Abstract. A predicted consequence of ocean acidification is its negative effect on the pools of Particulate Inorganic Carbon (PIC) that are essential for ‘ballasting’ the sinking of organic carbon, potentially leading to decreased subsurface oxygen. To explore such possible feedbacks, we investigated the relationships between PIC, coccolithophores, carbonate chemistry, and dissolved oxygen in the Southeast Pacific open ocean oxygen minimum zone, which naturally exhibits extremely low dissolved oxygen, low pH, and high $p\text{CO}_2$ levels. Measurements of PIC and coccolithophore counts during late-spring 2015 and mid-summer 2018 revealed that coccolithophores, particularly *Gephyrocapsa (Emiliana) huxleyi*, significantly contributed to PIC through the shedding of coccoliths in the upper waters. On average, about a half of the PIC was attributed to countable coccoliths, with significantly diminished quotas observed below the euphotic depth. Temperature, oxygen, and pH were identified as key variables influencing PIC variation. PIC quotas were similar to those reported in other upwelling zones. However, PIC:POC ratios were substantially lower than what has been reported both in other open ocean and coastal margin areas, an effect that was more pronounced within the vertically defined oxygen minimum zone core. This study contributes to understanding the role of coccolithophores in PIC pools and suggests that the presence of low O_2 /low pH subsurface waters does not inhibit coccolithophore PIC quotas but may decrease the role of PIC in ballasting the export of organic carbon.

1 Introduction

25 The Particulate Inorganic Carbon (PIC) pool, a significant component influencing marine C cycles and atmospheric reservoirs (Ridgwell and Zeebe, 2005), originates from various sources, including land transport to coastal margins (Cai, 2011) and biological processes such as phytoplankton calcification (Taylor and Brownlee, 2016). Coccolithophores, particularly the cosmopolitan species *Gephyrocapsa (Emiliana) huxleyi*, significantly contributes to PIC through coccolith production, impacting C sequestration and nutrient cycling in the global pelagic ocean (Monteiro et al., 2016; Balch, 2018). In turn, changes in PIC dynamics driven by alterations in coccolithophore community at different spatial and temporal scales feedback into the ocean-atmosphere system (Balch et al., 2016; Claxton et al., 2022). For example, ocean acidification (OA or decreased pH and

30

carbonate ion concentration) can impair coccolithophore calcification (Riebesell et al., 2000; Barcelos e Ramos et al., 2010; von Dassow et al., 2018; Kottmeier et al., 2022; von Dassow, 2022), which could lead to diminished CaCO_3 fluxes to the seafloor, favouring the respiration of more organic material and potentially decreasing both organic C flux and mid-water O_2 levels (Hofmann and Schellnhuber, 2009; Zhang et al., 2023). In this context, the relationships between coccolithophore PIC quotas with $\text{pH}/p\text{CO}_2$ and O_2 in natural oxygen minimum zones (OMZs), where pH and O_2 levels can become extremely low, are of particular interest.

While the Atlantic Ocean and the Atlantic sector of the Southern Ocean have been more extensively sampled for PIC, the Pacific Ocean remains underrepresented in PIC and coccolithophore data, although information is accumulating on coccolithophore distributions in the Indian Ocean, the subpolar Pacific, and the Southern Ocean (Balch et al., 2018; Oliver et al., 2023). Early satellite imagery showed relatively lower PIC levels in extensive upper Pacific waters compared to the Atlantic (Brown and Yoder, 1994). However, higher subsurface PIC concentrations, at depths greater than the detection limit of satellites, have been associated with coccolithophore blooms in remote Southeast Pacific waters (Beaufort et al., 2008; Oliver et al., 2023). The Great Calcite Belt, a remarkable basin-scale coccolithophore feature in the Southern Ocean, is primarily sustained by the growth of *G. huxleyi* (Balch et al., 2016; Balch and Mitchell, 2023) and has attracted particular attention, as it progresses southward every year with peaks in the austral summer (Hopkins et al., 2019). Temperature, competition with diatoms for nutrients, and Fe availability have been proposed as factors controlling coccolithophore distributions in the Southern Ocean (Oliver et al., 2023 and references therein).

