightning occurrence rate of  $\sim$ 45 48 flashes per second (Christian et al., 2003; Cecil et al., 2014). We refer to Pérez-Invernón et al. (2022b) for a detailed description of the performance of the parameterizations used in EMAC. In turn, we show the simulated annual spatial distributions of lightning flash density in Figure \$1. LNO<sub>x</sub> is calculated by using a modified version of the LNOX submodel of MESSy (Tost et al., 2007). Originally, the LNOX submodel imposes a constant amount of  $NO_x$  molecules injected emitted per flash that can be different or equal for CG and IC lightning based on Price et al. (1997). As a second step, the LNO<sub>x</sub> molecules are vertically distributed by following a prescribed vertical profile that can vary latitudinally or between land and ocean, following the C-shaped vertical profiles reported by Pickering et al. (1998). We modify the LNOX submodel to include the LNO $_x$  parameterization reported by [Fig. 11(c)]bucsela2019midlatitude, which calculates the moles of produced LNO<sub>x</sub> based on the lightning frequency in boxes with a dimension of 1° × 1° in latitude and longitude. We check that the percentage of boxes that contain a flash frequency

lower than a specified value in the simulation and in the gridded data of [Fig. 11(c)]bucsela2019midlatitude are comparable (Section ??)(Bucsela et al., 2019, Fig. 11(c)) and derived in Equation 1.

We conduct the simulations using the Quasi Chemistry-Transport Model (QCTM) approach (Deckert et al., 2011). The QCTM mode allows for the separation of dynamics and chemistry in order to operate the model as a chemistry-transport model. This means that minor chemical changes do not introduce noise by affecting the simulated meteorology. The overview of the performed simulations are listed in Table 1, including the meteorological variables that serve as proxy for lightning flash frequency, the scaling factors to get  $\sim$  48 flashes per second during 2000, and the production of LNO<sub>x</sub> per flash and per year.

First, we perform three fully coupled free-running 8-years simulations ("BASE", where the subindex indicates the lightning flash frequency parameterization) from 1 January 2000 to 1 January 2008 to derive the forcings for the subsequent simulations. In these-There is no consensus about the similarity or difference in the production of  $NO_x$  per flash depending on the type of lightning Schumann and Huntrieser (2007); Gordillo-Vázquez et al. (2019). However, climate-chemistry simulations usually set different LNO<sub>x</sub> PE for CG and IC lightning (Tost et al., 2007; Jöckel et al., 2016; Gordillo-Vázquez et al., 2019). In BASE simulations, we impose a production of 1,112 mol per CG flash and 111.2 mol per IC flash, obtaining annual global injections emissions of LNO<sub>x</sub> of 5.66 Tg(N)y<sup>-1</sup>, 4.94 Tg(N)y<sup>-1</sup> and 5.58 Tg(N)y<sup>-1</sup> for the lightning parameterizations by Price and Rind (1992), Grewe et al. (2001) and Luhar et al. (2021) (subscript P), Grewe et al. (2001) (subscript P) and Luhar et al. (2021) (subscript P) per IC flash and 10 × 10<sup>16</sup> molecules NO/J reported by Price et al. (1997). We employ the same chemical setup and chemical mechanism as detailed by Jöckel et al. (2016) for the RC1-base-07 simulations.

The second set of simulations, here referred to as control ("CTR") simulations, are similar to the BASE simulations in terms of lightning and  $LNO_x$  parameterizations, but using the radiative forcing fields from the BASE simulations, following the QCTM approach.

The third set of simulations, here refereed to as "LNOfs" simulations, is similar to the set of CTR simulations, but using the LNO $_x$  parameterization reported by [Fig. 11(e)]buesela2019midlatitude, and scaling the total injection of NO $_x$  to obtain the same total injection of LNO $_x$  as in the CTR simulations. We use three lightning flash frequency parameterizations and the same LNO $_x$  vertical profile (Pickering et al., 1998) in all the simulations to isolate the effect of the LNO $_x$  production parameterization on the chemical composition of the atmosphere. However, other lightning parameterizations (Tost et al., 2007) and vertical profiles of LNO $_x$  (Ott et al., 2010) can also be used, possibly producing slight variations of the results.

Overview of the performed simulations from 1 January 2000 to 1 January 2008. table

#### 2.1 Instantaneous flash frequency

At this point, we explore the applicability of Equation (1) within our model. Equation (1) is derived from data aggregated over  $1^{\circ} \times 1^{\circ}$  latitude-longitude grid boxes, whereas the simulations will be conducted using a coarser resolution of  $2.8^{\circ} \times 2.8^{\circ}$  grid

**Table 1.** Fraction Overview of  $2.8^{\circ} \times 2.8^{\circ}$  in latitude the performed simulations from 1 January 2000 to 1 January 2008. The subscript indicates the used lightning parameterization: P: Price and Rind (1992), G: Grewe et al. (2001), and longitude boxes (in percentile) containing less than a given instantaneous L: Luhar et al. (2021). The variables that serve as proxy for the lightning flash frequency in flashes per hour are the Cloud Top Height (fl/hCTH) from and the CTR simulationsupward flux of mass ( $M_{up}$ ). The scaling factors to get  $\sim$  48 flashes per second during 2000 are included.

Simulation	Set-up	Lightning flash frequency	Variable	Scaling factor	${\rm LNO}_{\mathcal{X}}$ parameterization	$LNO_x$ per CG/IC flash (mol per flash)	Production of LNO <sub><math>x</math></sub> $(Tg(N)y^{-1})$

boxes. We check that the percentage of boxes that contain a flash frequency lower than a specified value in the simulation and in the gridded data of (Bucsela et al., 2019, Fig. 11(c)) are comparable. The data in Table ?? shows Figure 1 show the total number of flashes per hour in the  $2.8^{\circ} \times 2.8^{\circ}$  in latitude and longitude boxes from EMAC. These values were estimated by selecting all the boxes at every output timestep of 720 s (13,566,603 total samples) from the CTR simulations for the year 2000. These data allow us to ensure that the use of the LNO<sub>x</sub> by [Fig. 11(c)]bucsela2019midlatitude (Bucsela et al., 2019, Fig. 11(c)) is applicable in the LNOX submodel of MESSy. According to Bucsela et al. (2019), who used the World Wide Lightning Location Network (WWLLN) mid-latitude lightning measurements corrected by the network's detection efficiency, nearly 90% of the  $1^{\circ} \times 1^{\circ}$  boxes in latitude and longitude have flash rates lower than 2 kfl/hr, while we obtain that 90% of the  $2.8^{\circ} \times 2.8^{\circ}$  boxes in latitude and longitude have flash rates lower than 2.225, 1.314.432 and 1.386 kfl/hr (Table ??Figure 1). In addition, comparison between the results of [Fig. 11(a)]bucsela2019midlatitude and Table ?? (Bucsela et al., 2019, Fig. 11(a)) and Figure 1 shows that the histogram of flashes per hour are roughly in agreement. This comparison of the instantaneous lightning frequency ensures the applicability of the LNO<sub>x</sub> parameterization by [Fig. 11(e)]bucsela2019midlatitude (Bucsela et al., 2019, Fig. 11(c)) in the LNOX submodel.

