**Abstract.** Boreal forests emit terpenoid biogenic volatile organic compounds (BVOCs) that significantly impact atmospheric chemistry. Our understanding of the variation of BVOC species emitted from boreal ecosystems is based on relatively few datasets, especially at the ecosystem-level. We conducted measurements to obtain BVOC flux observations above the boreal forest at the ICOS (Integrated Carbon Observation System) station Norunda in central Sweden. The goal was to study concentrations and fluxes of terpenoids, including isoprene, speciated monoterpenes (MT), and sesquiterpenes (SQT), during a Scandinavian summer. High-frequency (10 Hz) measurements from a Vocus proton-transfer-reaction time-of-flight mass spectrometer (Vocus PTR-ToF-MS) were used to quantify a wide range of BVOC fluxes, including total MT, using the eddy-covariance (EC) method. Surface-layer-gradient (SLG) flux measurements were performed on selected daytime sampling periods, using thermal-desorption adsorbent tube sampling, to establish speciated MT fluxes. The impact of chemical degradation on measured terpenoid fluxes relative to surface exchange rates (F/E) was also investigated using stochastic Lagrangian transport modeling in forest-canopy. While the impact on isoprene was within EC-flux uncertainty ( $F_{ISO}/E_{ISO} < 5\%$ ), the effect on SQT and nighttime MT was significant, with average F/E-ratios for nighttime  $F_{MT}/E_{MT} = \text{ca. } 0.9$  (0.87 - 0.93), nighttime  $F_{SQT}/E_{SQT} = 0.35$  (0.31 - 0.41) and daytime  $F_{SQT}/E_{SQT} = 0.41$  (0.37 - 0.47). The main compounds contributing to MT flux were  $\alpha$ -pinene and  $\Delta^3$ -carene. Summer shifts in speciated MT emissions for  $\Delta^3$ -carene were detected, indicating that closer attention to seasonality of individual MT species in BVOC emission and climate models is warranted.

## 1 Introduction

Biogenic volatile organic compounds (BVOCs) play a central role in tropospheric chemistry, influencing both regional air quality and global climate (Fall, 1999). Many BVOCs participate in new particle formation (NPF) and growth (Bianchi et al., 2016; Boucher et al., 2013; Kirkby et al., 2016; Mohr et al., 2019; Riipinen et al., 2012; Tunved et al., 2006; Went, 1960). As  
35 BVOCs react with ozone, OH, and NO<sub>3</sub> (in the case of nighttime chemistry), the subsequent reaction products often have lower volatility that in suitable conditions can condense into new secondary organic aerosol (SOA) particles or contribute to the growth of existing aerosol particles (Bonn et al., 2009; Hallquist et al., 2009; Hodzic et al., 2016; Kulmala et al., 2004). BVOCs also affect the production and lifetime of tropospheric ozone through their photooxidation in the presence of NO<sub>x</sub>, as well as through their interactions with OH and other radicals (Atkinson and Arey, 2003). As reactive BVOCs compete with methane  
40 for reacting with ambient OH, they may also have an influence on the atmospheric lifetime of this greenhouse gas (e.g., Kaplan et al., 2006). Oxygenated VOCs, such as acetone – one of the most abundant in the atmosphere (e.g., Singh et al., 1994), can also modify hydroxyl radical concentrations in the upper troposphere (Fehsenfeld et al., 1992; Mckeen et al., 1997; Monks, 2005) and/or contribute to the formation of peroxyacetyl nitrate (PAN) compounds that can act as a reservoir for NO<sub>x</sub> (Read et al., 2012; Roberts et al., 2002).

45 Globally, biogenic BVOC emissions are estimated to be several times higher than anthropogenic BVOC emissions (Guenther et al., 1995; Müller, 1992). In densely populated European regions, anthropogenic BVOC emissions are estimated to exceed biogenic emissions, but in most cases, particularly those areas which are sparsely populated, biogenic emissions are dominant (Lindfors and Laurila, 2000; Simpson et al., 1999). These include sparsely populated countries in the European boreal zone  
50 (Simpson et al., 1999). The boreal vegetation zone, one of the Earth's largest terrestrial biomes and forming a near-continuous band around the Northern Hemisphere, is one of the major sources of BVOCs to the atmosphere at the global scale (Guenther et al., 1995; Sindelarova et al., 2014). Across all plant functional types (e.g., Guenther et al., 2012), boreal MT emissions make up as much as ca. 26.3 % of the global summertime MT emission inventory (June: 28.3 %, July: 29.7 %, and August: 20.7 %), and up to ca. 37.1 % of it (June: 39.2 %, July: 41 %, and August: 30.5 %) for the Northern Hemisphere (Sindelarova et al.,  
55 2022).

Terpenoid compounds are an important fraction of BVOCs emitted globally (Guenther et al., 1995) and also from boreal forests (Rinne et al., 2009), and include isoprene (C<sub>5</sub>H<sub>8</sub>), the monoterpenes (C<sub>10</sub>H<sub>16</sub>), the sesquiterpenes (C<sub>15</sub>H<sub>24</sub>), and so on to diterpenes and larger compounds. Typically, for European boreal forests such as those largely composed of Scots pine and  
60 Norway Spruce (Rinne et al., 2009), isoprene emissions are relatively low while monoterpene emissions predominate during typical ambient conditions (Hakola et al., 2006; Hakola et al., 2017), with isoprene emission about 10% - 15% of monoterpene emissions by mass (Rinne et al., 2009). When under significant stresses such as insect herbivory or drought, boreal forests are also known to be significant sesquiterpene emitters (Rinne et al., 2009; Niinemets, 2010). Isoprene is mainly involved in

65 influencing production and lifetime of tropospheric ozone (Atkinson and Arey, 2003) and can be rather ineffective at increasing SOA yields in the troposphere with respect to MT. In the lower troposphere, isoprene can even inhibit SOA new particle formation (NPF) and early-stage particle growth, such as when present as an isoprene + MT mixture relative to a pure MT mixture (e.g., Heinritzi et al., 2020; Kiendler-Scharr et al., 2009; Mcfiggans et al., 2019). However, monoterpenes as such emitted by the boreal forest biome are mainly involved in SOA particle formation and growth (Spracklen et al., 2008).

70 Globally,  $\alpha$ -Pinene,  $\beta$ -pinene and limonene typically have the highest net atmospheric abundance for monoterpenes (MT). Many monoterpene isomers, however, are present and vary widely in structure (Geron et al., 2000; Guenther et al., 2012). In boreal forests, the emission of MT from predominant tree species, particularly Scots pine and Norway spruce, can vary as distinct chemotypes (referred to as  $\alpha$ -pinene and  $\Delta^3$ -carene types) (Hiltunen and Laakso, 1995; Holzke et al., 2006; Komenda and Koppmann, 2002; Manninen et al., 2002; Tarvainen et al., 2005). The speciation of MT emissions can also vary  
75 significantly within the same species population (e.g., Persson et al., 2016). This has direct impacts on the resulting atmospheric chemistry, as MT reactivity and SOA formation potential varies by isomeric structure (Friedman and Farmer, 2018; Griffin et al., 1999; Lee et al., 2006a; Zhao et al., 2015). For example, Lee et al. (2006b) reported SOA yields from ozonolysis of monoterpenes ranging from 17% for  $\beta$ -pinene to 54% for  $\Delta^3$ -carene (41% for  $\alpha$ -pinene) and in photolysis experiments (Lee et al., 2006a) found that  $\Delta^3$ -carene had an SOA mass yield that is ca. 16 – 30 % and 15 – 22 % greater than that of  $\beta$ -pinene and  
80  $\alpha$ -pinene, respectively. Accurately characterizing the speciation of MT fluxes from boreal forests is therefore of significant importance to parameterizing emission factors in current and future climate and air quality models.

Observations of BVOC concentration above forest canopy are important for interpreting atmospheric chemistry processes, particularly in the lower troposphere and surface boundary layer directly above the forest, which are dependent on the  
85 concentration of precursor BVOC compounds (Atkinson, 2000; Pryor et al., 2014; Tunved et al., 2006). Observed concentrations are impacted by both BVOC emission rate and micrometeorological conditions in the surface boundary layer (e.g., Karl et al., 2004; Petersen et al., 2023), as well as the chemical lifetime of relatively short-lived BVOC compounds (Atkinson and Arey, 2003). Very brief chemical lifetimes, such as for sesquiterpenes ( $\tau_{\text{SQT}} \sim$  seconds), can impact their observed above-canopy fluxes as well (e.g., Rinne et al., 2012). Meanwhile, BVOC flux observations are important for  
90 understanding BVOC exchange between forest ecosystems and the atmosphere. Quantifying fluxes is also important for accurately parameterizing the functional dependencies of BVOC emissions on environmental parameters, such as temperature and solar radiation, for regional and global atmospheric chemistry models (e.g. Rinne et al., 2002; Taipale et al., 2011).

There are multiple methods used to measure BVOC concentrations and fluxes (Rantala et al., 2014; Rinne et al., 2021). Proton-transfer-reaction mass spectrometry (PTR-MS) has been widely used to study BVOCs in the atmosphere (e.g., Yuan et al.,  
95 2017; Lindinger et al., 1998). In this technique, proton-transfer reactions with  $\text{H}_3\text{O}^+$  ions are used to ionize atmospheric VOCs for detection of the product ions by mass spectrometry. In recent years, it has become possible to perform eddy-covariance

(EC) measurements of BVOC fluxes using fast-response ( $\tau \lesssim 1$  s) PTR Time-of-Flight MS (PTR-ToF-MS) over a wide range of BVOC molar masses (Müller et al., 2010). The EC flux approach, based on the covariance between high-frequency observations of the fluctuations in chemical concentration and vertical wind speed (see section 2.4), has the advantage of being the most direct and accurate approach for measuring ecosystem-level BVOC fluxes, and thus is an important component for biosphere BVOC emission research. Fluxes measured by micrometeorological methods can be used to study the effects of environmental parameters on BVOC emissions. They can also be applied in up-scaling studies, where canopy-scale measurements provide an important intermediate step between leaf-level and regional-scale for use in model verification. The capability of PTR-ToF-MS to conduct high-frequency BVOC sampling makes it well-suited for measuring BVOC fluxes via the EC flux method, and combined with the high sensitivity and accuracy of current instrumentation (e.g., Krechmer et al., 2018), makes it one of the best currently available instrumental approaches for measuring ecosystem-scale BVOC fluxes. A limitation of PTR-MS analysis is, however, that it identifies compounds collectively by their mass-to-charge ratio, and cannot differentiate between compounds with the same molar mass and molecular composition (i.e. isomeric compounds). For example, the monoterpenes ( $C_{10}H_{16}$ ), which can be emitted in a boreal forest as any one of many structurally unique compounds, all have a protonated nominal mass-to-charge ( $m/z$ ) ratio of 137.130.

While BVOC flux studies have made great strides due the development of PTR instrumentation, improvements to the study of speciated MT fluxes are still lacking. In addition to total fluxes (such as total monoterpene flux), speciated flux information can be used to further improve model verification for compound-specific emission potentials used in emission models (e.g., MEGAN). Methods used to measure speciated BVOC fluxes include variants of the gradient method (see section 2.6), which assumes that a compound's ecosystem-atmosphere turbulent flux is proportional to its vertical concentration gradient above the forest canopy (where the proportionality constant is the turbulent exchange coefficient) (Fuentes et al., 1996; Goldstein et al., 1995; Guenther et al., 1996; Rinne et al., 2000a; Schween et al., 1997). By using Automated Thermal Desorption (ATD) gas chromatograph-mass spectrometry (GC-MS) for adsorbent tube sampling of the vertical BVOC gradient, in conjunction with PTR-MS measurements of the eddy-covariance-derived BVOC fluxes, the information from these two approaches to BVOC flux observations can provide additional insight into the ecosystem-atmosphere exchange of BVOCs between boreal forests and the troposphere.

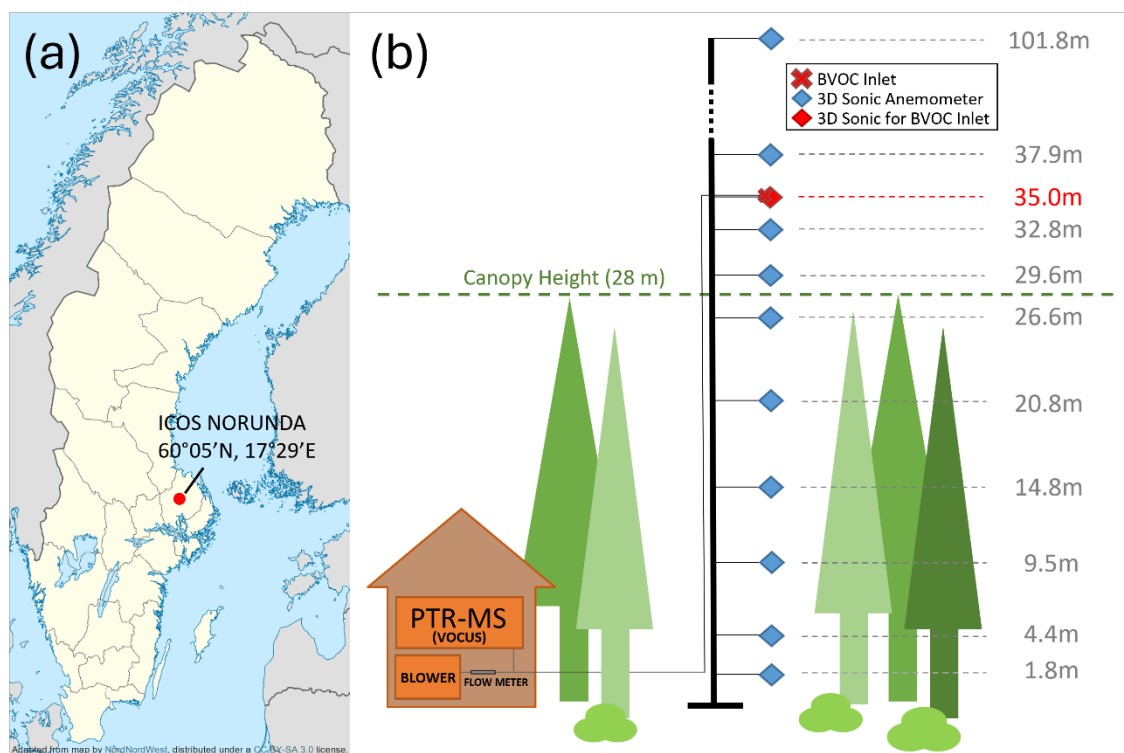

In this work, concentrations and fluxes of BVOCs, particularly the monoterpenes, at a Swedish site in the European boreal zone are presented. Six weeks of Vocus PTR-ToF-MS measurements were performed from July 21 to August 26, 2020. Thermal desorption (TD) tube samples of the BVOC concentration were collected during the daytime (typically between 9:00am and 5:00pm) at 37 m and 60 m a.g.l. on the Norunda flux tower over 3-day periods, during June 8-10 (prior to Vocus deployment), July 22-24, and August 16-18.