Vast OMZs are a persistent feature of the tropical and subtropical Eastern Pacific (Schmidtko et al., 2017), and it is known that these zones tend to have low pH and high $p\text{CO}_2$ levels (Torres et al., 2002, 2011; Beaufort et al., 2011; Vargas et al., 2017; Vargas et al. 2021). Although the pH and $p\text{CO}_2$ levels in these waters can inhibit coccolithophore growth and calcification in laboratory settings, field observations suggest more complex relationships (Beaufort et al., 2011; Müller et al., 2015; von Dassow et al., 2018). Nevertheless, there is still very limited data on how PIC, POC, pH , and O_2 might interact in OMZ systems. Here, we present measurements of PIC alongside counts of coccolithophores and estimates of PIC derived from them, collected during sampling in spring 2015 and summer 2018 off the Southeast Pacific margin ($\sim 20\text{-}35^\circ \text{S}$). We estimate the proportion of total PIC accounted for by coccospheres and detached coccoliths pools and examine how these coccolithophore-PIC quotas correlate with various physical and chemical parameters, with a particular focus on the effects of low pH /high $p\text{CO}_2$ conditions associated with O_2 -deficient waters. Additionally, we discuss other in-situ variables recognized as factors influencing coccolithophore growth. Finally, we compare the PIC concentrations in the Southeast Pacific with those reported in other oceanic regions.

2. Materials and Methods

2.1 Sampling

The sampling consisted of two cruises conducted in waters off the Southeast Pacific margin, north-central of Chile (Fig. 1a). In spring 2015 (LowpHOX 1), we vertically screened six stations along an inshore-offshore transect off Iquique (~20° S; sts. T1-T6), along with six stations arranged latitudinally between 22° S and 29.5° S (sts. L1-L6). During summer 2018 (LowpHOX 2), three of the inshore-offshore stations were replicated (sts. T1, T3, T5), along with seven stations sampled southward down to ~34° S (sts. Lander and Hydro; Fig. 1a). In depth, the sampling crossed both the euphotic zone and OMZ core (Fig. 1b, 2c-e, k-n). The predominant oceanographic conditions during these two cruises, as reported and discussed by Vargas et al., (2021), provide the context for the new data presented here.

At each station, discrete seawater samples were collected, filtered, stored, and moved to the lab for the determination of PIC (section 2.2) and coccolithophore standing stocks (section 2.3). Due to seawater availability onboard in 2018, sampling for coccolithophores only reached 100 m, except for station T5, which reached a depth of 2000 m. This contrasts with 2015 sampling reaching equal or greater 350 m depths (max. 1000 m in T3 and T4). Complete PIC measurements and coccolithophore abundances are provided in the Supplement (Tables S1-S2). As ancillary data, 1-m averaged SST, SSS, oxygen, and fluorescence continuous profiles, as well as, discrete profiles of Chl-*a*, nutrients, Particulate Organic Carbon (POC), and carbonate system were included (see methods in Vargas et al., 2021). These physical and chemical data were extracted from Vargas et al. (2023a, b, c). The euphotic depth (Z_{eu}) was estimated by calculating the depth at which the Photosynthetically Active Radiation (PAR) is reduced to 1 % of surface levels, using the attenuation coefficients ($K_d(490)$) provided by the Bio-Geo-Chemical products based on the Copernicus-GlobColour processor. The averaged $K_d(490)$ values (3 x 3 pixels and 3-day average) were converted into $K_d(PAR)$ values following the model of Morel et al. (2007), and the 4.6 optical depth calculated as $\ln(100)/K_d(PAR)$ (Morel, 1988). Where available, a good fit was found between the euphotic zone depth derived from satellite observations and PAR obtained from a sensor attached to the CTD (Fig. S1). Lastly, the OMZ core was defined to be within the thresholds of 5 % of the maximum O_2 concentration at each station occurring between 0 and 34 m depth.