120

125

The third set of simulations, here referred to as "LNOfs" simulations, is similar to the set of CTR simulations, but using the LNO<sub>x</sub> parameterization reported by (Bucsela et al., 2019, Fig. 11(c)), and scaling the total emissions of NO<sub>x</sub> from Equation (1) to obtain the same total emissions of LNO<sub>x</sub> as in the CTR simulations.

We use three lightning flash frequency parameterizations and the same LNO<sub>x</sub> vertical profile (Pickering et al., 1998) in all the simulations to isolate the effect of the LNO<sub>x</sub> production parameterization on the chemical composition of the atmosphere. However, other lightning parameterizations (Tost et al., 2007) and vertical profiles of LNO<sub>x</sub> (Ott et al., 2010) can also be used, possibly producing slight variations of the results.

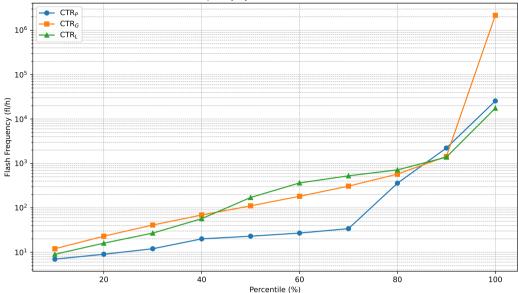

Figure 1. Fraction of  $2.8^{\circ} \times 2.8^{\circ}$  in latitude and longitude boxes (in percentile) containing less than a given instantaneous flash frequency in flashes per hour (fl/h) from the CTR simulations.

# Total injection emissions of LNO<sub>x</sub>

We extract the global total (CG+IC) flash frequency and the total amount of LNO $_x$  at every output time step of 720 s during 2000 to estimate the global distribution of the injected produced LNO<sub>x</sub> per year from the CTR and the LNOfs simulations. Figure 2 shows the mean daily data for June-July-August (JJA) of LNO<sub>x</sub> obtained from the CTR and the LNOfs simulations, as well as the difference between them. We select the season JJA to facilitate the comparison with OMI-WWLLN based measurements by Fig. 3]bucsela2019midlatitude (Bucsela et al., 2019, Fig. 3). The LNOfs simulations predict a larger amount of  $LNO_x$  over tropical ocean, where thunderstorms have a lower lightning frequency than over land. In turn, the decrease of the production of  $LNO_x$  is larger over land in tropical regions than in mid-latitudes, as tropical thunderstorms are more active. The LNOfs<sub>P</sub> and LNOfs<sub>G</sub> simulations present a smoother distribution of the LNO<sub>x</sub> distribution over land than the  $CTR_P$  and the  $CTR_G$  simulations, with a significant decrease of the peak production of  $LNO_x$  in North America. The difference of the land/ocean constrast of the production of LNO $_x$  between the simulations  $CTR_L$  and LNOfs $_L$  is lower, because the parameterization by Luhar et al. (2021) detects more active thunderstorms over the oceans. In terms of the spatial distribution of LNO $_x$ production, the parameterizations based on lightning flash frequency rates reduces differences between the three employed lightning parameterizations. The differences between the LNOfs and the CTR simulations can also be seen in the difference

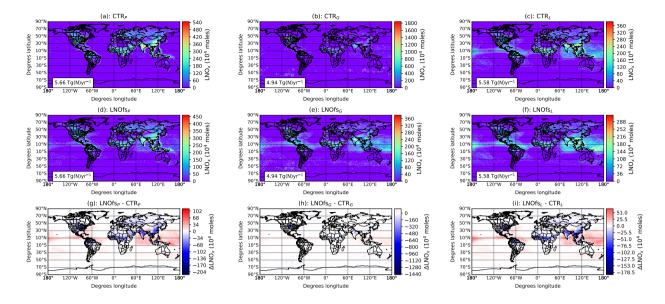

Figure 2. Daily mean LNOx production ( $\times$  10<sup>4</sup> moles) in June-July-August (JJA) per 2.8° latitude  $\times$  2.8° longitude box obtained from the CTR (a-c) and the LNOfs (d-f) simulations. Panels (g-i) shows the difference between CTR and the LNOfs simulations. Note that the color scales are different in each panel.

between the annual averaged mixing ratios of  $NO_x$  at the 800 hPa pressure level (Figure 3). The new parameterization of the production of  $LNO_x$  produces a larger injection larger emissions of  $LNO_x$  over oceans, with the exception of except for the high latitude oceanic regions in the  $LNOf_G$  simulation, where we obtain a smaller injection production of  $LNO_x$  than in the  $CTR_G$  simulation. The reason of this difference is that the lightning parameterization by Grewe et al. (2001) detects more active and sparsed sparse thunderstorms in these oceanic regions than the parameterizations based on the CTH (Tost et al., 2007, Fig. 2). The spatial distribution of the mean monthly  $LNO_x$  obtained from the LNOfs simulations during 2000 is shown in Figure S1S2. During one complete year, the parameterizations based on the CTH ( $LNOfs_P$  and  $LNOfs_L$  simulations) produce a smoother spatial distribution of  $LNO_x$ , while the parameterization by Luhar et al. (2021) ( $LNOfs_L$  simulation) produced the largest amount of relatively more  $LNO_x$  over the oceans.

155

160

170

When comparing Figure 2 to the mean daily LNO<sub>x</sub> injection emissions during JJA as reported by [Fig. 3(e)]bucsela2019midlatitude (Bucsela et al., 2019, Fig. 3(c)), it becomes apparent that the LNO<sub>x</sub> parameterization based on the lightning frequency in the LNOfs simulations produces a spatial distribution of LNO<sub>x</sub> that aligns with space-based measurements more accurately (Bucsela et al., 2019, Fig. 3(c)) than the parameterization used in the CTR simulations. In particular, LNO<sub>x</sub> emissions over the ocean in the CTR<sub>P</sub> and CTR<sub>G</sub> simulations are too low to be noticeable compared to those over land, whereas they are larger in (Bucsela et al., 2019, Fig. 3(c)). However, the LNOf<sub>P</sub> and LNOf<sub>G</sub> simulations produce significant LNO<sub>x</sub> emissions over the oceans. Apart from that, the LNOfs simulations yield a spatial distribution of LNO<sub>x</sub> that exhibits a more homogeneous distribution in the tropics and mid-latitudes compared to the CTR simulations.