## 130 2 Methods

### 2.1 Measurement site

This study was conducted at the Norunda research station, located at 60°05'N, 17°29'E, ca. 30 km north of Uppsala, in central Sweden. The station is part of the Integrated Carbon Observation System (ICOS) research infrastructure ([www.icos-cp.eu](http://www.icos-cp.eu); (Heiskanen et al., 2022)), a network for monitoring greenhouse gases and short-lived climate forcers (more recently, part of  
135 Aerosol, Clouds, and Trace Gases Research Infrastructure (ACTRIS) in Sweden ([www.actris.eu](http://www.actris.eu)) as well). The station was surrounded by a mixed-conifer forest of Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*). This forest was between 80 and 120 years old (Lagergren et al., 2005) and the forest canopy height was ca. 28 m (Wang et al., 2017). The forest (subsequently clearcut in 2022 for lumber) has been managed for economic purposes for approximately the last 200 years. The research station has been in operation since 1994 as a CO<sub>2</sub> and trace gas flux station and is equipped with a 102m tower  
140 (Lindroth et al., 1998; Lundin et al., 1999). A station map and its location in Sweden are presented in Figure 1.

**Figure 1: Location of the measurements station Norunda and BVOC inlet setup. (a) Location of ICOS station Norunda. (b) Shown are the heights of the on-site collection of 3D sonic anemometers (blue diamonds) and BVOC inlet (red cross) at the station flux tower. The canopy top height was at approximately 28 m. The instrument shed contained the Vocus PTR-ToF-MS and zero-air generator for the Vocus. A blower was used to pull air through the tower inlet.**

145 Together, Norway spruce (53.4 %) and Scots pine (39.8 %) make up 93.2 % of mean tree number per hectare. There was also a small number of deciduous trees, consisting primarily of Black Alder (*Alnus glutinosa* (L.) Gaertn; 2.5 %) and Downy Birch

(*Betula pubescens Ehrh.*; 3.9 %). The dominant ground vegetation at the station was Bilberry (*Vaccinium myrtillus*) and Lingonberry (*Vaccinium vitis-idaea*), in addition to several species of dwarf-shrubs, ferns, and grasses. The bottom layer vegetation predominantly consisted of a thick layer of feather moss (*Pleurozium Schreberi* and *Hylocomium Splendens*).  
150 During the 25 years prior to 2020, the mean monthly temperature varied between  $-5^{\circ}\text{C}$  and  $25^{\circ}\text{C}$ , and the mean annual precipitation was approximately 540 mm. The growing season, with daily air temperatures above  $5^{\circ}\text{C}$ , ranges typically from May to September. During the same calendar period as the collected 2020 Norunda campaign measurements (8 June – August 28), the local 25-year climatological average daily temperature was  $16.4 \pm 2.7^{\circ}\text{C}$ , with an average nighttime minimum of  $10.7 \pm 3^{\circ}\text{C}$  and daytime maximum of  $21.2 \pm 3.6^{\circ}\text{C}$ . New needle growth typically begins in April. Foliation of existing deciduous  
155 trees and plants usually occurs in May and senescence usually in October ( $\pm 15$  days). From 2009 to 2014, the leaf area index (LAI) of the Norunda forest in proximity of the tower was determined to be approximately 3.6 ( $\pm 0.4$ ) using a LAI 2000 (Li Cor Inc., Lincoln Nebraska, USA).

## 2.2 Instrumentation & sampling setup

The wind velocity components were measured using a three-dimensional sonic anemometer (USA-1, Metek GmbH, Germany).  
160 BVOC volume mixing ratios were measured using a Vocus PTR-ToF-MS (Vocus-2R, TOFWERK, Thun, Switzerland) (Krechmer et al., 2018). The VOCUS has several advantages over previous PTR-ToF-MS designs, such as in detecting low-volatility BVOC compounds (Krechmer et al., 2018). The Metek sonic anemometer and BVOC sampling inlet were co-located at 35 m on the Norunda flux tower. Ambient air at 35 m was transported from the BVOC inlet head through a heated and insulated perfluoroalkoxy (PFA) Teflon tube mounted on the station flux tower (Fig. 1) to the instrument shed housing the  
165 Vocus PTR-ToF-MS using a side-channel blower. The tower Teflon tubing was ca. 49m in length with an outer diameter (OD) of 3/8 in (inner diameter 1/2 in). The flow rate through the BVOC inlet tubing to the Vocus was 20 L/min to minimize BVOC losses from prolonged residence time within sample tubing. Sample air residence time in tower Teflon tubing before reaching instrumentation was ca. 4.7 s.

170 Inside the instrumentation shed, 6 L/min of the flow coming from the main inlet tubing were directed to the Vocus-inlet, and 100 ml/min were sampled into the Vocus, and the remainder was directed to the inlet exhaust. The Vocus ion source was set at 2 mbar. From field measurements, the mass-resolving power ( $m/\Delta m$ ) of the Vocus, where  $\Delta m$  is the full-width at half-maximum (fwhm) of a spectrum peak, was found to be ca. 9900 Th/Th fwhm for the MT parent ion  $\text{C}_{10}\text{H}_{16}\text{H}^+$  (nominal  $m/z = 137$ ). During the campaign, data from the Vocus were recorded at a frequency of 10 Hz. Reference measurements to determine  
175 the instrumental background of the Vocus PTR-MS were periodically performed (for 1 min each hr) using zero air from a heated catalytic converter (Zero Air Generator, Parker Balston, Haverhill, MA, USA). The mass flow controller for the Vocus zero-air was set to 500 mL/min. The Vocus calibration was performed using a gravimetrically prepared calibration standard (Ionimed Analytik). The calibration standard gas was diluted before sampling by the Vocus using a Gas Calibration Unit (GCU-b, Ionicon).

## 180 2.3 Vocus data processing

For compounds present in the calibration gas standard bottle, the corresponding calibration factor was applied directly to the processed Vocus trace data. For the remaining compounds, calibration factors were calculated using the analysis approach implemented by the *PTR data toolkit* as described by Jensen et al. (2023) (See table A2 of calibration coefficients and calculated terpenoid sensitivities). The fractionation rate estimate for sesquiterpenes ( $0.20 \pm 0.1$ ) is based on *PTR Library* reference of  
185 proton-transfer reactions in trace gas sampling (Pagonis et al., 2019).

The processing of the raw Vocus data was performed using Julia-based analysis scripts from the software package *TOF-Tracer2* (Breitenlechner et al., 2017; Fischer et al., 2021; Stolzenburg et al., 2018), modified for use with the Vocus PTR-ToF-MS dataset. For each campaign day, all Vocus spectra data acquired within 24 h were mass-scale calibrated every 6 minutes  
190 and averaged for peak shape analysis. The program *PeakFit* (Fischer et al., 2021) was used for peak fitting and identification. *PeakFit* was used to create a mass peak list of more than 2000 identified compounds for our Vocus dataset. Based on this mass peak list and using the modified *TOF-Tracer2* scripts, the 10 Hz time traces were obtained by integrating the spectra for intervals around each mass, then applying deconvolution to reduce cross-talk caused by signal contributions from neighboring masses and isotopes in each spectrum (Müller et al., 2010). The script runtime on an 10-core processor system with 1 Tb  
195 harddrive and 96 GB of RAM is about 2.5 hours for 24 hours of 10 Hz data. The recorded amount of raw Vocus data collected each day in the native HDF5-file format was about 20 GB.

## 2.4 Eddy-Covariance fluxes

The most direct method for measuring a chemical flux above a forest canopy is the eddy-covariance (EC) method. It requires simultaneous high-frequency measurements of the compound concentration ( $c$ ) and vertical wind velocity ( $w$ ). The covariance  
200 between the time-dependent fluctuations of these variables gives the flux ( $F_c$ ), with

$$F_c = \overline{w'c'} = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} w'(t)c'(t) dt,$$

Where the overbar denotes time-averaging from time  $t_1$  to time  $t_2$ ,  $c' = c - \bar{c}$ , and  $w' = w - \bar{w}$ . Further information regarding the EC approach can be found in the literature (e.g., Aubinet et al., 2012a). As a significant proportion of a turbulent flux in the atmospheric surface layer is carried by relatively small eddies, for the EC-flux method to accurately quantify the  
205 vertical exchange, the BVOC concentration and vertical wind speed must be measured by fast-response instrumentation. Typically, many analyzers for greenhouse gas fluxes have response times of around 0.1 s. While the PTR analyzer's characteristic response time  $\tau$  (i.e., time for  $100 \times 1/e \% \approx 63.2 \%$  of instrument signal to fully transition between two levels of concentration) is around 1 s, due to transit time of the BVOC product ions in the Vocus drift tube reaction chamber (Krechmer et al., 2018), the effect of this is relatively minimal for evaluating BVOC EC flux (high-frequency attenuation of

210 total flux signal is about 1%), and can be accounted for by a transfer function correction factor (Striednig et al., 2020). This is sufficient for fluxes measured above tall vegetation, such as forest canopies (Rantala et al., 2014).

The EC flux calculations were performed using the MATLAB-code *innFLUX* (Striednig et al., 2020). The analysis routines implemented in this code include a wind sector-dependent tilt correction, lag time determination, and calculation of several  
215 quality tests. In particular, a tilt-correction was performed on the Metek sonic data to align the instrument's coordinate system with the mean wind streamlines (e.g., Wilczak et al., 2001). The time delay between the Metek sonic and Vocus BVOC signals was determined by maximizing the correlation coefficient of the Vocus signals with the vertical wind component. For the final processing of the data points for the Vocus EC flux timeseries, 30-minute ensemble averages were selected.

## 2.5 TD sampling & GC-MS analysis

220 For a gradient-flux approach targeting the speciated monoterpene fluxes, ambient air BVOC samples were collected over three-day periods, approximately once a month, from June to August, from two heights. These air samples were simultaneously collected at 37 and 60 m on the Norunda flux tower for 30 min periods, once an hour, starting at 9:30 am and concluded with the collection of the last sample-pair at 5:00 pm from the tower.

225 Air samples were collected using stainless steel thermal desorption (TD) tubes (10 cm in length and 1/4 inch in diameter) and filled with Tenax GR and Carbograph 5TD (Markes International Inc., USA). Ambient air was pumped through these TD tubes at 200 mL/min for 30 min (6 L total per sample) using flow-controlled sampling pumps (Pocket Pump Pro, SKC Ltd., Dorset UK). Two MnO<sub>2</sub>-coated copper mesh filters (50 mm grid, type ETO341FC003, Ansyco, Karlsruhe, Germany) were placed inside a Teflon inlet head affixed in front of each sampling tube, to remove ozone from the ambient air. In previous  
230 studies it was found that these MnO<sub>2</sub>-coated mesh filters destroy about 80% of the ozone but leave  $\alpha$ -pinene,  $\beta$ -pinene, limonene,  $\Delta^3$ -carene and other terpenoids intact (e.g., Bäck et al., 2012; Calogirou et al., 1996). TD samples were refrigerated and then analyzed within 30 days of collection. Calibration tubes were also prepared and analyzed to calibrate the subsequent GC-MS analysis (e.g., Bai et al., 2016).

235 TD tubes were thermally desorbed and cryo-focused using a Perkin Elmer TurboMatrix 650 automatic thermal desorber (ATD). This ATD was operated in splitless mode. Samples were then injected into a gas chromatograph-mass spectrometry system (GC-MS, Shimadzu QP2010 Plus, Shimadzu Corporation, Japan). For the gas chromatography, the BVOC gas samples were separated using a BPX5 capillary column (50m, I.D. 0.32mm, film thickness 1.0  $\mu$ m, Trajan Scientific, Australia). The carrier gas was helium. The GC oven temperature program was as follows: start temperature, 40C; hold time, 1 min; ramp 1,  
240 6 C per min to 210 C; ramp 2, 10 C per min to 250 C; final hold time, 5 min. The GC-MS was run simultaneously in both SIM and SCAN modes (e.g., Duhl et al., 2013). This choice was to enable detection of both common and unanticipated compounds. For sample calibration, a pure standard solution containing isoprene,  $\alpha$ -pinene,  $\beta$ -pinene, p-cymene, eucalyptol, limonene, 3-

carene, linalool,  $\alpha$ -humulene,  $\beta$ -caryophyllene, longifolene and myrcene (Merck KGaA, Darmstadt, Germany) was prepared in methanol. This standard solution was injected onto conditioned adsorbent sampling tubes in a helium stream, with cartridges receiving different concentrations of the standard solution. These prepared TD tubes were then analyzed with the samples in order to provide a calibration curve (e.g., Noe et al., 2012).