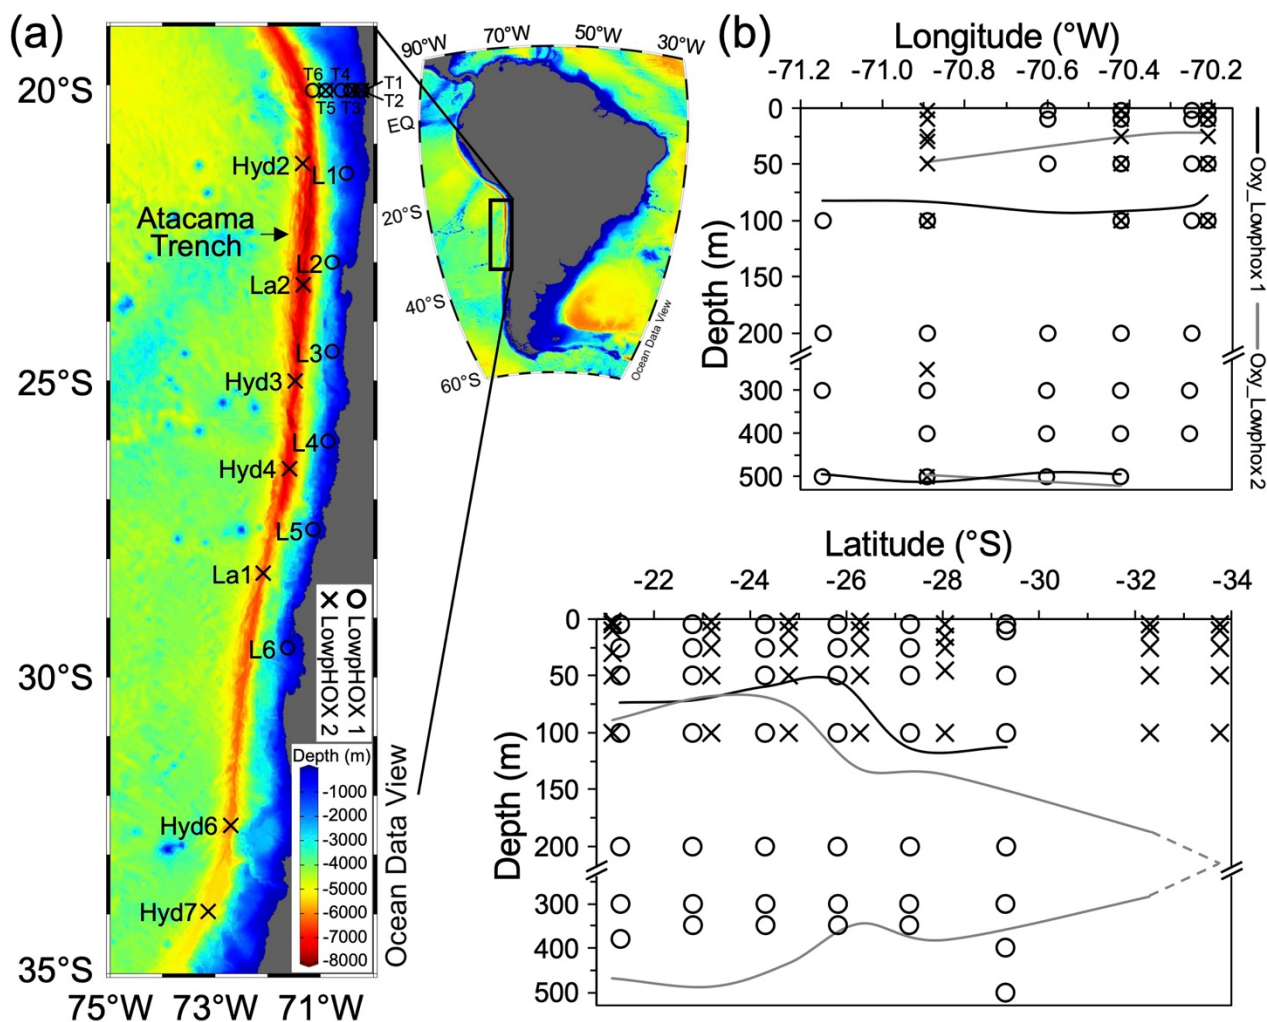

2.2 Particulate inorganic carbon standing stocks

For the measurements of PIC (hereinafter referred to as PIC_{Total}), we followed a slightly modified version of the procedure introduced by Poulton et al. (2006). In summary, we filtered between 0.1-1.5 L of seawater (increasing with sampled depth) onto 25 mm polycarbonate filters with a 0.4 μm pore size. The filters were immediately rinsed with a squirt of potassium tetraborate solution (to maintain $\text{pH} > 8.0$ while in storage) and stored in metal-free Falcon tubes at -20° C until transit to the lab. Subsequently, Ca^{2+} was extracted with nitric acid and quantified using Inductively Coupled Plasma Atomic Mass Spectrophotometry facilities at the Bigelow Laboratory for Ocean Sciences. A correction was made to correct for potential excess of Ca^{2+} due to Na^+ residues that might be left on the filters. The PIC calculations were expressed in mmol C m^{-3} . We

examined the association between calcification (PIC) and POC (from Vargas et al., 2021) using PIC:POC ratios. Moreover, PIC:POC ratios were built (both PIC_{Cocco} and PIC_{Total} values recorded in 2015 and 2018 are mostly equivalent building
 95 PIC:POC ratios, except for a large mismatch at the 2015 station L4, see Fig. S2), and binned above, within, and below the OMZ core, to assess the influence of this OMZ on PIC and POC concentrations. These ratios were plotted against those reported for other open ocean or coastal margins (see Balch et al., 2018). To that, PIC and POC data was obtained from the SEABASS (Werdell et al., 2003) and BCO-DMO repositories (Balch, 2010), and PIC:POC ratios binned at surface (< 5 m depth), sub-surface (5-100 m), and below surface layers (100-500 m).

Figure 1: (a) Map of the Southeast Pacific margin showing the study site and stations sampled during late-spring 2015 (circles) and mid-summer 2018 (crosses). (b) Sampling depth coverage for coccolithophores, highlighting areas crossing the OMZ core (black and grey lines), defined as the depths within 5 % of the maximum O₂ concentration at each station. Note the OMZ core at stations T1-T2 and in the 2015 latitudinal section extends to the seafloor. ‘Oxy’ indicates the oxycline. Map produced by Ocean Data View (Schlitzer, 2024), with bathymetry based on the GEBCO chart (GEBCO, 2023).