# 3.2 Implications for the chemical composition of the troposphere

185

190

200

We compare the effect of LNO<sub>x</sub> on the chemistry of the troposphere between the CTR and the LNOfs simulations. The spatial distributions of the annual global difference in the mixing ratio of the analyzed chemical species at the 600 hPa, 400 hPa and 200 hPa pressure level between the LNOfs and the CTR simulations are shown in the Supplemental Material (Figures S3-S11). Figures 4 and 5 show the implications of using a LNO<sub>x</sub> parameterization based on the flash frequency in the annually and zonally averaged vertical profiles of NO<sub>x</sub>=NO+NO<sub>2</sub>, O<sub>3</sub>, CO, HO<sub>x</sub>=OH+HO<sub>2</sub>, HNO<sub>3</sub> and HNO<sub>4</sub>. The vertical profile of N<sub>2</sub>O is not shown because the variations are negligible, as expected (absolute value lower than -0.005%). We exclude plots of LNOf<sub>L</sub> from Figures 4 and 5 because the influence of the new parameterization of LNO<sub>x</sub> production is spatially similar to that in the LNOf<sub>P</sub> simulations but reduced in absolute value (see Figures S3-S11). The first column of Figures 4 and 5 shows the annually and zonally averaged vertical profiles of the mixing ratios of these species from the CTR<sub>P</sub> simulation, the second column shows the differences of the profiles between the LNOfs<sub>P</sub> and to the CTR<sub>P</sub> simulations, the third column shows the difference in the mixing ratio of the analyzed chemical species at the 600 hPa, 400 hPa and 200 hPa pressure level between the LNOfs and the CTR simulations are shown in the Supplemental Material (Figures S2-S10).

The LNOfs simulations produce a larger mixing ratio of NO, NO<sub>2</sub> and NO<sub>x</sub> in the middle level of the tropical troposphere (around 350 hPa in Figure 4(a-i)) than the corresponding CTR simulations. However, the mixing ratio of NO<sub>x</sub> at altitudes above the 300 hPa pressure level is larger in the CTR simulations. In addition, Figure 3 indicates that the difference at the 800 hPa pressure level is larger (more positive) over the ocean, where the flash frequency in thunderstorms is lower. In turn, the differences are lower (more negative) in the lightning chimneys over land in Africa, North America and South America, where the flash frequency is notably higher. At the 200 hPa level (Figures 88-81089-811(a)), the differences of NO<sub>x</sub> mixing ratio between the LNOfs and the CTR simulations are negative in more areas. The spatial distributions of the NO<sub>x</sub> mixing ratios in Figures  $\frac{$8-10}{$9-11}$ (a) indicate that the mixing ratio of  $NO_x$  in the upper troposphere is lower in the LNOfs simulations, because more LNO<sub>x</sub> is injected emitted in weak thunderstorms (thunderstorms with a lower flash frequency), that are less efficient in elevating the LNO<sub>x</sub> to the upper troposphere. Therefore, the parameterization of LNO<sub>x</sub> production based on the flash frequency (LNOfs simulations) lead-leads to a lower contribution of lightning to the sources of  $NO_x$  of the upper troposphere compared to the CTR simulations. There are differences in the vertical profile of the variation of  $NO_x$  between the LNOfs<sub>P</sub> and LNOfs<sub>G</sub> simulations, as can be seen by comparing panels (h) and (i) in Figure 4(h,i)). Below the 500 hPa pressure level, the difference of the mixing ratio of  $NO_x$  between the simulations LNOfs<sub>P</sub> and CTR<sub>P</sub> is positive, while the opposite is found when comparing the  $LNOfs_G$  and with the  $CTR_G$  simulations. Nevertheless, these differences are small, both in absolute and in relative terms. We consider that these small differences are due to the fact that in the CTR simulations, the  $LNO_x$  depends on the CG/IC ratio, while in LNOfs simulations, both CG and IC inject produces the same amount of LNOx.

Differences of the  $NO_x$  mixing ratio between the LNOfs and the CTR simulations cause differences in other chemical species. The obtained differences of the mixing ratios of  $O_3$  between the LNOfs and the CTR simulations are connected to the different spatial distributions of LNO<sub>x</sub> production. LNO<sub>x</sub> can produce or deplete  $O_3$  depending on the background mixing

ratio of  $NO_x$  caused by photochemistry (Crutzen, 1979; Schumann and Huntrieser, 2007; Liu, 1977; Verma et al., 2021). The NO directly produced by lightning can destroy  $O_3$  by the chemical reaction (Levine et al., 1984)

$$NO + O_3 \rightarrow NO_2 + O_2, \tag{2}$$

and the resulting NO<sub>2</sub> can produce atomic oxygen by photolysis following the reaction (Levine et al., 1984)

$$NO_2 + h\nu \rightarrow NO + O.$$
 (3)

Finally, the produced atomic oxygen can increase the mixing ratio of  $O_3$  by interacting with a third body M as (Levine et al., 1984)

$$O + O_2 + M \rightarrow O_3 + M. \tag{4}$$

Overall, LNO<sub> $\tau$ </sub> contributes to ozone depletion in regions with low background mixing ratio of NO<sub> $\tau$ </sub>, such as over the tropical marine boundary layer. In turn, LNO<sub>x</sub> produces ozone in regions, where the background mixing ratio of  $NO_x$  is high, such as over the continents. Figure 4(j-l) illustrates that the LNOfs simulations lead to a larger mixing ratio of ozone in the lower and middle troposphere caused by a larger production of LNO<sub>x</sub> at these vertical levels, especially in the tropics. Additionally, the larger production of LNO<sub>x</sub> results in very low changes of the ozone mixing ratio in the upper troposphere, due to the presence of a high  $NO_x$  background. At these higher altitudes, the efficiency of ozone production by  $NO_x$  is larger, but the injected emitted LNO<sub>x</sub> is lower. Figures  $\frac{$5-7}{6}=8(b)$  indicate that the larger positive change in the mixing ratio of O<sub>3</sub> at the 400 hPa level is located at oceanic regions, where the LNOfs simulation produces more LNO $_x$  than the CTR simulation. In turn, the LNOfs simulations produce a lower mixing ratio of  $O_3$  in the tropical Atlantic ocean, where the background  $O_3$  is not produced by local oceanic thunderstorms, but by LNO<sub>x</sub> transported from land. Figures 6-9 show the seasonal total O<sub>3</sub> column integrated between the ground and the top of the troposphere. During DJF, winter thunderstorms in the Northern Hemisphere are less active intense than in other seasons. On the contrary, summer thunderstorms in South America and Australia are more active. This is visible in Figure 6, showing that the tropospheric column of ozone is larger over the continents in the Northern Hemisphere in the LNOfs simulations, and smaller or similar over land in South America, Australia and Southern Africa. During JJA (Figure 8), the opposite situation occurs. Winter thunderstorms over the continents of the Southern Hemisphere lead to an increase of tropospheric ozone in the LNOfs simulations, while continental summer thunderstorms in the Northern Hemisphere produce less ozone. During the MAM and SON seasons (Figures 7 and 9), lightning activity is more homogeneously distributed across the globe, resulting in the major changes in the tropospheric ozone column in the LNOfs simulations being primarily confined to land/ocean contrasts. More ozone is produced over the oceans, where less active thunderstorms produce more LNO $_x$  than in the CTR simulations. The main difference between the LNOfs $_P$  and the LNOfs $_G$  simulations can be seen during the season DJF. During DJF, more tropospheric ozone is produced in the LNOfs<sub>P</sub> simulations compared to the CTR<sub>P</sub>, while less tropospheric ozone is produced in the LNOfs $_G$  simulations than in the CTR $_G$ .