## 2.6 Gradient-method fluxes

In the Surface Layer Gradient (SLG) method we obtain the turbulent flux by using the vertical gradient of the measured volume mixing ratios (i.e., concentrations  $\bar{c}$ ) and a turbulent exchange coefficient  $K$  in the manner analogous to molecular diffusion, with  $F_C = -K \frac{\delta \bar{c}}{\delta z}$ . The turbulent exchange coefficient  $K$  can be obtained in several approaches, such as using results from another scalar quantity through the modified Bowen ratio approach or by application of Monin-Obukhov similarity theory (e.g., Rannik, 1998; Rantala et al., 2014). In the case of BVOC gradient sampling using TD tubes at two heights, we use the Monin-Obukhov similarity approach as in e.g., Fuentes et al. (1996) and Rinne et al. (2000b),

$$F_C = \frac{-ku_*[\bar{c}(z_1) - \bar{c}(z_2)]}{\ln\left(\frac{z_2-d}{z_1-d}\right) + \psi_h\left(\frac{z_1-d}{L}\right) - \psi_h\left(\frac{z_2-d}{L}\right)}, \quad (1)$$

where  $u_*$  is the friction velocity,  $d$  is the displacement height,  $L$  is the Obukhov length,  $\psi_h$  is the Monin-Obukhov stability function for heat,  $k$  is the von Kármán constant, and  $\bar{c}(z_1)$  and  $\bar{c}(z_2)$  are the BVOC concentrations at heights  $z_1$  and  $z_2$ , respectively. The values of the integrated stability functions  $\psi_h$  were calculated using the Businger-Dyer equations (Dyer, 1974), with

$$\begin{aligned} \psi_h &= 2 \ln\left(\frac{1+Y}{2}\right), \quad (\text{for } \zeta < 0), \\ \psi_h &= -\beta_h \zeta, \quad (\text{for } \zeta > 0) \end{aligned} \quad (2)$$

where  $\zeta = (z-d)/L$ , and coefficients  $Y = (1 - 12\zeta)^{1/2}$  and  $\beta_h = 7.8$  were selected based on those used in previous investigations (Businger et al., 1971; Dyer, 1974; Rannik, 1998; Rantala et al., 2014; Rinne et al., 2000a).

In the atmosphere directly above rough surfaces, such as forest canopy, flux-gradient laws tend to break down (Cellier and Brunet, 1992; Fazu and Schwerdtfeger, 1989; Garratt, 1980; Högström et al., 1989; Mölder et al., 1999; Simpson et al., 1998). The layer in which these laws are not directly applicable is called the roughness sublayer (RSL). In the RSL, the eddy diffusivities are increased, and consequently, vertical gradients are decreased compared to their nondimensionalized gradient form, which for a scalar concentration  $C$  is expressed by  $\Phi_C(\zeta) = \frac{k(z-d)}{c_*} \frac{\partial \bar{c}}{\partial z}$ , where  $c_*$  is the scalar flux concentration (e.g.,

Rannik 1998). The decrease in gradients due to the influence of the RSL layer can be quantified and corrected for by using the nondimensional factor  $\gamma$ , expressed as

275 
$$\gamma = \frac{\Phi_S}{\Phi} \quad (3)$$

where  $\Phi_S$  is the dimensionless gradient of a scalar according to the Monin–Obukhov similarity theory (i.e., Eq. 3) and  $\Phi$  is the dimensionless gradient according to the measurements. The observed  $\gamma$ -coefficients above a forest canopy at the heights our TD samples were collected typically vary from unity to 3 depending on the measurement height and type of the forest (e.g.,  
280 Simpson et al., 1998).

From  $\gamma$ , it is possible to calculate a mean enhancement factor  $\Gamma$  by integrating the  $\gamma$ -coefficient from the measurement height  $z_1$  to  $z_2$  (e.g., Rinne et al., 2000b), such that in general we have

$$\Gamma(z_1, z_2) = \frac{1}{z_2 - z_1} \left[ \int_{z_1}^{z_2} \gamma(z) dz \right]. \quad (4)$$

285 Details of the  $\gamma$ -coefficient profile analysis for the RSL above the Norunda canopy, as well as determination of displacement height  $d$  (24 m), are included in the Appendix. Based on this analysis, we have found a  $\Gamma$ -coefficient value of  $1.36 \pm 0.09$  for TD gradient flux calculation.

## 2.7 Gradient-method error analysis

The chemical sampling and analysis of the BVOCs represents the largest single source of uncertainty in the flux calculation.  
290 The two error sources which can be evaluated for the chemical gradient measurements are the sampling uncertainty and the analysis uncertainty from the ATD-GC-MS (e.g., Kajos et al., 2015). Measurement results from the ATD-GC-MS include values for peak area mean and standard deviation, as well as signal-to-noise ratio, which were used in the uncertainty analysis. Sampling uncertainty during field measurements includes the sampling pump flow rate (typically  $\pm 5\%$  of set flow rate), whereas sources of uncertainty in the analysis include the preconditioned tube background, as well as the ATD-GC-MS  
295 instrumental uncertainty and standard calibration uncertainty. From the combined (in quadrature) uncertainties of TD sampling and laboratory analysis, a total estimated uncertainty of  $\pm 15\%$  is assumed for each monoterpene compound. The total gradient uncertainty is determined by summing the  $\bar{c}(z_1)$  and  $\bar{c}(z_2)$  in quadrature.

## 2.8 Correction for chemical degradation

300 One of the assumptions of any surface layer flux measurement technique is the constancy of the vertical flux between the surface and the measurement level. In the case of reactive trace gases, such as VOCs, this assumption is not strictly valid, and the invalidity can cause systematic errors if interpreting the measured fluxes as surface exchange rates. This systematic error can be quite substantial for compounds with high Damköhler number ( $Da$ ), i.e. the ratio of time-scale of the turbulent mixing

to that of the chemical reactions, such as certain sesquiterpenes (Rinne et al., 2012). The ratio of flux to the surface exchange  
( $R=F/E$ ) depends on the chemical lifetime ( $\tau_c$ ) of the compound in question and its turbulent mixing time-scale ( $\tau_t$ ). The  
305 chemical lifetime of BVOCs typically depends on  $O_3$ , OH and  $NO_3$  mixing ratios and reactivities of the VOC in question  
against these reactants. The turbulent mixing time-scale depends on friction velocity ( $u_*$ ) and measurement height ( $z$ ). Thus,  
we can estimate the surface exchange rate ( $E$ ) of a compound if we can estimate the reactant levels and friction velocity by

$$E = \frac{F}{R(Da(\tau_t/\tau_c), z/h)}$$

and using the look-up tables by Rinne et al. (2012) to estimate the  $R$ . Furthermore, the  $R$  varies considerably depending on the  
310 emission height, i.e. between canopy and soil surface emission. For example, for isoprene,  $Da$  ranged from 0.0003 to 0.014.  
For MT (based on the reactivities of  $\alpha$ -pinene),  $Da$  ranged from 0.005 to 0.037, and for SQT (based on the reactivities  
 $\beta$ -caryophyllene) between 0.3 to 0.9.

The effect of chemical degradation on isoprene, MT, and SQT surface exchange rates was explored using the modeling work  
of Rinne et al. (2012), which made use of a stochastic Lagrangian transport chemistry model, and by parameterizing the diurnal  
315 cycle of the reaction rates for ozone, OH and  $NO_3$ , to estimate the surface exchange rates for the 2020 Norunda campaign's  
terpenoid EC flux dataset. The OH,  $O_3$ , and  $NO_3$  reaction rate constants of isoprene, MT, and SQT for the SER analysis are  
from those reported by Atkinson (1997) and Shu and Atkinson (1995). A full description of the surface exchange rate  
calculations can be found in the appendix.

## 2.9 Emission algorithm fitting

320 To estimate the mixed contribution of *de novo* biosynthesis and storage pool emission to terpene landscape-scale emissions, a  
hybrid emission algorithm (Taipale et al., 2011; Ghirardo et al., 2010) was fitted to emission measurements. This hybrid  
algorithm was developed under the hypothesis that the two origins of emission can be combined as  $E = E_{synth} + E_{pool}$ , where  
 $E_{synth}$  represents emission originating directly from biosynthesis and  $E_{pool}$  represents emission from specialized storage  
structures, such as resin ducts. This hybrid algorithm formulation takes the form

325

$$E = E_o [f_{denovo} C_T C_L + (1 - f_{denovo}) \gamma],$$

where  $E_o = E_{o,denovo} + E_{o,pool}$  is the total emission potential,  $f_{denovo} = E_{o,denovo}/E_o$  is the ratio of the *de novo* emission  
potential to the total emission potential,  $C_T$  and  $C_L$  are the synthesis activity factors for temperature and light, respectively  
330 (Guenther 1997), and  $\gamma$  is the temperature activity factor ( $\exp[\beta(T - 30^\circ C)]$ ) for the traditional pool emission algorithm,  
where  $\beta$  is an empirical constant and  $T$  is the canopy temperature.

335 As isoprene is widely understood to have no storage source for emission (Guenther 1993, 1995, 1997), fitting for isoprene emission was investigated by setting  $f_{denovo}$  to 1 (i.e., pure *de novo* synthesis emission). Meanwhile, pool emission for MT and SQT was investigated by setting  $f_{denovo}$  to 0. In the case of investigating the fraction of MT and SQT emissions deriving as a mix of *de novo* synthesis and pool emission,  $f_{denovo}$  was allowed to vary as a fitting parameter.

### 3 Results

#### 3.1 Meteorological & other conditions during campaign

340 Temperatures during the campaign varied between 13 and 22 °C. The typical prevailing wind direction was between South and Northwest. Light precipitation occurred on manual sampling day June 9. Suitable soil water content was available to prevent the vegetation from suffering from drought stress. The meteorological conditions during the campaign EC-measurements are displayed in Fig. 2. Typical peak daytime photosynthetic photon flux density (PPFD) varied from 700 to 1500  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . Conditions during days when TD sampling was performed (June 8-10, July 22-24, and August 16-18) had  
345 consistent temperature (mean 17.7 °C) and PPFD (daily mean 680  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) conditions. Ozone monitoring was available throughout the campaign from the nearby Norunda-stenen station, located 1.4 km east of the Norunda tower. One interruption to Vocus sampling occurred on August 12-13 due to an electrical failure in the instrument shelter. A summary of the campaign timeseries is presented in Fig. 2, in which the campaign observations of the station water vapor, vapor pressure deficit (VPD), and dewpoint temperature are also included.

350

**Figure 2:** The 30-min BVOC concentrations (ppbv) and fluxes (nmol m<sup>-2</sup> s<sup>-1</sup>) sampled at the 37 m BVOC inlet at ICOS Norunda, as well as related meteorological measurements. Shaded areas depict manual TD BVOC sampling periods at 37 and 60 m on the Norunda flux tower. The pie charts indicate the relative speciation of MT compound concentrations at 37 m (top) and fluxes (via SLG flux method) (bottom) as determined from the TD BVOC samples (percentages shown are >5%). (a) MT, isoprene, and SQT concentrations (ppbv) and (b) eddy-covariance derived fluxes (nmol m<sup>-2</sup> s<sup>-1</sup>) from the Vocus PTR-ToF-MS. (c) Ozone concentration (ppbv) and water vapor (mmol mol<sup>-1</sup>). (d) PPFD (μmol m<sup>-2</sup> s<sup>-1</sup>; at height 55 m) and air temperature (°C; at 37 m). Set of displayed measurements span from 21 July 2020 to 27 August 2020.

355

## 360 3.2 Gradient sampling conditions during campaign

### 3.2.1 Sampling footprint comparison

To properly interpret the BVOC fluxes inferred from measurements of the concentration gradient, it is important to evaluate differences in the sampling footprints of the two sampling levels (i.e., 37 and 60 m). A footprint comparison between the two sampling levels on the Norunda flux tower was performed for the daily time-period when each TD tube sampling of the BVOC  
365 gradient occurred. Each footprint was calculated using the flux footprint model developed by Kljun et al. (2015). It was found that the footprints, particularly for ca. 85<sup>th</sup> percentile and below footprint contours (depicted in Fig. 3), compared well with each other in terms of the forest canopy area sampled, while the total extent of the 60 m footprint tended to be larger.

370 **Figure 3: Daytime (9:00 CEST to 17:00 CEST) flux footprints at 37 m (red) and 60 m (blue) on the Norunda flux tower during the combined Vocus and TD sampling. The panels show (a-c) the tower footprints for June 8, 9, and 10, (d-f) the tower footprints for July 22, 23, and 24, and (g-f) the tower footprints for August 16, 17, and 18, respectively.**

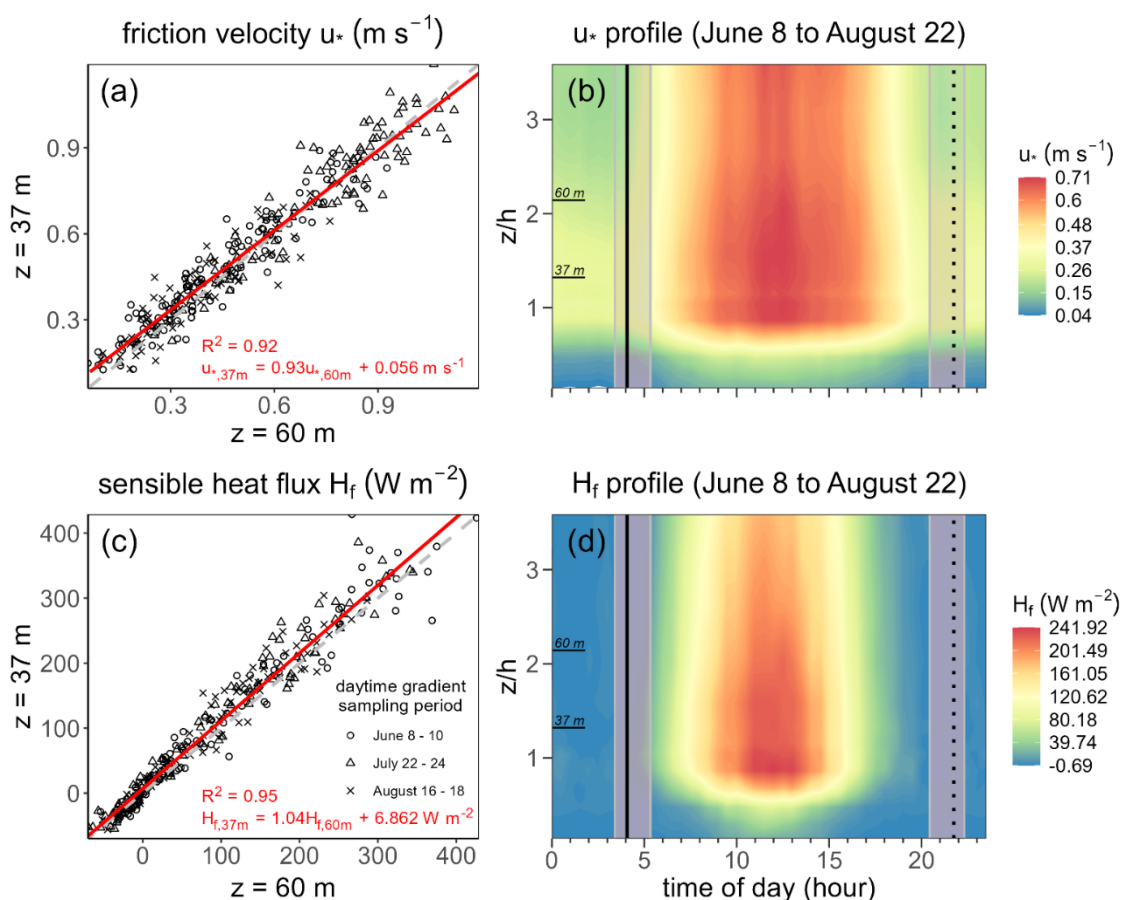

During the campaign TD measurements, approximately 90 % of the flux measured by the Vocus tower inlet at the 37 m level originated within 350 m of the tower itself. At 60 m, approximately 90 % of the observations originated from within 500 m of the tower.

375

### 3.2.2 Vertical micrometeorological conditions

An important prerequisite for the gradient flux method is that vertical fluxes remain constant within the observation layer. To validate this constant-flux assumption, we compared the friction velocities, heat fluxes, and roughness lengths measured at both the 37 m and 60 m measurement levels.

380

385

**Figure 4: Comparison between friction velocity  $u_*$  ( $\text{m s}^{-1}$ ) and sensible heat flux  $H_f$  ( $\text{W m}^{-2}$ ) measured at two heights above the forest canopy. (a; c) A best-fit comparison between 37 m and 60 m for (a) friction velocity and (c) sensible heat flux during the 3-day sampling periods in June, July and August. The dashed line indicates a 1:1 relation, while the solid red line indicates the best fit linear regression. (b; d) Diurnal mean contour profiles for the 2020 Norunda campaign of (b) friction velocity  $u_*$  and (d)  $H_f$  with respect to the normalized height  $z/h$  (canopy height  $h=28 \text{ m}$ ) in and above the Norunda forest. The relative heights of the 37 and 60 m sampling levels on the normalized height scale are indicated on the y-axis. In (b) and (d) panels, mean daily sunrise (solid vertical line) and sunset (dotted vertical line) are indicated. Shaded region indicates the range of sunrise and sunset times during the June 9<sup>th</sup> to August 22<sup>th</sup> campaign period.**

390 Measured sensible heat and momentum fluxes were similar at both measurement heights (see Fig. 4), with the mean linear fit  
of friction velocity and sensible heat flux between the 37 m and 60 m heights being  $u_{*,37\text{ m}} = 0.93 u_{*,37\text{ m}} + 0.056\text{ m s}^{-1}$  and  
 $H_{f,37\text{ m}} = 1.04 H_{f,60\text{ m}} + 6.9\text{ W m}^{-2}$ , respectively. Table A1 (see Appendix) provides a summary of these friction velocity and  
sensible heat flux ratios under different stability conditions and wind directions. It was found that, while near-neutral and stable  
conditions could lead to relatively large deviations in these ratios, for unstable atmospheric conditions the ratios were close to  
1.

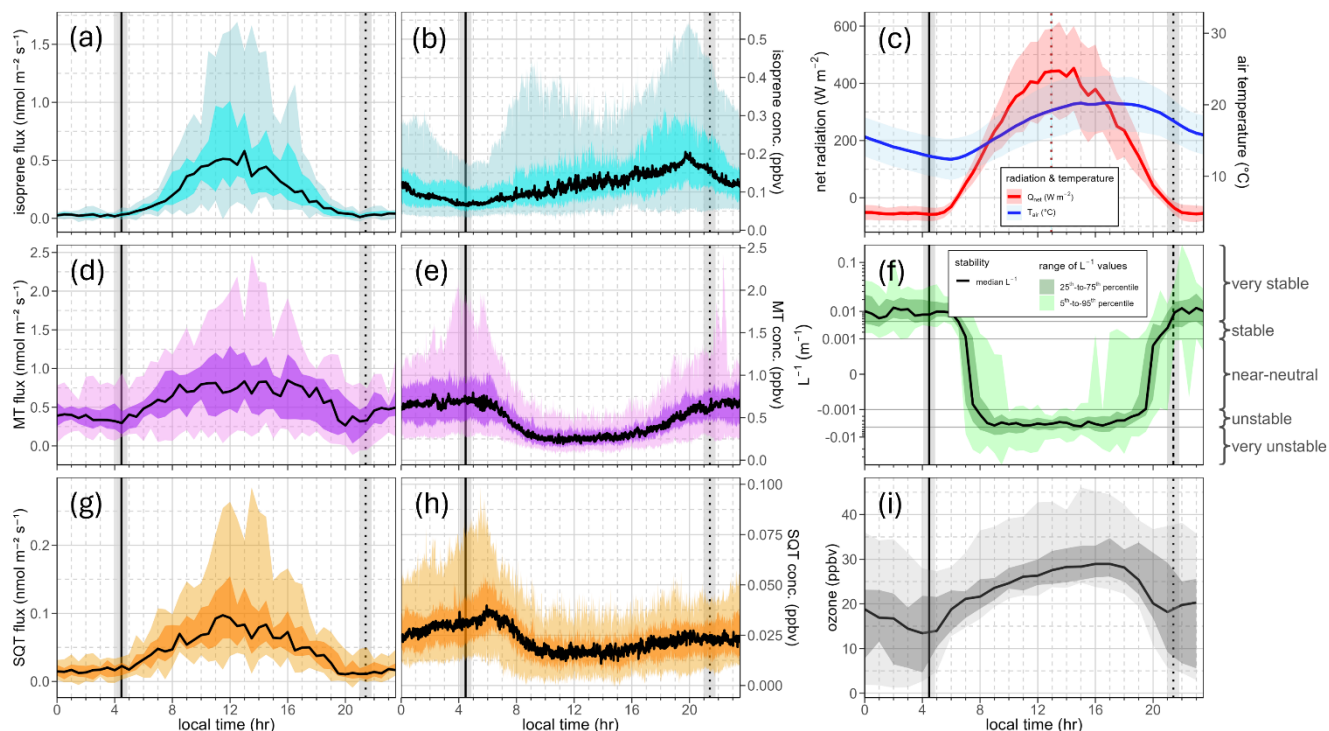

395

### 3.3 Concentrations and fluxes of terpenes and other VOCs

400 During the campaign, the mean daytime isoprene concentration measured by the Vocus PTR-ToF-MS was 250 pptv. As shown  
in Figure 2, the maximum value occurred during daylight hours, at a time when temperature and PPFD were high ( $>20^{\circ}\text{C}$  and  
 $>1000\text{ }\mu\text{mol m}^{-2}\text{ s}^{-1}$ ) as well, with concentrations falling to daily lows towards the evening. Little to no isoprene emission was  
observed at night. Peak total monoterpene concentrations (1 – 1.4 ppbv) were typically significantly higher than isoprene  
concentrations. Unlike isoprene, peak total MT concentration typically occurred at night during stable atmospheric conditions  
in the canopy similarly to the observations by Petersen et al. (2023).

405 Such diurnal cycles in concentration were regularly observed throughout the campaign. Fig. 5 shows the diurnal variation in  
isoprene, total MT, and total SQT from the Vocus PTR-ToF-MS measurements over the course of the 2020 Norunda field  
season.

**Figure 5: Diurnal range of fluxes and concentrations for (a,b) isoprene, (d,e) total MT, and (g, h) total SQT, as measured from the tower BVOC inlet using Vocus PTR-ToF-MS during the Norunda 2020 BVOC field campaign. Diurnal fluxes shown represent 30-min EC ensemble averages and diurnal concentrations represent 1-min averaged timeseries data. Shaded regions in panels indicate the 5th-to-95th and the 25th-to-75th quantile range, as well as the mean (solid line). (c) Net radiation (red) and canopy temperature (blue). Shaded regions for net radiation and temperature indicate one standard deviation. (f) Plot of the inverse of the Obukhov length ( $L^{-1}$ ), indicating atmospheric stability above the canopy (measured at 36 m). (i) local diurnal ozone concentration (ppbv).**

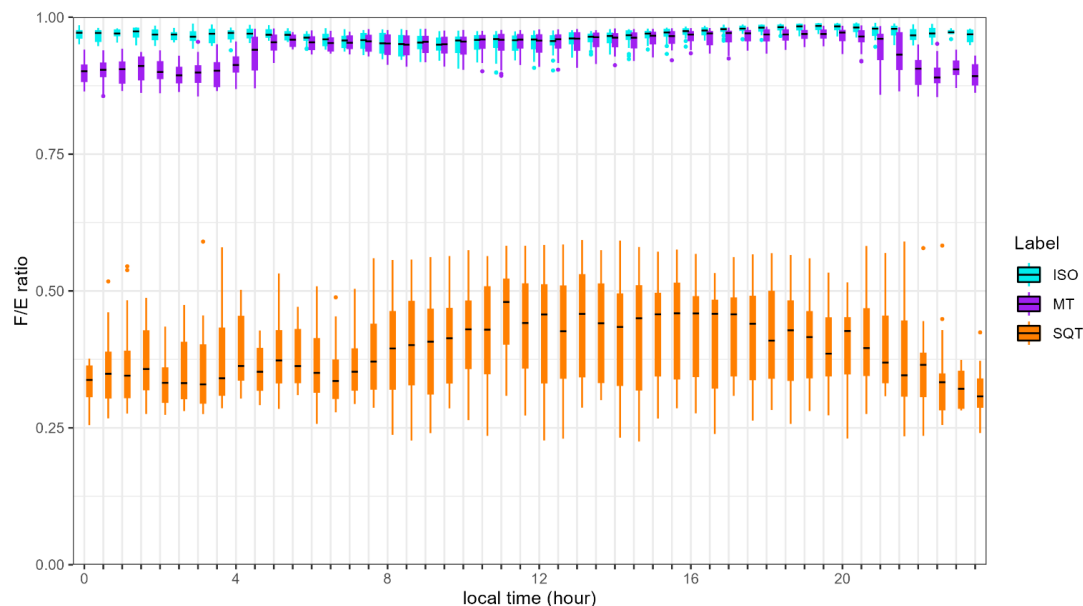

415 Isoprene had its highest concentrations above forest canopy during the day, with peaks typically in the morning between 7:00 -11:00 CEST and more strongly between 16:00 CEST and sunset, whereas MT and SQT concentrations typically peaked at night. Isoprene and terpene fluxes, meanwhile, generally all peaked around noon. This diurnal concentration behavior by isoprene and total SQT, as was observed for total MT, was due to interplay of emission dynamics and the changes in atmospheric stability in the surface boundary layer. For isoprene, this was due to the light-dependent nature of emissions (i.e., *de novo* synthesis emissions (e.g., Guenther et al., 1995; Guenther et al., 1993)), with emissions effectively shut down with the cessation of photosynthesis activity at night. On the other hand, the MT and SQT emissions of evergreen boreal tree species like Scots pine and Norway Spruce still have considerable night-time emission from resin ducts and other tissue structures that are temperature-only-dependent (i.e., storage emission, rather than wholly *de novo* emission (e.g., Ghirardo et al., 2010; Guenther et al., 1995; Guenther et al., 1993; Tingey et al., 1980)). It should also be noted that many SQTs have a short (~0.1

425 – 10 s) chemical lifetime relative to MT, and that this is reflected in the observed concentrations measured by the Vocus, as a  
substantial fraction is expected to react with atmospheric radicals or other compounds before reaching the measurement height  
(e.g., Atkinson and Arey, 2003; Rinne et al., 2012). This diurnal behavior highlights the interplay between constitutive (non-  
stress induced) emissions, driven by environmental conditions (principally, photosynthetic light and temperature), and the  
atmospheric stability within the forest canopy. Despite lower emission rates of terpenes at night, as observed from their EC  
430 fluxes (see Fig. 5e&h), the stable nighttime atmosphere, as indicated by the Obukhov length (see Fig. 5f), causes a buildup in  
their concentrations at night. It was observed that terpene concentrations are typically greatest at or just following sunrise.  
Similar diurnal behavior was observed in other VOC compounds measured by the Vocus, such as acetone, acetaldehyde, and  
toluene, among others, and is also consistent with previous BVOC PTR-MS field campaigns at ICOS Norunda (Petersen et  
al., 2023). This diurnal terpene behavior is also consistent with observations at other boreal sites (e.g., Borsdorf et al., 2023;  
435 Hakola et al., 2012; Hellén et al., 2018).

### 3.3.1 Surface exchange rates

To quantify the actual surface exchange rate of reactive VOCs, the effect of chemical degradation on the surface exchange rate  
(SER) of isoprene, MT and SQT was estimated. The impact of chemical degradation on the ratio of measured flux to surface  
440 exchange rate,  $R=F/E$ , is shown in Fig. 6. Following the modeling work of Rinne et al. 2012 for a similar boreal forest, the F/E  
ratios for MT are based on the reaction rate constants of  $\alpha$ -pinene and for SQT on the reaction rate constants of  $\beta$ -caryophyllene.  
The impact of the chemical degradation rate of isoprene and MT, relative to the observed fluxes, was found to be minimal.  
The influence of chemical degradation on isoprene ( $F/E = 0.981 \pm 0.013$  at night and  $0.957 \pm 0.013$  during day) was within  
the EC flux measurement uncertainty. The main influence of chemical degradation for total MT was found to be at night and,  
445 in terms of absolute emission increases, during peak flux periods around noon. For total MT, a daytime average of  $F/E = 0.957$   
 $\pm 0.013$  due to chemical degradation was calculated for daytime (within the uncertainty of EC flux measurements), while the  
nighttime loss was estimated at an average  $F/E = 0.90$  (varying from 0.87 to 0.93).