225

The relationship between  $HO_x$  and  $LNO_x$  is not linear (Schumann and Huntrieser, 2007). Under clean air conditions and in medium polluted regions, OH is produced as a consequence of  $LNO_x$  by  $O_3$  and  $NO_2$  photolysis. However, in regions with large amounts of  $NO_x$ ,  $LNO_x$  contributes to a depletion of the  $HO_2$  mixing ratio by reactions between  $NO_2$  and  $HO_2$ , contributing to a decrease of the  $HO_x$  mixing ratio. At the 600 hPa level (Figures \$2-\$4\$3-\$5), where in general the background  $NO_x$  is low, increases of  $NO_x$  led to increases of  $NO_x$  (Figure 5(d-i) and Figures \$2-\$4\$3-\$5). We obtain the opposite situation at the 200 hPa level, where the background  $NO_x$  is large (Figure 5(d-i) and Figures \$8-\$10\$9-\$11). At the 400 hPa pressure level, where the background  $NO_x$  is medium in comparison with other vertical levels (Figure 4)(g), the relationship between the  $NO_x$  and the  $NO_x$  is more complex (Figure 5(d-i) and Figures \$5-\$7\$6-\$8).

235

240

250

255

260

To exemplify the influence of  $LNO_x$  on the mixing ratio of  $HO_x$ , we show the impact of  $LNO_x$  on the  $HO_x$  mixing ratio in the geographical region of Europe (bounded by 42°N and 52°N degrees latitude, and 0° to 24°E degrees longitude) in Figure 10. The first panel illustrates the disparity in the hourly total column injection emissions of  $LNO_x$  between the  $LNOfs_P$  and  $CTR_P$  and  $CTR_L$  simulations over a 1-year period, where negative values represent a reduced  $LNO_x$  injection production in the  $LNOfs_L$  simulation. In the second panel, the hourly differences of the  $NO_x$  and  $HO_x$  mixing ratios at the 400 hPa level are shown. Lastly, the third panel shows the hourly background mixing ratio of  $NO_x$  at the 400 hPa level. Before day 140, when the background mixing ratio of  $NO_x$  is low, changes of  $NO_x$  and  $HO_x$  follow the same trend. Conversely, during the summer when the background mixing ratio of  $NO_x$  is large, the changes of  $NO_x$  and  $HO_x$  are of opposite signs, implying that increased  $NO_x$  leads to a decrease in the mixing ratio of  $HO_x$ .

In Figures S11 and S12 and S13, we show analogous plots to Figure 10, but at different pressure levels (200 hPa and 600 hPa, respectively). At the 200 hPa level, characterized by a large background mixing ratio of  $NO_x$  (see Figures4(g)), the changes of  $NO_x$  and  $HO_x$  exhibit opposing behaviours. Conversely, at the 600 hPa level, where the background mixing ratio of  $NO_x$  is low (see Figures4(g)), the changes of  $NO_x$  and  $HO_x$  follow the same trend. In turn, we gather the background mixing ratio of  $NO_x$  across each cell domain at 200 hPa, 400 hPa, and 600 hPa pressure levels during hours when the changes of  $NO_x$  and  $HO_x$  share the same sign, resulting in an average mixing ratio of  $NO_x$  at  $7.2 \times 10^{-11}$  mol/mol. Conversely, when the changes of  $NO_x$  and  $HO_x$  are of opposite signs, the averaged mixing ratio of  $NO_x$  is  $1.8 \times 10^{-10}$  mol/mol. The observed disparity of the  $NO_x$  background mixing ratio under conditions of opposite sign changes confirms that the influence of  $LNO_x$  on the mixing ratio of  $HO_x$  is largely dependent on the background mixing ratio of  $NO_x$ . Additional details regarding the distribution of the background mixing ratio of  $NO_x$  under similar or opposite sign variations are shown in the Supplementary materials.

Figures 4(m-o) and 5(a-c) shows a clear inverse correlation between the variation of OH and CO, given that the CO in the troposphere is removed by OH through

$$CO + OH \rightarrow CO_2 + H.$$
 (5)

The differences between the mixing ratios of  $HNO_3$  and  $HNO_4$  between the simulations can all be explained by the differences of  $NO_x$ . In the troposphere,  $LNO_x$  contributes to the production of  $HNO_3$  and  $HNO_4$ . Therefore, in the  $LNO_5$  simulations, smaller mixing ratios of  $NO_x$  in the upper troposphere lead to lower mixing ratios of these species (Figure 5(j-o)).

**Table 2.** Annually averaged tropospheric methane lifetime with respect to OH  $(\tau_{CH_4+OH})$  in years and standard deviation resulting from different simulation results.

Simulation	Period	Global $\tau_{CH_4+OH}$ (y)	Northern Hemisphere $\tau_{CH_4+OH}$ (y)	Southern Hemisphere $\tau_{CH_4+OH}$ (y)
$CTR_P$	2002-2008	$7.62 \pm 0.08$	$7.99 \pm 0.08$	$9.18 \pm 0.10$
LNOfs <sub>P</sub>	2002-2008	7.45±0.07	7.79±0.07	8.86±0.09
$CTR_G$	2002-2008	7.70±0.06	8.05±0.05	9.26±0.08
$LNOfs_G$	2002-2008	7.44±0.05	7.55±0.04	9.06±0.06
$CTR_L$	2002-2008	7.44±0.06	7.77±0.04	8.82±0.09
$LNOfs_L$	2002-2008	7.39±0.06	7.68±0.04	8.69±0.08

The global annual means shown in Figures  $\frac{\$2-10}{\$3-11}$  (e,f) indicate that the reduction of HNO<sub>3</sub> and HNO<sub>4</sub> in the LNOfs simulations is larger in the upper troposphere over land, while increased mixing ratios are located over ocean.

The OH radical is a significant oxidant that reacts with methane (CH<sub>4</sub>), influencing its atmospheric lifetime. Therefore, 270 variations in the mixing ratio of OH caused by different parameterizations of  $LNO_x$  production can potentially affect the lifetime of CH<sub>4</sub>. We calculate the tropospheric lifetime of CH<sub>4</sub> with respect to OH  $(\tau_{CH_4+OH})$  on a monthly basis using feq. (1)ljockel2016earth(Jöckel et al., 2016, eq. (1)). Table 2 shows the annually averaged tropospheric methane lifetime with respect to OH resulting from different simulations, together with the standard deviation. To calculate the means shown in 275 Table 2, we first compute the mean for each simulated year based on the monthly means of the 12 months. Then, we calculate the overall mean and standard deviation as the average and the standard deviation of the yearly means. At a global scale, the annually averaged lifetime of methane with respect to OH in the LNOfs simulations is reduced by 2.1%, 2.72.2%, 3.4%, and in  $\frac{0.80.7\%}{0.80.7\%}$  for the lightning parameterizations P, G, and L, respectively. When using the mean and standard deviation as metrics to evaluate the significance of differences in methane lifetime, the results indicate that the differences between CTR and LNOfs are significant in the P and G simulations. In contrast, no significant differences are observed in the L simulations. In 280 the Northern Hemisphere, the corresponding decreases are 2.3%, 3.12.5%, 6.2%, and 1.11.2%, respectively. In turn, we obtain decreases of 3.5%, 4.62.2%, and 1.71.5% in the Southern Hemisphere. The decreases are larger in the Southern Hemisphere, where more LNO<sub>x</sub> is injected emitted due to the larger oceanic area than in the Northern Hemisphere. The new parameterization of the LNO<sub>x</sub> production affects the lifetime of methane in the P and the G simulations more than in the L simulations. The reduction of the global methane lifetime with respect to OH deviates from that obtained by the multi-model mean 9.7±1.5 years 285 (Naik et al., 2013).