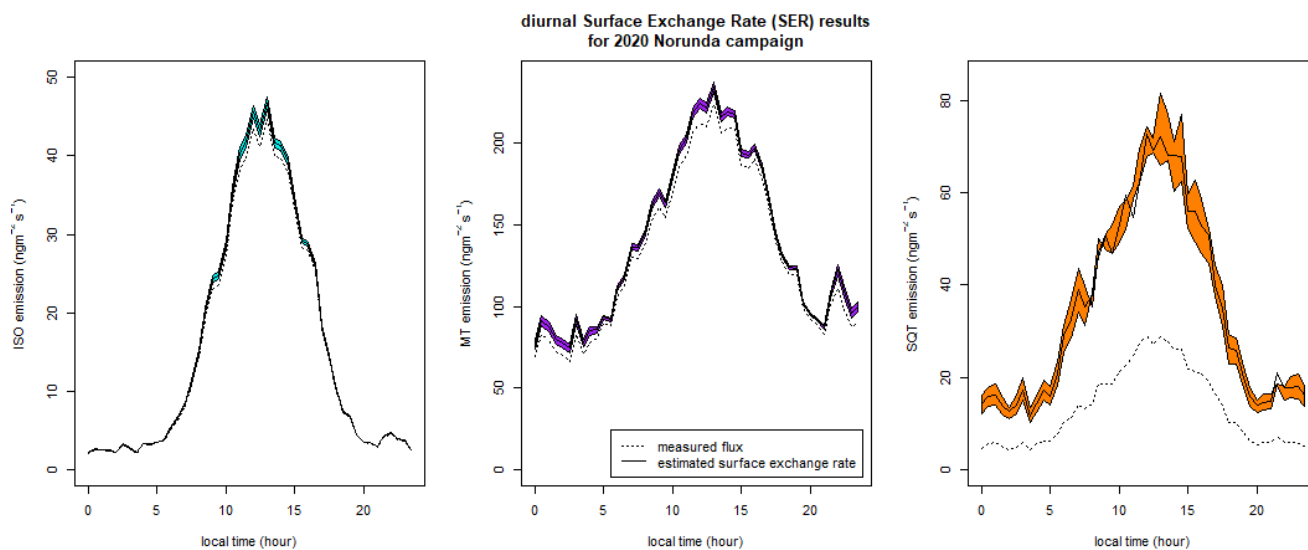

**Figure 6: Boxplot of mean diurnal F/E ratios for chemical degradation estimates of isoprene (cyan), MT (purple), and SQT (orange) for the 2020 Norunda BVOC campaign. Black dash of whisker plot indicates the median value.**

450

In contrast, the measured SQT flux was significantly impacted by chemical degradation (see Fig 7). For the full campaign, the estimated SQT nighttime F/E ratio is typically ca. 0.35 (varying from 0.31 to 0.41), while the daytime ratio is ca. 0.41 (varying from 0.37 to 0.47). The mean diurnal measured fluxes and inferred surface exchange rates of isoprene, MT and SQT, for their respective OH, O<sub>3</sub>, and NO<sub>3</sub> reaction rate constants (table A3 in the Appendix), are shown in Figure 7. As a consequence, for the diurnal average over the full campaign, peak SQT nighttime emission rates are typically ca. 240 % to 310 % (mean ca. 290 %) times greater, and SQT daytime emissions ca. 240 % to 290 % (mean ca. 260 %) times greater than would otherwise be inferred solely from EC flux measurements if the impact of chemical degradation on SQT exchange and subsequent SQT flux observations were neglected.

455

460

**Figure 7: mean diurnal surface exchange rates for isoprene, MT, and SQT during the 2020 Norunda campaign. Shaded region indicates the range of uncertainty for the modeled ozone, OH, and NO<sub>3</sub> reaction rate coefficients. Dashed black line indicates the corresponding measured flux.**

465 The impact of chemical degradation on the F/E ratio between the TD sampling heights was also investigated. This was done to gauge an underpinning assumption of the SLG method: that there is no significant chemical sink between the sampling heights used to determine the above-canopy gradient. This was performed by evaluating, instead of  $R = F/E$ , the value of  $R_2/R_1 = F_2/F_1$ , where  $R_1$  and  $R_2$  are the flux-to-emission ratios for the sampling heights  $z_1 = 37$  m and  $z_2 = 60$  m, respectively. This provides a measure for the percent of flux lost between the lower and upper heights for the gradient measurement. For MT, typically just 1.7 ( $\pm 0.5$ ) % flux loss between sampling heights, with  $R_{2,MT}/R_{1,MT} = 98.3$  (varying from 97.8 to 98.8). This is less than the F/E ratio previously found for the total MT EC flux measurements. In contrast, for SQT, there was typically between 33 and 43 % loss in SQT flux between these heights, with  $R_{2,SQT}/R_{1,SQT} = 61.8$  (varying from 57.1 to 66.6). As expected, this demonstrates significant SQT chemical loss between the two intervening heights, and that the SLG method would be inapplicable to SQT fluxes without significant modification to account for chemical degradation.

### 475 3.3.2 Comparing measured terpenoid emissions with emission algorithms

The presented emission algorithm regression results (specifically, for the terpenes) are presented in Fig. 8. As the estimated isoprene surface exchange rates were within the range of uncertainty of the measured fluxes, only the measured isoprene fluxes were used for the regression analysis. For isoprene, we used the fixed  $\beta = 0.09$  °C<sup>-1</sup> of Guenther (1997), and the emission algorithm was set to pure *de novo* synthesis emission by setting  $f_{denovo}$  to 1. The fitted isoprene  $E_o$  was found to be 85.0 ( $\pm 1.5$ )  
480 ng m<sup>-2</sup> s<sup>-1</sup>.

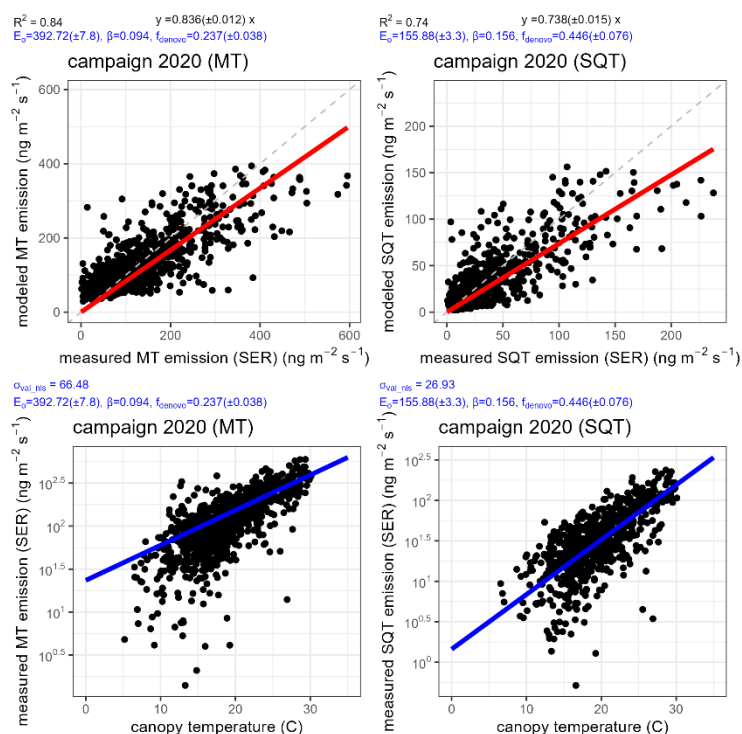

For MT emissions based on the temperature-dependent pool emission algorithm (Guenther et al. 1993; Guenther et al. 2012), by setting  $f_{\text{denovo}}$  to 0, the fitted MT standardized emission  $E_o$  was found to be  $386 (\pm 5) \text{ ng m}^{-2} \text{ s}^{-1}$  for  $\beta = 0.1$  (Guenther et al., 2012). Allowing  $\beta$  to vary as a regression coefficient for the pool algorithm as well yields  $370 (\pm 9) \text{ ng m}^{-2} \text{ s}^{-1}$  and  $\beta = 0.094 (\pm 0.003)$ . Applying the full hybrid MT emission algorithm, combining *de novo* synthesis and pool storage emission (e.g., Taipale et al., 2011), with the previously fitted  $\beta = 0.094$ , yields  $E_o = 374 (\pm 7) \text{ ng m}^{-2} \text{ s}^{-1}$ , and the fraction of MT emissions originating from *de novo* synthesis as  $f_{\text{denovo}} = 26 (\pm 4) \%$ . When using the MT surface exchange rates instead of the observed EC fluxes at 37 m, fitting the hybrid algorithm then yields  $E_o = 393 (\pm 8) \text{ ng m}^{-2} \text{ s}^{-1}$  and  $f_{\text{denovo}} = 24 (\pm 4) \%$ .

485

490 As the SQT emission rate is significantly underrepresented by the measured flux due to chemical degradation, we have fitted the hybrid emission algorithm to the estimated SQT surface exchange rates for the campaign. For fitting from SQT surface exchange rates, based on the temperature-dependent pool emission algorithm of Guenther (Guenther et al. 1993; Guenther et al. 2012), the fitted standardized SQT emission  $E_o$  was found to be  $171 (\pm 3) \text{ ng m}^{-2} \text{ s}^{-1}$  for  $\beta = 0.17$  (Guenther et al., 2012). Allowing  $\beta$  to vary as a regression coefficient for the pool algorithm as well yields  $160 (\pm 5) \text{ ng m}^{-2} \text{ s}^{-1}$  and  $\beta = 0.156 (\pm 0.004)$ .

495 Applying the hybrid emission algorithm, combining *de novo* synthesis and pool storage emission (e.g., Taipale et al., 2011), with the previously fitted  $\beta = 0.156$ , yields  $E_o = 156 (\pm 3) \text{ ng m}^{-2} \text{ s}^{-1}$ , and the fraction of SQT emissions originating from *de novo* synthesis as  $f_{\text{denovo}} = 45 (\pm 8) \%$ . Fitting the hybrid algorithm using the estimated surface exchange rates for SQT yielded better fits than simply applying the measured SQT flux data without the corresponding correction for chemical degradation. From the surface exchange rates, the hybrid algorithm estimates for  $f_{\text{denovo}}$  for both MT and SQT were found to be quite similar

500  $(38 (\pm 8) \%$  and  $31 (\pm 7) \%$ , respectively).

505 **Figure 8: Hybrid emission algorithm comparison to terpene measurements. (a,b) Comparison of measured vs modeled emission (using the fitted coefficients) for (a) MT and (b) SQT surface exchange rates. The red line indicates the linear regression best-fit line for the data points, and dashed grey line indicates the one-to-one line. (c,d) Plots of the canopy temperature vs (c) MT emission and (d) SQT emission. Blue line shows the best-fit regression line.**

### 3.3.3 Other VOCs

510 Acetaldehyde ( $m/z$  45.034) concentrations exhibited a mean daily concentration of 0.7 ppbv. Toluene ( $m/z$  93.07) concentrations were generally low during daytime (ca. 12 pptv) and increased during nighttime (ca. 30 pptv). This behavior by toluene is consistent with the build-up of anthropogenic background emissions during night in the shallow nocturnal boundary layer (Karl et al., 2004). Similar behavior was found for mass peak at  $m/z^+ = 95.049$  (i.e., phenol), which had a daytime low concentration (ca. 9 pptv), and maximum during nighttime (ca. 40 pptv).

515 Acetic acid concentrations ( $m/z$  61.028) tended to be at a minimum following sunrise (10 pptv), and gradually increased throughout the day until peaking before sunset (ca. 33 pptv), at which point concentrations typically decreased until the next sunrise. The exception to this trend appears to be when there was a persistent high nighttime concentration in the canopy, which was associated with similar peaks in acetone and acetaldehyde concentrations in the canopy. The diurnal concentration

of  $m/z^+ = 41.039$  and  $m/z^+ = 103.112$ , associated with the PTR-MS protonated hexanol fragment and the hexanol parent ion, respectively, typically followed a similar pattern to acetone. The minimum in hexanol concentration (about 50 pptv) typically occurred in the morning following sunrise. Concentrations then usually peaked after sunset (about 130 pptv).

The mean daily methyl vinyl ketone and methacrolein (MVK+MACR, nominal  $m/z^+ = 71.049$ ) concentration, two important intermediate products from the photochemical oxidation of isoprene, was 7 pptv. The range of observed methyl ethyl ketone (MEK) concentrations was 6 – 16 pptv and was comparable to those reported by Ruuskanen et al. (2009) for a similar boreal forest site.

### 3.4.1 Speciated MT concentrations and fluxes

During the campaign,  $\alpha$ -pinene,  $\Delta^3$ -carene,  $\beta$ -pinene, camphene, myrcene, and limonene were detected in the ATD-GC-MS analysis. The most abundant monoterpene species throughout the campaign was  $\alpha$ -pinene, followed by  $\Delta^3$ -carene (see Fig. 2). Limonene concentrations contributed about 5-10% of total monoterpene concentrations. An overview of the monthly sampling-period mean concentrations and SLG method-derived fluxes of the speciated MT compounds, observed via thermal desorption sampling at 35 m above the forest canopy, during the 3-day monthly sampling periods in June, July, and August is shown in Fig. 9 A daily mean evaluation can be found in the Appendix. During all sampling periods,  $\alpha$ -pinene was the most prevalent MT compound present, fairly constant and typically representing between ca. 28 to 34 % of the total MT concentration. The second most prevalent MT compound was  $\Delta^3$ -carene. From June to August, fraction of  $\Delta^3$ -carene among the MT compounds decreases by 8 %, from monthly sampling-period averages of ca. 30 % in June, to ca. 24% in July and ca. 22 % in August. During the June measurements, the typical concentration abundance at 37 m above the forest canopy among the MT species were 32 ( $\pm 4$ ) %  $\alpha$ -pinene, 30 ( $\pm 4$ ) %  $\Delta^3$ -carene, 7.6( $\pm 0.8$ ) % myrcene, 5( $\pm 0.6$ ) % limonene, and 10( $\pm 1.1$ ) %  $\beta$ -pinene, 7.2( $\pm 0.6$ ) % camphene, and 5.6( $\pm 0.5$ ) % cymene. In July, the typical abundances were 31 ( $\pm 3$ ) %  $\alpha$ -pinene, 24 ( $\pm 6$ ) %  $\Delta^3$ -carene, 12( $\pm 2$ ) % myrcene, 7( $\pm 2$ ) % limonene, and 10.8( $\pm 0.9$ ) %  $\beta$ -pinene, 4.5( $\pm 0.7$ ) % camphene, and 4.5( $\pm 0.7$ ) % cymene. In August, the typical abundances were 32( $\pm 3$ ) %  $\alpha$ -pinene, 22( $\pm 2$ ) %  $\Delta^3$ -carene, 5.9( $\pm 0.4$ ) % myrcene, 6.9( $\pm 0.6$ ) % limonene, 13( $\pm 2$ ) %  $\beta$ -pinene, 10.3( $\pm 0.8$ ) % camphene, and 7( $\pm 0.5$ ) % cymene.

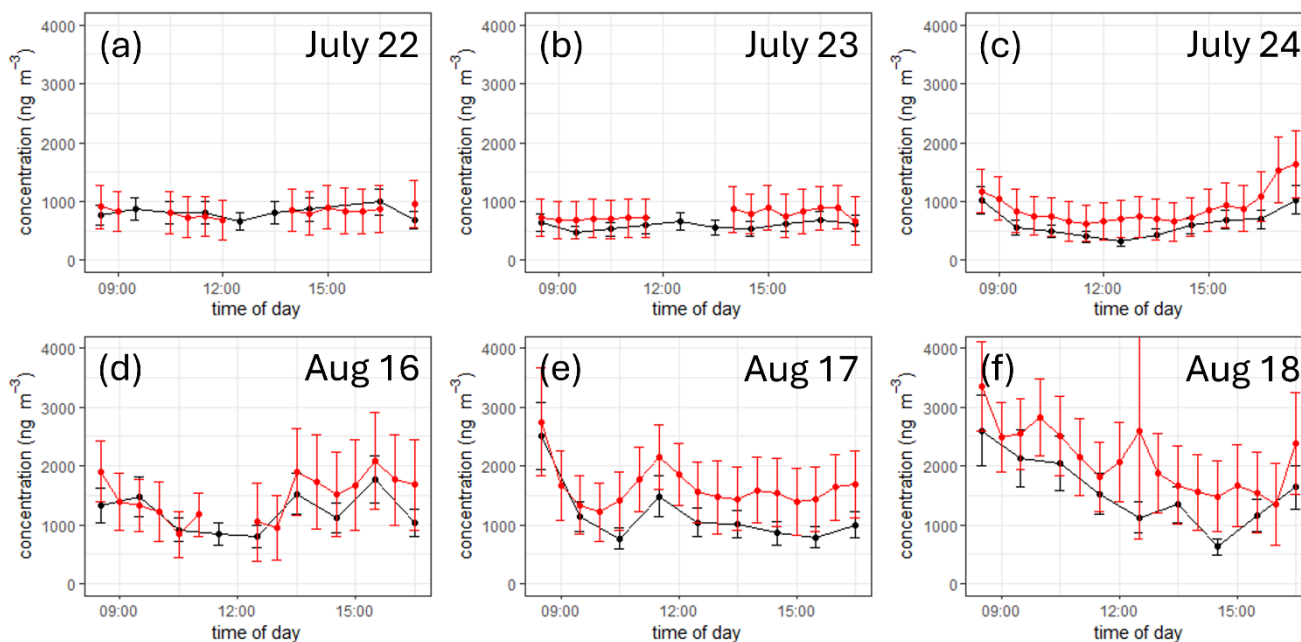

545 **Figure 9: Monthly sampling-period mean concentrations of MT compound species at 37 (red) and 60 m (blue) on the station flux tower at the ICOS Norunda boreal forest, as well as sampling period mean speciated MT fluxes (green), during June 8 – 10 (a), July 22 - 24 (b) and August 16 - 18 (c). Vertical error bars indicate the standard mean error. The daily mean concentrations and fluxes are shown in Fig. A8 in the Appendix.**

### 3.4.2 Vocus & ATD-GC-MS concentration comparison

550 We compared the sum of speciated MTs measured by GC-MS with the total MT concentration measured by Vocus PTR-ToF-MS. The comparison is displayed in Fig. 10. Based on comparison with 2022 pre-cut TD measurements, it is expected that the sum of MT compounds identified by TD sample analysis represent 70 - 80% of total atmospheric MT concentration. During July 22 - 24, the ATD-GC-MS obtained a concentration of 610(±30) ng m<sup>-3</sup> while the Vocus measured 851(±27) ng m<sup>-3</sup> for MTs. During August 16 - 18, the ATD-GC-MS obtained a daytime concentration of 1201(±73) ng m<sup>-3</sup> while the Vocus  
 555 measured 1790(±73) ng m<sup>-3</sup> for MTs.

560 **Figure 10: Comparison of MT concentration measurements from the Vocus PTR-ToF-MS (black) and the sum of speciated MT concentrations (red) from the TD sample GC-MS analysis. Error bars (red) indicate standard deviation of 30min Vocus MT concentration. Shown are half-hourly timeseries of the MT concentration measurements from both Vocus and manual TD sampling for the (a-c) 2020 July 22 - 24 and (d - f) 2020 August 16 - 18 TD sample periods.**

### 3.5 Vocus EC flux results

565 During daytime sampling, the values of the Vocus monoterpene flux typically ranged from 100 to 150  $\text{ng m}^{-2} \text{s}^{-1}$  (see Fig. 9).  
570 Nighttime flux measurements should be treated with care, as stable atmospheric conditions during the evening lead to large uncertainties (e.g., Aubinet et al., 2012b). A combined estimate of the mean flux from the three-day sampling periods in June, July (start of Vocus campaign) and August (end of combined campaign) was performed for the surface layer gradient (SLG) fluxes. The mean flux for each of these three-day sampling periods was calculated to reduce the large uncertainty in the SLG flux estimates, by reducing the influence of random errors in the calculation. For the period of June 8-10 gradient samples, the estimated mean summed MT flux was  $108(\pm 14) \text{ ng m}^{-2} \text{ s}^{-1}$ . For the period of July 22-24 TD gradient samples, the estimated mean of the summed MT flux was  $70(\pm 20) \text{ ng m}^{-2} \text{ s}^{-1}$ . For the period of August 16-18 TD gradient samples, the estimated mean summed MT flux was  $90(\pm 20) \text{ ng m}^{-2} \text{ s}^{-1}$ . For comparison, during the 2020 campaign period when the Vocus was also operating, for the daytime sampling periods when TD sampling was performed the mean total MT flux from Vocus eddy-covariance measurements for July 22-24 was  $105(\pm 3) \text{ ng m}^{-2} \text{ s}^{-1}$  and during August 16-18 was  $155(\pm 7) \text{ ng m}^{-2} \text{ s}^{-1}$ . For these  
575 same periods, the estimated isoprene flux was  $20(\pm 9) \text{ ng m}^{-2} \text{ s}^{-1}$  and  $23(\pm 10) \text{ ng m}^{-2} \text{ s}^{-1}$ , respectively.

To determine whether there were any significant changes in the relative mixture of speciated MT compounds emitted over the course of the 2020 campaign, a two-way ANOVA statistical analysis was performed using the gradient-derived speciated MT fluxes. First, to eliminate the temperature-dependence of the MT emissions, the speciated fluxes were used to calculate temperature-normalized (to 30°C) emissions  $E_0$  using the equation  $E = E_0 \exp[\beta(T - 30^\circ\text{C})]$  (Guenther et al., 1993), where  $E$  are the total MT emissions,  $\beta$  is an empirically fitted coefficient (found for the Norunda 2020 campaign to be  $\beta = 0.094$ ), and  $T$  is the temperature in °C. Next, for the two-way ANOVA analysis, the flux data was sorted according to the monthly period (i.e., June, July, or August), and day of each sampling period (i.e., day 1, 2, or 3) when each gradient sample was collected. This allowed for the comparison of MT fluxes between sampling days and between sampling periods. The p-values from the analysis indicated that there was no significant ( $p < 0.05$ ) trend in the measured flux between the monthly sampling periods for the speciated MT compounds observed, with the exception of a weak negative trend in the emission of  $\Delta^3$ -carene when comparing the three monthly sampling periods, in particular, between June and August ( $p < 0.0309$ ). This indicates that at a landscape-scale level of emissions from the Norunda forest canopy, at least during the summer months of June to August, following from the gradient samples there does not appear to be in general a substantial variation in the relative mixture of MT compounds emitted with respect to the time of season.

#### 4 Discussion

We conducted a measurement campaign in a boreal forest in order to estimate speciated monoterpene concentrations and fluxes during Scandinavian summer. The flux of MT compounds at Norunda was observed to primarily consist of  $\alpha$ -pinene, followed by  $\Delta^3$ -carene at ca. 2/3rds of  $\alpha$ -pinene. This is similar to the preponderance of  $\alpha$ -pinene, followed by  $\Delta^3$ -carene, observed by Hakola et al. (2012) above the boreal forest at the Hyytiälä research station in Finland, a predominantly Scots pine forest with nearby Norway Spruce, as well. Speciated MT emissions showed no clear significant differences during summer-seasonal cycle. Only a slight weakening of the temperature-normalized emission rate for  $\Delta^3$ -carene was observed over the course of the 2020 measurements (June – August). It should be noted that observations did not extend to the spring and autumn, hence further attention to the seasonal behavior of individual MT species in BVOC emission and climate models may be warranted in future investigations.

These gradient method flux measurements allow the speciated flux to be evaluated at an ecosystem-level scale, which sidesteps a potential issue for understanding ecosystem-atmosphere MT exchange, the large variability in speciated MT emissions that can exist among pine or spruce groups, as observed in chamber measurement studies, which can occur even among members of the same tree species and population (Bäck et al., 2012; Hakola et al., 2017).

The observed MT emissions were significantly temperature-dependent (fitting well to the storage-based pool emission algorithm of Guenther et al. (1993)) and that most of the forest MT emission originates from plant storage structures rather

than from de novo synthesis as is the case for certain boreal tree species (e.g., Ghirardo et al., 2010). This is consistent with  
610 the forest tree species composition and the fact that MT mixing ratios were higher at night, with the lower boundary layer  
height and stable atmosphere, despite that nighttime MT emission rates are lower (e.g., Davison et al. 2009, Seco et al. 2013).  
The influence of chemical degradation on the surface exchange rates of isoprene, MT, and SQT was also investigated. While  
the impact of chemical degradation on isoprene exchange rates was negligible (<5%; less than EC flux uncertainties), a  
significant influence on the nighttime MT exchange rate was observed, with the exchange rate being on average ca. 10.8 %  
615 (varying from 6.8 to 14.1 %) greater than measured MT flux. This was far more evident with the overall SQT exchange rates,  
which diurnally were on average ca. 160 % (varying 130 to 180 %) greater during day and ca. 190 % (varying from 140 to  
230 %) greater during night than the measured SQT flux.

The impact of MT and SQT chemical speciation on SER with respect to chemical degradation should also be noted. This can  
620 have a large impact on the influence of chemical degradation with respect to the exchange rates of these compounds. For  
example, for  $\Delta^3$ -carene (the 2<sup>nd</sup> most commonly observed MT compound during the 2020 Norunda campaign, following  $\alpha$ -  
pinene) the reaction rates for the radicals OH, O<sub>3</sub>, and NO<sub>3</sub> are  $8.8 \times 10^{-11}$ ,  $3.7 \times 10^{-17}$ , and  $9.1 \times 10^{-12}$  cm<sup>3</sup> molec<sup>-1</sup> s<sup>-1</sup>, respectively  
(Atkinson, 1997). When these values are implemented in our quantification of chemical degradation effects on the MT SER  
rates, in lieu of the reaction rate constants for  $\alpha$ -pinene, it yields nighttime SER values that are ca. 12.6 % (varying 7.7 to 16.9  
625 %) greater than measured flux. This is an increase from the nighttime SER estimate based on the reaction rates of  $\alpha$ -pinene of  
ca. 10.8 % (varying 6.8 to 14.1 %) for this SER-to-flux comparison. Also present are MT compounds that are far more reactive  
than either  $\alpha$ -pinene or  $\Delta^3$ -carene. For example, relative to individual MT compounds, it was observed that the combined  
concentration of b-myrcene and d-limonene was exceeded only by  $\alpha$ -pinene and  $\Delta^3$ -carene. The OH, O<sub>3</sub>, and NO<sub>3</sub> rate constants  
for b-myrcene are  $2.2 \times 10^{-10}$ ,  $4.7 \times 10^{-16}$ , and  $1.1 \times 10^{-11}$  cm<sup>3</sup> molec<sup>-1</sup> s<sup>-1</sup>, while for d-limonene they are  $1.7 \times 10^{-10}$ ,  $2 \times 10^{-16}$ , and  
630  $1.22 \times 10^{-11}$  cm<sup>3</sup> molec<sup>-1</sup> s<sup>-1</sup>, respectively (Atkinson, 1997). When we substitute these reaction rate constants into our SER  
evaluation procedure, for our SER-to-flux comparison, we find for b-myrcene during nighttime ca. 24.6 % (varying from 16.7  
to 33.3 %) and during daytime ca. 17.5 % (varying from 13.1 to 21.8 %). Meanwhile, for d-limonene, we find during nighttime  
ca. 19.3 % (varying from 12.7 to 26.4 %) and during daytime ca. 10.8 % (varying from 7.9 to 13.4 %). These values are ca.  
2.4 and 1.8 times greater during nighttime, and ca. 3.8 and 2.3 times greater during daytime, for b-myrcene and d-limonene,  
635 respectively, than the corresponding increases found for  $\alpha$ -pinene. For the average concentration apportionment, over the  
course of the 2020 Norunda campaign, of the identified MT compounds  $\alpha$ -pinene,  $\Delta^3$ -carene, b-myrcene, d-limonene,  $\beta$ -pinene,  
and camphene, the mean values of their reactivities for OH, O<sub>3</sub>, and NO<sub>3</sub> are  $8.9 \times 10^{-11}$ ,  $9.79 \times 10^{-17}$ , and  $6.83 \times 10^{-12}$  cm<sup>3</sup>  
molecule<sup>-1</sup> s<sup>-1</sup>, respectively. When using these reaction rate constants instead of those of  $\alpha$ -pinene for the MT SER evaluation,  
this yields a diurnal SER estimate for total MT that is very close (~1%) to the estimate formed using the OH, O<sub>3</sub>, and NO<sub>3</sub>  
640 reactivities of  $\alpha$ -pinene, with a nighttime increase in SER from the measured MT fluxes of 12 % (varying from 7.7 to 15.7  
%), and a daytime increase of 6.1 % (varying from 4.3 to 7.8 %). This indicates that  $\alpha$ -pinene likely acts as a good proxy for

the mixture of MT emissions from this and similar boreal forests when attempting to infer the impact of chemical degradation on observed fluxes as collected using total MT measurement instruments such as PTR-ToF-MS.