#### 3.3 Comparison with data of zonal ozone distribution

290

The simulated zonal ozone distribution from the CTR and LNOfs simulations can be compared with ozone profile data from Hassler et al. (2009) and Bodeker (2014), as previously carried out by Luhar et al. (2021), to assess the impact of different lightning parameterizations on global ozone mixing ratios. The Bodeker scientific global vertically resolved ozone database includes monthly mean vertical ozone profiles spanning from 1979 to 2016 across 70 vertical levels. In this study, we utilize the Tier 1.4 vn1.0 product, specifically the version containing the mean annual cycle derived from anthropogenic, natural, and

volcanic emissions. We re-grid the data to match the resolution of the model. The comparison between the simulated seasonal zonal ozone distribution and the Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product between 2002 and 2007 is shown in Figures 11-14. During all the seasons, the LNOfs simulations produce more tropospheric ozone than the corresponding CTR simulations in the tropics, causing more disagreement with measurements than the CTR simulations. The effect of the LNOfs simulations in the mid-latitude tropospheric ozone varies with the lightning parameterization and with the seasons. DJF: The new parameterization of the production of  $LNO_x$  produces a larger content of tropospheric ozone in the Northern Hemisphere, contributing to produce a better agreement with measurements. In the Southern Hemisphere, the LNOfs simulations produce more tropospheric ozone in the P simulations, but less ozone in the P simulations, producing a better agreement with the measurements only in the case of the P simulations. MAM: the  $LNOfs_P$  simulation shows more ozone in both hemispheres, while the  $LNOfs_P$  simulations results in more ozone in the tropics but less ozone in the mid-latitudes in both hemispheres. In this case, only the  $LNOfs_P$  simulations show a better agreement with the measurements, and only in the Northern Hemisphere. JJA: The LNOfs simulations result in a better agreement with observations in the Southern Hemisphere, and less agreement in the Northern Hemisphere.

The seasonal variations in the simulated zonal ozone distribution between 2002 and 2007 (Figures 11-14) can be compared with the corresponding interannual zonally averaged differences in the vertical O<sub>3</sub> mixing ratio provided by the Bodeker Scientific Global Vertically Resolved Ozone Database (Tier 1.4, version 1.0) Hassler et al. (2009). These differences, calculated relative to the seasonal mean for 2002–2007, are shown in Figures S26–S29. This comparison aims to evaluate the significance of the observed variations. The seasonal variations between the simulated tropospheric O<sub>3</sub> and the Tier 1.4 product are most pronounced in the tropics and the middle troposphere (Figures 11-14), whereas the interannual variations of the Tier 1.4 product peak in the extratropics and the upper troposphere (Figures S26–S29). Consequently, we conclude that the differences in tropospheric O<sub>3</sub> between the simulation and the Tier 1.4 product are relevant, since they exceed the interannual variability of tropospheric O<sub>3</sub>.

The interannual zonally averaged differences during each season of the vertical  $O_3$  mixing ratio between the annual Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product Hassler et al. (2009) and the annually mean during the period 2002-2007 for each season are shown in Figures S26-S29.

[Fig. 29]jockel2016earth (Jöckel et al., 2016, Fig. 29) compared the annual tropospheric partial column of ozone from the RC1-base-07 simulation with AURA Microwave Limb Sounder/Ozone Monitoring Instrument (MLS/OMI, Ziemke et al. (2011)) measurements (reproduced in Figure S30), obtaining an overestimation of ozone in the tropics, especially over Africa, Indonesia and the Indian Ocean. In turn, the RC1-base-07 simulation produced an underestimation of the tropospheric partial column of ozone below about  $50^{\circ}$ S latitude. We show in Figure 15 a comparison of the annual average tropospheric partial column of ozone between the CTR and the LNOfs simulations. The LNOfs simulations with the parameterizations based on the CTH (LNOfs<sub>P</sub> and LNOfs<sub>L</sub>) produce a smaller tropospheric column of ozone in tropical Africa compared to the CTR parameterizations, resulting in a better agreement with measurements (Jöckel et al., 2016, Fig. 29) (Jöckel et al., 2016, Fig. 29)

simulations, leading to a better agreement with measurements. The  $LNOfs_L$  simulation results in a smaller column of tropospheric ozone above 50°N latitude, showing again a better agreement with observations. However, the obtained overestimation of tropospheric ozone over the tropical oceans disagrees more with the measurements. In the case of the G simulations, the  $LNOfs_G$  simulation produces a better agreement with measurements above 30°N latitude than the simulation  $CTR_G$ , but less agreement over the rest of the globe.

#### 3.4 Limitations and uncertainties

330

335

340

345

350

355

In this study, we examine the impact on atmospheric chemistry of parameterizing the  $LNO_x$  production based on lightning frequency. In particular, we use the global relationship between  $LNO_x$  production and flash frequency as derived by [Fig. 11(c)]bucsela2019midlatitude(Bucsela et al., 2019, Fig. 11(c)). While substantial evidence exists, suggesting possible relationships between  $LNO_x$  production per flash and flash frequency (Bucsela et al., 2019; Allen et al., 2019, 2021; Zhang et al., 2022; Pérez-Invernón et al., 2023b; Pickering et al., 2024), quantifying this relationship on a global scale using satellite-based data and global lightning measurements remains challenging and uncertain, as discussed by Bucsela et al. (2019). Firstly, it is important to emphasize that the relationship provided by Bucsela et al. (2019) was derived over mid-latitude land regions, but it is applied globally in this study. However, Allen et al. (2019) used a similar method to derive  $LNO_x$  PE within the tropics (including oceans) by obtaining that tropical PE is only 10% less than the midlatitude PE derived by Bucsela et al. (2019). In addition, Allen et al. (2019) reported evidence for a decrease in  $LNO_x$  PE with increasing flash rate on a regional basis within the tropics.

The low detection efficiency of WWLLN in some regions (Holzworth et al., 2009) together with the uncertainty of satellite-based derived vertical column density of  $NO_x$  introduce a large uncertainty of the estimated  $LNO_x$  production. Bucsela et al. (2021) used TROPOMI  $NO_2$  and cloud measurements together with GLM lightning data to improve the estimation of  $LNO_x$  production. They reported that the relationship between the production of  $LNO_x$  per flash and the flash frequency for thunderstorms producing less than 3,000 flashes per hour and degree in America (98% of all the analyzed cases) could be weaker than the relationship reported by Bucsela et al. (2019). Therefore, the results obtained in this study should be regarded as the upper limit of the impact that an  $LNO_x$  production parameterization based on lightning flash frequency may have on the chemical composition of the atmosphere.

# 4 Conclusions

For the first time, a parameterization of  $LNO_x$  production, based on the flash frequency, is introduced in the climate-chemistry model EMAC. This  $LNO_x$  parameterization is based on OMI  $NO_2$  measurements provided by Bucsela et al. (2019), who reported an inverse relationship between the lightning flash frequency in thunderstorms and the production of  $LNO_x$  per flash. Although more recent studies have reported a weaker relationship between the production of  $LNO_x$  per flash and the flash frequency in America (Bucsela et al., 2021), there are no new estimates of this relationship on a global scale. Therefore, the results obtained in this study should be considered the upper limit of the impact that an  $LNO_x$  production parameterization

based on lightning flash frequency could have on atmospheric chemical composition. Six 8-years simulations by using three different lightning parameterizations (Price and Rind, 1992; Grewe et al., 2001; Luhar et al., 2021) enable us to investigate the influence of this LNO<sub>x</sub> production parameterization for the mixing ratios of NO<sub>x</sub>=NO+NO<sub>2</sub>, O<sub>3</sub>, CO, HO<sub>x</sub>=H+OH+HO<sub>2</sub>, N<sub>2</sub>O, HNO<sub>3</sub> and HNO<sub>4</sub> in the troposphere.

365

370

375

380

385

Based on our findings, the LNO $_x$  production parameterization based on the lightning flash frequency leads to an enhanced production of LNO $_x$  in thunderstorms with lower flash rates compared to those that impose a constant LNO $_x$  production rate per flash. This increase of LNO $_x$  production in weaker thunderstorms results in less LNO $_x$  over land and more over the oceans. In turn, more LNO $_x$  is injected emitted in winter thunderstorms than in summer thunderstorms. In general, the simulations with the new parameterization of the LNO $_x$  production lead to a spatial distribution of LNO $_x$  that is more homogeneously distributed over the globe than the simulations with a constant LNO $_x$  production per flash (Figure 3). As a result, we obtain a larger tropospheric column of ozone over the tropical ocean (Figures 6-9). The influence of the new LNO $_x$  production parameterization on tropospheric ozone in other regions of the globe depends on the employed lightning flash frequency parameterization. For the lightning flash frequency parameterizations based on the CTH (Price and Rind, 1992; Luhar et al., 2021), we obtain a smaller tropospheric column of ozone over tropical Africa. In the case of the lightning parameterization based on the upward flux of mass (Grewe et al., 2001), we obtain a smaller column of tropospheric ozone at mid-latitudes in the northern hemispheres. The maximum change of the tropospheric ozone mixing ratio when using the new scheme are in the order of  $\sim$ 3%, with the lowest variations in the case of the lightning parameterization by Luhar et al. (2021), that included already a modification of lightning frequency over oceans.

The oxidation capacity of the atmosphere is influenced by the new  $LNO_x$  production parameterization, as tropospheric  $NO_x$  plays an important role for the chemical budget of tropospheric  $HO_x$ . In particular, we obtain a global decrease of the tropospheric lifetime of methane with respect to OH ranging between  $\frac{0.8\%}{0.8\%}$  and  $\frac{3.4\%}{0.7\%}$ , especially over the Southern Hemisphere.

The new parameterization of the production of  $LNO_x$  leads to a decrease of tropospheric CO by about 2% worldwide, reaching its maximum over the tropical oceans. The mixing ratio of tropospheric  $HNO_3$  is reduced up to 8% globally, especially over land. Finally, we obtain an increase of the tropospheric tropospheric  $HNO_4$  mixing ratio of about 4%, with significant increases over ocean and decreases over land.

These findings highlight the importance of understanding the variability of  $LNO_x$  production to enhance the chemical budget of key trace gas species in climate-chemistry models. Geostationary satellite measurements of  $NO_2$  have the potential to significantly contribute to more accurate  $LNO_x$  production parameterizations. Examples of such satellites include the Geostationary Environment Monitoring Spectrometer (GEMS, launched in February 2020, Kim et al. (2020)), the Tropospheric Emissions Monitoring of POllution (TEMPO, launched in April 2023, Zoogman et al. (2017)), and the Meteosat Third Generation (MTG) Imaging and Sounding satellites (Holmlund et al., 2021). In particular, continuous (1-hourly) measurements of  $NO_2$  provided by geostationary satellites over an area can offer unprecedented insight into the temporal evolution of  $LNO_x$  in thunderstorms at a quasi-global scale, revealing the relationships between  $LNO_x$  production per flash and thunderstorm evolution.

Code and data availability. The data of the simulations generated in this study have been deposited in the Zenodo repository Pérez-Invernón et al. (2024). The Modular Earth Submodel System (MESSy) (MESSy-Consortium, 2021) is continuously developed and applied by a consortium of institutions. The usage of MESSy and access to the source code are licensed to all affiliates of institutions which are members of the MESSy Consortium. Institutions can become a member of the MESSy Consortium by signing the MESSy Memorandum of Understanding. More information can be found on the MESSy Consortium website (http://www.messy-interface.org, last access: 10 Frebruary 2025). As the MESSy code is only available under license, the code cannot be made publicly available. The parameterization of LNO<sub>x</sub> production has been developed based on MESSy version 2.55.

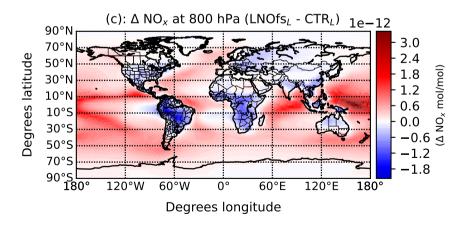

Figure 3. Annually (2002-2007) and globally averaged differences of the mixing ratio of  $NO_x$  between the simulations with the  $LNO_x$  production based on the flash frequency (LNOfs) and the simulation with a constant quantity of  $LNO_x$  production per flash (CTR) at the 800 hPa pressure level. The subscript indicates the used lightning parameterization: P: Price and Rind (1992), G: Grewe et al. (2001), and L: Luhar et al. (2021).

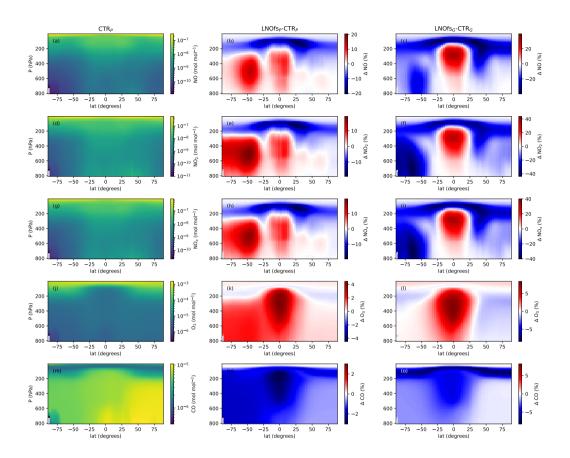

Figure 4. First column: Annually (2002-2007) and zonally averaged vertical profiles of the NO, NO<sub>2</sub>, NO<sub>x</sub>, O<sub>3</sub> and CO mixing ratios for a simulation with a constant amount of LNO<sub>x</sub> production per flash (CTR<sub>P</sub>). Second column: Differences (in %) between the annually and globally averaged mixing ratio of the chemical species from the simulation with the LNO<sub>x</sub> production based on the flash frequency (LNOfs<sub>P</sub>) and from the CTR<sub>P</sub> simulation. Third column: Same as the first column but showing differences between the simulations LNOfs<sub>G</sub> and CTR<sub>G</sub>. The differences have been calculated as  $100 \times (\text{LNOfs} - \text{CTR})/\text{CTR}$ . The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001).