645 For the speciated MT fluxes it has been observed that, despite the relatively large uncertainty involved with the speciated MT  
fluxes (compared to total MT EC flux measurements), the fraction of MT flux from the most common MT compound,  $\alpha$ -  
pinene, is somewhat higher than the fraction of their concentration relative to the other MT compounds (see Fig. 2 & 10). This  
condition is also found in other studies (e.g., Rinne et al. 2000). A potential explanation of this observation is the influence of  
chemical degradation, particularly with respect to more reactive compounds such as myrcene and d-limonene, during turbulent  
650 transport within and above canopy. Another potential influence on speciated MT flux versus concentration observations is  
from transport from outside the flux tower footprint. The observed concentrations used for gradient measurements are the  
result of emissions, sinks, chemical transformation and transport, whereas the observed fluxes reflect the emissions and sinks  
solely in the flux footprint of the tower.

## 5 Implications

655 A significant implication of this work is the role that seasonal changes can have on the speciation of MT compounds and  
subsequently their impact on air chemistry. BVOCs like MT influence the tropospheric ozone budget (Archibald et al. 2020).  
MTs also contribute to the formation and/or growth of atmospheric SOA due to the gas/particle partitioning of their reaction  
products in the troposphere. The structure of MTs has a significant role in their reactivity. For example, endocyclic  
monoterpenes (e.g., limonene,  $\alpha$ -pinene, and 3-carene) have a greater aerosol formation potential and tend to react faster than  
660 compounds with exocyclic double bonds (e.g.,  $\beta$ -pinene and camphene). b-myrcene, an acyclic monoterpene with three double-  
bonds, has a significant impact on the overall MT reactivity of MTs investigated by TD sampling, despite being at lower  
concentrations than many of the observed MT compounds. For example, in July, while less than 14% of total MT concentration,  
b-myrcene made up more than half (52 %) of overall observed MT ozone reactivity. Fast-reacting MTs can represent a  
significant fraction of total reactivity even at low concentrations (e.g., Yee et al., 2018). Subsequently, even small seasonal  
665 changes in their concentration can represent large changes in the reactivity of the overall MT population emitted.

From July to August, the average of the OH, ozone, and NO<sub>3</sub> reaction rate coefficients for the observed MT mixture decreased.  
This was mainly driven by month-to-month trends in the relative abundance of 3-carene and b-myrcene. While overall  
reactivity of MT towards OH, ozone, and NO<sub>3</sub> increased from July to August, due to an increase in overall MT concentration,  
670 that increase is less than would be expected if changes in speciation were neglected, particularly for ozone (from July to  
August, for example, a  $31 \pm 18$  % overestimate of ozone's MT reactivity). The relative average decrease in total oxidative  
capacity between July and August sampling periods amounts to  $16 \pm 1$  %, when evaluated at the average ozone and OH  
concentrations investigated during the TD sampling periods. This is primarily due to the impact of speciation changes on

675 ozone's oxidation capacity ( $\sim 24 \pm 4$  % decrease for ozone, vs.  $\sim 10 \pm 1$  % decrease for OH). At night, when NO<sub>3</sub> can form (modeled at 1pptv), and when average OH and ozone concentration are lower, this drop in total oxidative capacity was  $12 \pm 1$  % (decrease for NO<sub>3</sub>'s capacity was  $8 \pm 1$  %). While this is within the uncertainty of modeled OH, ozone, and NO<sub>3</sub> concentrations utilized in our evaluation of chemical degradation, it is still a significant difference that warrants further attention when considering the impacts of MTs on air chemistry at the landscape-scale for boreal forests in BVOC emission modeling.

680

While not the main focus of this investigation, the impact on SQT speciation is likewise significant. For example, at the 37 m height used for TD sampling, the measured concentration of longifolene greatly exceeds that of  $\alpha$ -humulene at a ratio of 80%-to-20%. However, the reactivity of  $\alpha$ -humulene towards ozone is more than  $2.3 \times 10^4$  times greater than that of longifolene. An approximate calculation using the same chemical degradation evaluation presented in this investigation indicates the converse for the speciation of these SQT emissions, indicating that  $\alpha$ -humulene emission dominates that of longifolene at a ratio of nearly 90%-to-10%. As can be seen, this presents a useful potential tool for investigating the landscape-scale speciation of SQT emissions.

690 Another potential implication is the determination of SQT surface exchange rates at the landscape-scale using a combination of measured fluxes and modeled F/E ratio. The breakdown of SQT has long-been a limiting factor in evaluating surface emissions based on observed fluxes (e.g., Duhl et al., 2008; Helmig et al., 2006; Pollmann et al., 2005). As demonstrated in this investigation, the determination of chemical degradation's impact on the surface exchange of reactive BVOC fluxes can be evaluated using station measurements of ozone and the radicals OH and NO<sub>3</sub>. While OH measurements have classically been difficult to conduct (e.g., Heard, 2006; Heard and Pilling, 2003; Stone et al., 2012), many stations regularly monitor 695 ozone, often the leading contributor to (by an order of magnitude (see Fig. A2)) to the SQT chemical degradation that attenuates observed SQT fluxes. In combination with GC-MS or more recent tools such as ultrafast GC (e.g., Materić et al., 2015) instrumentation to determine SQT speciation at PTR eddy-covariance inlet height, the use of PTR-ToF-MS eddy-covariance flux observations with this approach presents a promising avenue for evaluating landscape-scale surface exchange rates of SQTs and other highly reactive BVOC compounds in the future.

### Code and data availability

Station atmospheric and ecosystem data from the ICOS Norunda station is publicly available at <https://www.icos-sweden.se/norunda>. The campaign data and scripts are available from the authors upon request. The original Julia code for TOF-Tracer2 (e.g., Fischer et al., 2021), which was modified to process the raw Vocus PTR-ToF-MS spectral data, can be

705 found at <https://github.com/lukasfischer83/TOF-Tracer2>. The Matlab code for the eddy-covariance package InnFLUX (e.g.,  
Striednig et al., 2020) can be found at <https://www.atm-phys-chem.at/innflux>.

### Author contributions

JR, RCP, and TH initiated the study. JR and TH supervised the study and acquired the primary funding to support this research.  
CW, CM and RCP conducted the Vocus PTR-ToF-MS campaign measurements, and TH assisted with Vocus field calibration  
710 preparation and measurements. RCP performed the TD gradient sampling and laboratory analysis at Lund University. JC  
assisted with post-processing of GC-MS laboratory files following TD sample analysis. RCP conducted the main study analysis  
and prepared the manuscript and figures, with contributions from all co-authors.

## 1000 **Appendix sections:**

### **Determination of displacement height $d$ and the $\Gamma$ correction factor**

The displacement height  $d$  was determined using the velocity  $u$  and friction velocity  $u_*$  data from the vertical profile of sonic anemometers on the Norunda flux tower, using the approach described in Meelis et al. (1999), as well as with the empirical relation  $d = 0.86h$  found therein (where  $h$  is canopy height). The  $u$  and  $u_*$  data was filtered according to the selection criteria:  $u(87\text{ m}) - u(44\text{ m}) > 0.2\text{ m s}^{-1}$  and  $u_* > 0.1\text{ m s}^{-1}$ . Good agreement for the displacement height  $d$  was found for  $d = 24\text{ m}$ .

To correct the SLG flux measurements of speciated MT flux for the influence of the roughness sublayer (RSL) above canopy, the  $\Gamma$  correction factor was determined by integrating the profile for  $\gamma(z)$  above the canopy (and within the RSL) from the lower TD sampling height (37 m) to upper sampling height (60 m).

1010 The  $\gamma$ -coefficients above the canopy were calculated from the sensible heat flux  $H$ , temperature  $T$ , and friction velocity  $u_*$  from the sonic anemometer profile according to  $\gamma = \Phi_h^{MO}(\zeta) / \Phi_h^{meas}(z)$ , where  $\Phi_h^{MO}$  is the dimensionless gradient for sensible heat according to Monin-Obukhov similarity theory (where  $\zeta$  is the stability parameter  $(z-d)/L$ ),  $\Phi_h^{meas}(z)$  is the dimensionless gradient for sensible heat according to measurements on the flux tower,  $k$  is the von Kármán constant,  $\rho$  is the density of air, and  $c_p$  is the specific heat capacity of dry air. To minimize errors in the derivative of  $\theta(z)$  when calculating  $\Phi_h^{meas}(z)$ , the gradient  $d\theta/dz$  was determined by fitting the profile sonic data for potential temperature  $\theta(z)$  using the equation  $\theta = a + b\ln(z) + c\ln^2(z)$  (e.g., Mölder et al., 1999).

1020 Measured  $\gamma$  values during the TD sampling periods on June 8-10, July 22-24, and August 16-18, between 9:30 CEST to 17:00 CEST, were collected. This vertical  $\gamma$ -profile above forest canopy was then used to fit the coefficients for a continuous profile for  $\gamma(z)$ . We applied the following formula

$$\gamma \cong 1 + Ae^{-B(z-d)}, \text{ (A1)}$$

where  $A$  and  $B$  are undetermined coefficients. This fitting formula derives from consideration of Garratt (1980) and Harman and Finnigan (2007). Following nonlinear regression, the fitted coefficients were found to be  $A = 5.26$  and  $B = 0.12$  ( $\Delta A = 1.01$ ,  $\Delta B = 0.02$ ). A plot of the vertical  $\gamma$ -coefficient profile between the TD sampling levels at  $z_1=37\text{ m}$  and  $z_2=60\text{ m}$  during the 2020 Norunda campaign is shown in Figure A1 (the fitted curve for eq. A1 appears in blue).

1030

**Figure A1: Vertical profile of  $\gamma$  above the Norunda forest canopy during daytime TD sampling.** The x-axis shows the value of  $\gamma = 1/\phi_h = \Phi_h^{MO}(\zeta)/\Phi_h^{meas}$ , and the y-axis shows the normalized height  $z/h$ . Points indicate median  $\gamma$  ( $\pm$  standard error of median) measured from  $\Phi_h^{MO}(\zeta)/\Phi_h^{meas}$  during for the TD sampling periods (9:30 to 16:30 CEST; June 8-10, July 22024, & Aug 16-18). Blue points (near or within RSL) indicate  $\gamma$  used to fit function for the RSL layer. Dark blue curve indicates regression fit of  $\gamma = 1 + Ae^{-B(z-d)}$  to the measured  $\gamma$ -profile values ( $A = 5.26$ ,  $B = 0.12$ ). Vertical dashed line indicates  $\gamma = 1$ . Horizontal lines indicate (dashed black) displacement height  $d$ , (solid black) canopy height  $h$ , and (green) the  $z_1=37$  m and  $z_2=60$  m TD sampling heights.

1035

Using  $z_1 = 37$  m,  $z_2 = 60$  m,  $d = 24$  m, and fitted coefficients  $A = -5.26$  and  $B = 0.12$ , the integral of equation A1 was then used to determine a mean enhancement factor  $\Gamma = \frac{1}{z_2 - z_1} \int_{z_1}^{z_2} \gamma(z) dz$ . For the Norunda 2020 SLG flux measurements, this yielded  $\Gamma = 1.36 \pm 0.09$ .

1040

$$\Gamma(z_1 = 37 \text{ m}, z_2 = 60 \text{ m}) = \frac{1}{z_2 - z_1} \int_{z_1}^{z_2} \gamma(z) dz = \frac{A}{B} \left[ \frac{e^{-B(z_2-d)} - e^{-B(z_1-d)}}{z_2 - z_1} \right] + 1 \cong 1.36. \text{ (A2)}$$

The uncertainty of this fitted estimate was determined using the standard errors of coefficients A and B, and propagation of uncertainty  $\Delta\Gamma = \sqrt{\left(\frac{\partial\Gamma}{\partial A} \Delta A\right)^2 + \left(\frac{\partial\Gamma}{\partial B} \Delta B\right)^2} \cong 0.09$ .

1045

### Effect of chemical degradation on isoprene, MT, and SQT surface exchange rates (model calculations)

The effect of chemical degradation on isoprene, MT, and SQT surface exchange rates was explored using the modeling supplement of Rinne et al. (2012), which made use of a stochastic Lagrangian transport chemistry model, and by parameterizing the reaction rates for ozone, OH and NO<sub>3</sub>, to estimate the surface exchange rates for the 2020 Norunda campaign's terpenoid EC flux dataset.

The impact of chemical degradation on measured fluxes of reactive compounds is closely related to the ratio the mixing timescale  $\tau_t$  to the compound's chemical timescale  $\tau_c$ , also known as the Damköhler number  $Da$  (Damköhler 1940), which can be written as

$$Da = \frac{\tau_t}{\tau_c}. \text{ (A3)}$$

In the case of  $Da \ll 1$ , the flux at the measurement height closely corresponds to the emission rate. For relatively large  $Da$  values, however, the compound will be impacted by chemical degradation before reaching the measurement height, and the observed flux will be lower than the primary emission.

To estimate the flux-to-emission ratio (F/E) from measured  $Da$ -number ratios, lookup tables were used from the supplementary materials provided by Rinne et al. 2012. These tables relate the canopy-top Damköhler number ( $Da_h$ ) to the flux-to-emission ratio (F/E) for specific normalized heights  $z/h$  above the forest canopy-top height  $h$ . In this model, the LAI of the canopy, modeled according to the typical profile of a Scotts pine forest, is 3.5. For comparison, LAI at Norunda is  $3.6 (\pm 0.4) \text{ m}^2 \text{ m}^{-2}$  (Petersen et al., 2023). Using an approximation for the mixing timescale of  $\tau_t = z/u_*$ , the canopy-top Damköhler number ( $Da_h$ ) was calculated using the relation

$$Da_h = \frac{h}{u_* \tau_c}, \text{ (A4)}$$

Where the friction velocity  $u_*$  was measured at 37 m on the station flux tower (see example station BVOC inlet setup in Fig. 1 of the main text),  $h$  is the canopy height (28 m), and  $\tau_c$  is the chemical lifetime of a given BVOC compound. The chemical lifetime  $\tau_c$  can be calculated as

$$\tau_c = \left( k_{X,OH}[OH] + k_{X,O_3}[O_3] + k_{X,NO_3}[NO_3] + k_{X,photolysis} \right)^{-1}, \text{ (A5)}$$

where  $[OH]$ ,  $[O_3]$ , and  $[NO_3]$  are the concentrations of OH,  $O_3$ , and  $NO_3$ , respectively, and where  $k_{X,OH}$ ,  $k_{X,O_3}$ , and  $k_{X,NO_3}$  are the reaction rate constants between the compound of interest  $X$  (i.e., isoprene, MT, SQT, ect.) and the radicals OH,  $O_3$ , and  $NO_3$ , respectively. Finally,  $k_{X,photolysis}$  is the photolysis rate of compound  $X$ . As  $k_{X,photolysis}$  for isoprene, MT, and SQT is much less than the rate of reactions with radicals OH,  $O_3$ , and  $NO_3$ , as in Rinne et al. (2012), it is dropped from subsequent calculations.