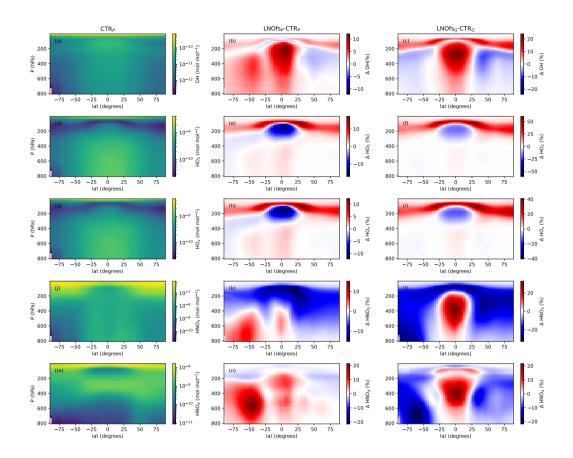

Figure 5. First column: Annually (2002-2007) and zonally averaged vertical profiles of the OH,  $HO_2$ ,  $HO_x$ ,  $HO_3$  and  $HNO_4$  mixing ratios for a simulation with a constant amount of  $LNO_x$  production per flash ( $CTR_P$ ). Second column: Differences (in %) between the annually and globally averaged mixing ratio of the chemical species from the simulation with the  $LNO_x$  production based on the flash frequency ( $LNOfs_P$ ) and from the  $CTR_P$  simulation. Third column: Same as the first column but showing differences between the simulations  $LNOfs_G$  and  $CTR_G$ . The differences have been calculated as  $100 \times (LNOfs - CTR)/CTR$ . The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001).

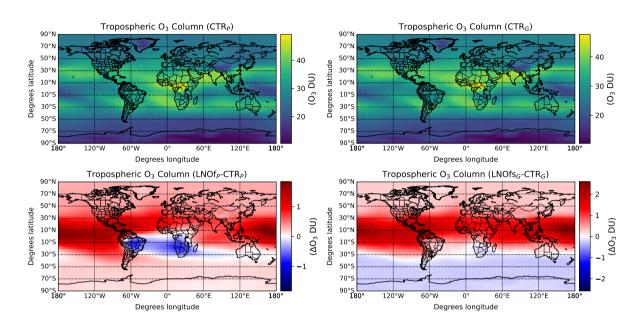

Figure 6. Global tropospheric column of  $O_3$  in the CTR simulations (top panels) and differences of the  $O_3$  total column (integrated between the ground and the top of the troposphere) between the simulations LNOfs and CTR (bottom panels) averaged during DJF (2002-2007). The values are given in Dobson Units (DU). The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001). The monthly total  $O_3$  column from the CTR<sub>L</sub> simulation can be seen in Figures  $S_2-S_1S_3-S_1A$ .

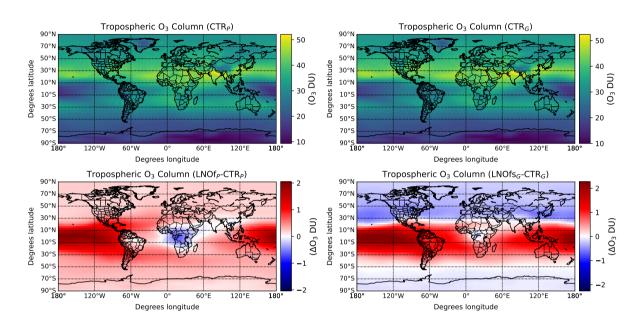

Figure 7. Global tropospheric column of  $O_3$  in the CTR simulations (top panels) and differences of the  $O_3$  total column (integrated between the ground and the top of the troposphere) between the simulations LNOfs and CTR (bottom panels) averaged during MAM (2002-2007). The values are given in Dobson Units (DU). The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001). The monthly total  $O_3$  column from the CTR<sub>L</sub> simulation can be seen in Figures  $S_2-S_1S_3-S_1A$ .

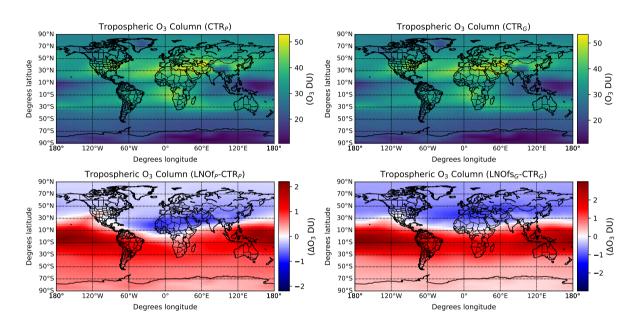

Figure 8. Global tropospheric column of  $O_3$  in the CTR simulations (top panels) and differences of the  $O_3$  total column (integrated between the ground and the top of the troposphere) between the simulations LNOfs and CTR (bottom panels) averaged during JJA (2002-2007). The values are given in Dobson Units (DU). The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001). The monthly total  $O_3$  column from the CTR<sub>L</sub> simulation can be seen in Figures  $S_2-S_1S_3-S_1A$ .

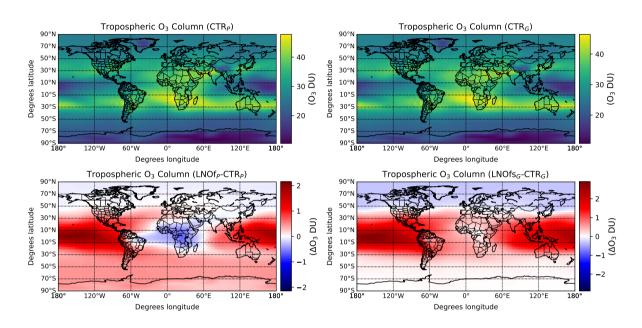

Figure 9. Global tropospheric column of  $O_3$  in the CTR simulations (top panels) and differences of the  $O_3$  total column (integrated between the ground and the top of the troposphere) between the simulations LNOfs and CTR (bottom panels) averaged during SON (2002-2007). The values are given in Dobson Units (DU). The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001). The monthly total  $O_3$  column from the CTR<sub>L</sub> simulation can be seen in Figures  $S_2-S_1S_3-S_1A$ .

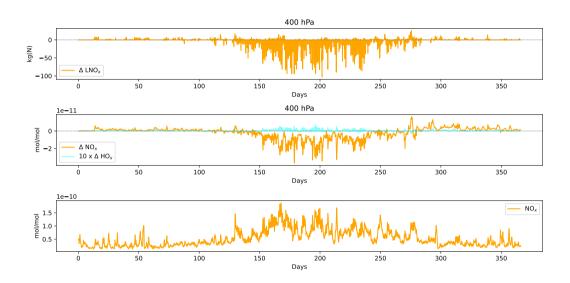

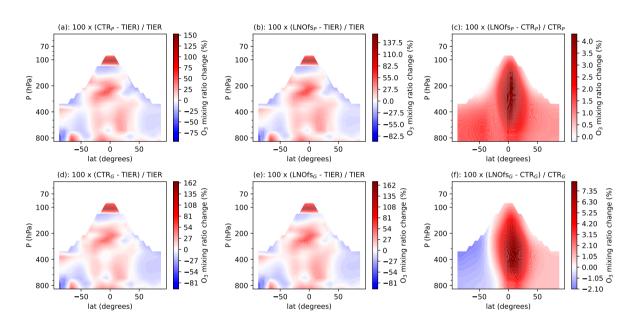

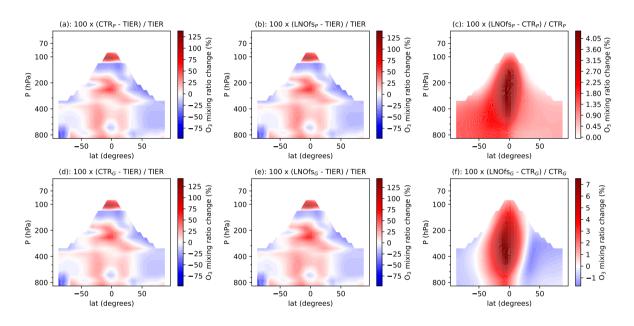

Figure 10. (aUpper panel): Difference in the hourly total column injection production of LNO<sub>x</sub> between the LNOfs<sub>P-L</sub> and CTR<sub>P-L</sub> simulations over a 1-year period (day 1 corresponds to 1 January, 2000). (bMiddle panel): Hourly differences in the mixing ratios of NO<sub>x</sub> and HO<sub>x</sub> at the 400 hPa. (eLower panel): Hourly background mixing ratio of NO<sub>x</sub> at the 400 hPa level in the LNOfs<sub>L</sub> simulation. The three panels correspond to a spatial average over Europe (bounded by 42°N and 52°N latitude degrees, and 0° to 24°E longitude degrees). The subscript P indicates the used lightning parameterization: Price and Rind (1992).

**Figure 11.** Seasonally <u>December-January-February</u> (DJF) and zonally averaged differences (in %) of the vertical O<sub>3</sub> mixing ratio between the simulations and the Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product Hassler et al. (2009). The <u>border</u> with the white <u>line region</u> represents the zonally averaged mean altitude of the climatological tropopause. <u>The subscript indicates the used</u> lightning parameterization: *P*: Price and Rind (1992), and *G*: Grewe et al. (2001).

**Figure 12.** Seasonally March-April-May (MAM) and zonally averaged differences (in %) of the vertical O<sub>3</sub> mixing ratio between the simulations and the Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product Hassler et al. (2009). The border with the white line region represents the zonally averaged mean altitude of the climatological tropopause. The subscript indicates the used lightning parameterization: *P*: Price and Rind (1992), and *G*: Grewe et al. (2001).

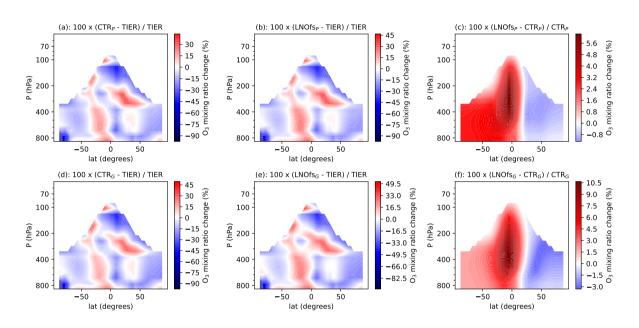

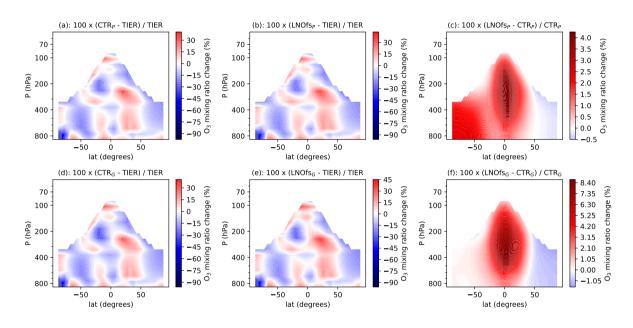

Figure 13. Seasonally (JJA) and zonally averaged differences (in %) of the vertical  $O_3$  mixing ratio between the simulations and the Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product Hassler et al. (2009). The border with the white line region represents the zonally averaged mean altitude of the climatological tropopause. The subscript indicates the used lightning parameterization: P: Price and Rind (1992), and G: Grewe et al. (2001).

**Figure 14.** Seasonally <u>September-October-November</u> (SON) and zonally averaged differences (in %) of the vertical O<sub>3</sub> mixing ratio between the simulations and the Bodeker scientific global vertically resolved ozone database Tier 1.4 vn1.0 product Hassler et al. (2009). The <u>border</u> with the white <u>line region</u> represents the zonally averaged mean altitude of the climatological tropopause. The <u>subscript indicates the used</u> lightning parameterization: *P*: Price and Rind (1992), and *G*: Grewe et al. (2001).

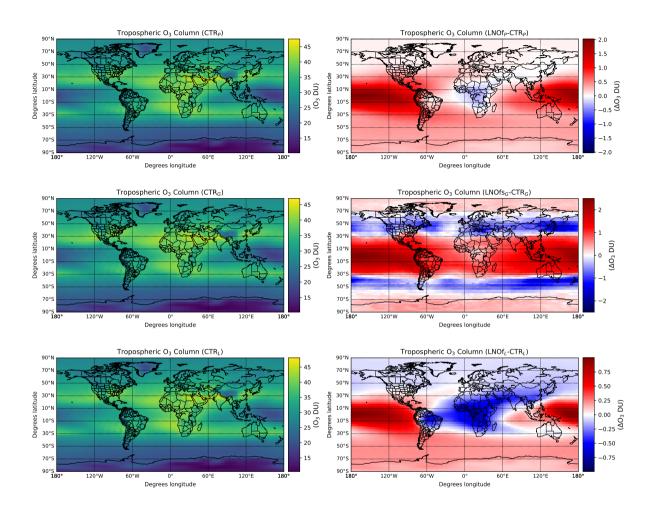

Figure 15. Annually (2002-2007) and globally averaged tropospheric column of O<sub>3</sub> in the CTR simulations (top-left panels) and differences of the O<sub>3</sub> total column (integrated between the ground and the top of the troposphere) between the simulations LNOfs and CTR (bottom-right panels). The values are given in Dobson Units (DU). The subscript indicates the used lightning parameterization: *P*: Price and Rind (1992) . *G*: Grewe et al. (2001), and *L*: Luhar et al. (2021) (see Table 1). The monthly total O<sub>3</sub> column from the CTR<sub>G</sub> simulation can be seen in Figures \$13-\$24\$14-\$25.