The reaction rate constants for isoprene,  $\alpha$ -pinene and  $\beta$ -caryophyllene with respect to OH,  $O_3$ , and  $NO_3$  used for the Norunda 2020 campaign SER analysis are shown in table A3.

For the 2020 Norunda campaign SER analysis, modeling of the diurnal cycle of OH and  $NO_3$ , as well as local ozone data from the nearby Norunda-Stenen monitoring site, were used to calculate the timeseries of  $\tau_c$  for isoprene, MT, and SQT, to then calculate  $Da_h$  for applying the Rinne et al. (2012) F/E lookup tables.

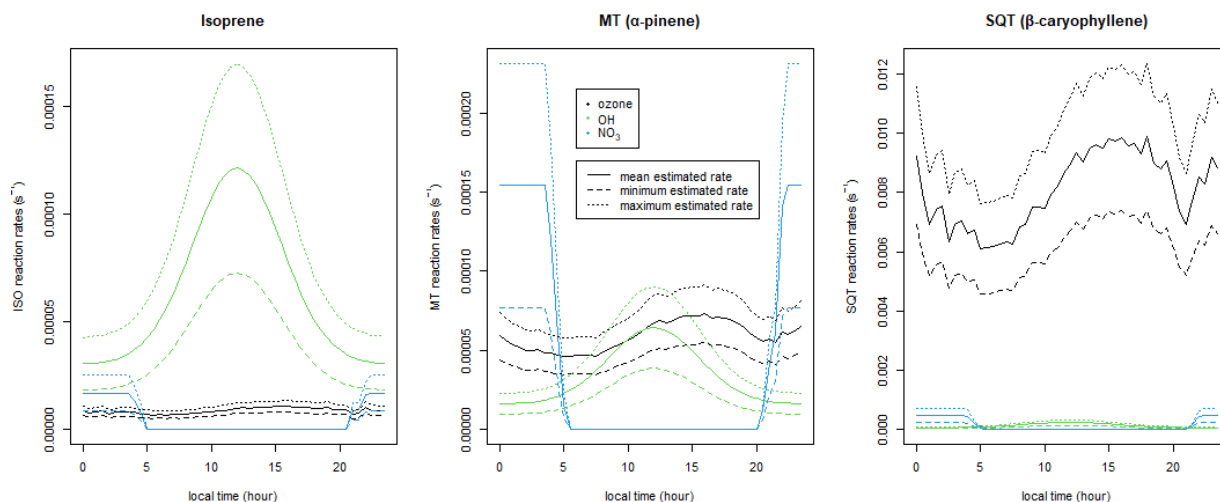

The radicals OH and  $NO_3$  were diurnally simulated for the  $Da_h$  calculations. The modeling choices for OH and  $NO_3$  were informed by the HUMPPA-COPEC-2010 measurement campaign in Hyytiälä, Finland, and the settings implemented in Rinne et al. (2012). The OH concentration was assumed to vary diurnally between  $0.3 \times 10^6$  and  $1.2 \times 10^6$  molecules  $cm^{-3}$  over a Gaussian peak profile ( $t_{mean} = 12:00$  CEST,  $\sigma_t = 3.5$  hrs). The uncertainty  $\Delta OH$  was assumed to be 40% of concentration.

$NO_3$  was assumed to vary as a step function, with a daytime concentration of zero and a nighttime concentration of  $2.5 \times 10^7$  molecules  $cm^{-3}$  (1 pptv), consistent with the breakdown of  $NO_3$  under direct sunlight. The  $NO_3$  concentration was assumed to linearly ramp between daytime and nighttime values during a 30-min widow before the daily sunrise and after daily sunset. The uncertainty  $\Delta NO_3$  was assumed to be 50% of concentration.

The ozone data used for the  $\tau_c$ -calculations came from the Norunda-Stenen monitoring station (1.4 km east of Norunda flux tower). To accurately reflect above-canopy nighttime concentrations, as model ozone data was collected well below canopy height, a nighttime minimum concentration was set at  $5 \times 10^{11}$  molecules  $cm^{-3}$  (ca. 20 ppbv). This conforms with previous campaign studies of the diurnal vertical ozone profile within and above the Norunda forest summer canopy (Petersen et al. 2023), where a significant nighttime sink was observed below canopy height (28 m). The uncertainty  $\Delta O_3$  was assumed to be 25% of concentration.

The diurnal mean reaction rates of ozone, OH, and  $NO_3$  with isoprene, as well as with  $\alpha$ -pinene and  $\beta$ -caryophyllene (used as examples for MT and SQT, respectively), are shown in Fig. A2 below.

1100

**Figure A2: Diurnal mean reaction rates of ozone (black), OH (green), and NO<sub>3</sub> (blue) for isoprene, MT ( $\alpha$ -pinene) and SQT ( $\beta$ -caryophyllene). Lines indicate the mean (solid) reaction rates, as well as the minimum (dashed) and maximum (dotted) -estimated values of the reaction rates based on the concentrations of OH, O<sub>3</sub>, and NO<sub>3</sub> as well as the uncertainties  $\Delta$ OH,  $\Delta$ O<sub>3</sub>, and  $\Delta$ NO<sub>3</sub>.**

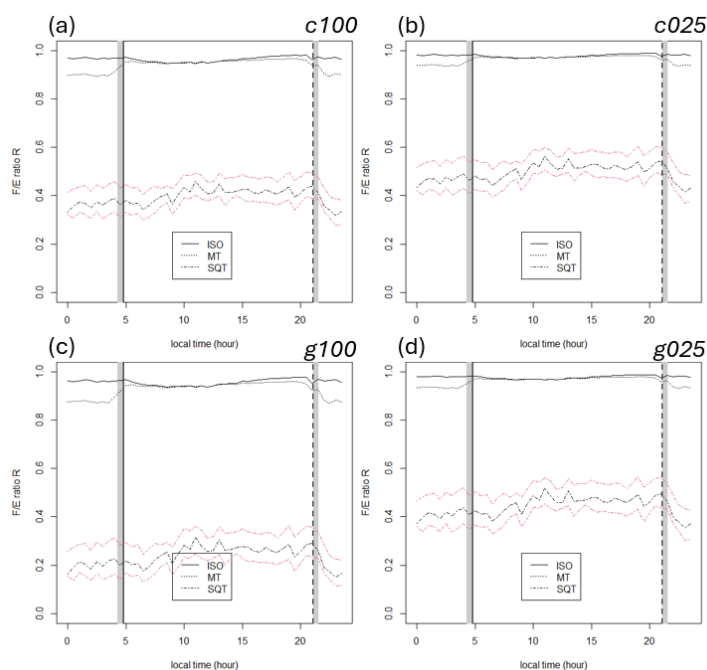

1105

For the estimate of F/E from  $Da_h$ , the lookup tables were used from the supplementary materials provided by Rinne et al. 2012. These tables relate the canopy-top Damköhler number ( $Da_h$ ) to the flux-to-emission ratio (F/E) for specific normalized heights  $z/h$  above the forest canopy-top height  $h$ . In this model, the LAI of the canopy, modeled according to the typical profile of a Scotts pine forest, is 3.5.

1110

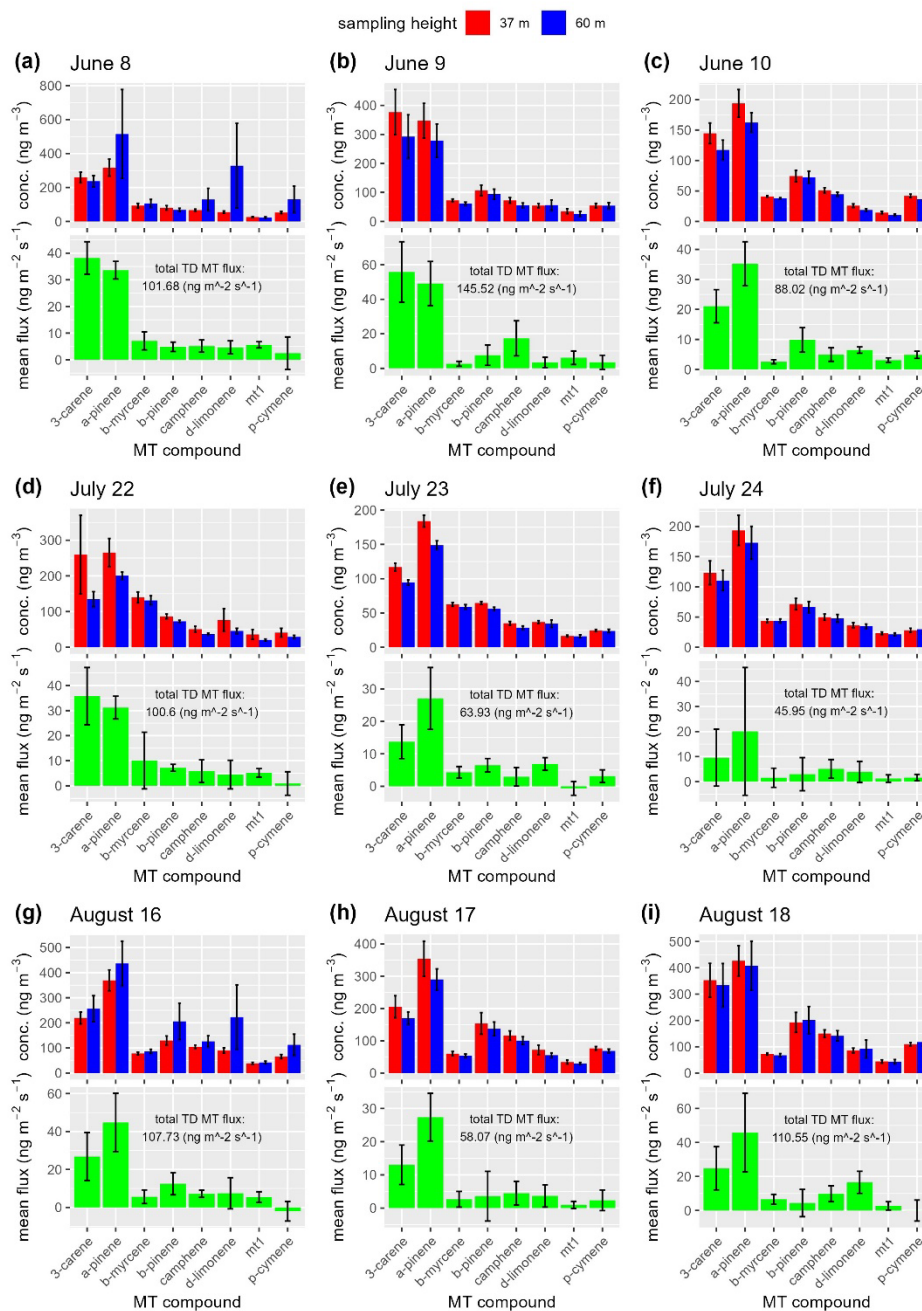

The F/E modeling also includes the output for different parameterizations, such as canopy-source emission vs ground-source emission, as well as the relative scaling of oxidation rates above vs below-canopy. Several examples of the estimated diurnal F/E ratios for the 2020 Norunda campaign under these different parameterizations are shown below (Fig. A3).

1115 The ground source, for example, is likely appropriate for certain types of forest floor SQT emission (cite  
field studies) In addition, daytime mixing may lead to equal or similar oxidation levels above and below  
canopy, as the canopy is well-mixed, while nighttime oxidation rates can become very stratified within  
stable canopy air, as was frequently observed for vertical profile of ozone within the Norunda canopy at  
night (see Fig. 7 therein). For the SER estimates presented in the main text, the source is modeled as being  
in the canopy, and the relative oxidation rates above and below canopy are modeled as being equal. For  
1120 SQT (and for predominantly a canopy source), this can be addressed by interpolating between table  
*lookup\_C\_o025.txt* (i.e., nighttime stratified ozone) and table *lookup\_C\_o100.txt* (i.e., daytime well-mixed  
ozone) using the Monin-Obukhov atmosphere stability length  $L$ .

1125 **Figure A3: Diurnal F/E ratios for isoprene, MT ( $\alpha$ -pinene) and SQT ( $\beta$ -caryophyllene) for a range of different model parameterizations. (a, b) parameterized for canopy source. (c, d) parameterized for ground source. (a, c) below-canopy oxidation rate equals that of above-canopy. (b, d) below-canopy oxidation rate 0.25x that of above-canopy. The estimated F/E ratios for the minimum and maximum of the ozone, OH, and NO<sub>3</sub> reactions rates are shown as dashed red lines.**

**Appendix figure: Daily mean concentrations and fluxes of MT compound species**

1135

**Figure A4: Daily mean concentrations of MT compound species at 37 m (red) and 60 m (blue) on the station flux tower at the ICOS Norunda boreal forest, as well as daily mean speciated MT fluxes (green), during June 8 – 10 (a – c), July 22 – 24 (d – f) and August 16 – 18 (g – i). Vertical error bars indicate the standard mean error.**

### Comparison of friction velocity and sensible heat flux between 37 and 60 m

1140 For Table A1, the data was divided into three wind-direction classes based on the two prevailing wind directions (between 245°-310° and 310°- 80°) during the campaign TD sampling on the Norunda flux tower on June 8-10, July 22-24, and August 16-18. The heterogeneity of the forest tree heights can be observed from the lidar height map presented in Fig. 3.