2.3 Coccospheres and detached coccoliths standing stocks

For enumeration of coccospheres and detached coccoliths, between 0.1 to 1.0 L of seawater (increasing with depth) were filtered onto 25 mm polycarbonate filters with a 0.8 μm pore size, left to dry at room temperature in Petri dishes, and stored with desiccant until microscopy analyses. The counts of total coccospheres were made as described in Díaz-Rosas et al. (2021), through cross-polarized light microscopy (Zeiss, Axioscope 5) covering 5.1 mm^2 of the filter area corresponding to a range of 1.9-16.3 mL of seawater analysed. For counts of total detached coccoliths, eleven fields of view per filter were screened (224 x 165 μm per frame) at 630x magnification (oil immersion objective), covering 0.41 mm^2 of the filter area, corresponding to total volumes of 0.2-1.3 mL of seawater analysed. An issue arose where the filters from inshore-offshore 2015 sampling (20° S; Stations T1-T6) exhibited excessive brightness under cross-polarized light microscopy, for which counts were made through scanning electron microscopy (SEM) analysis (Quanta FEG 250). For the quantification of coccosphere abundances (see equation in Díaz-Rosas et al., 2021), between 28-48 images taken at 800-1500x magnification were examined per filter, covering from 5 to 6 mm^2 of the filter area corresponding to a range of 2.1-18.4 mL of seawater analyzed. For total detached coccolith abundances, between 4-5 images were examined per filter, covering from 0.6 to 1.0 mm^2 of the filter area corresponding to a range of 0.2-2.8 mL of seawater analyzed. Layers of coccoliths detached from *G. huxleyi* (Fig. S3a-d) were added to the detached-coccolith counts. Collapsed coccospheres were included when they remained mostly intact, but when more disintegrated could not be accurately counted, especially as they were often less reflective than intact coccospheres and coccoliths (Fig. S3e-h). In a subset of samples, collapsed coccospheres were estimated to contribute < 21 % (min. = 0 %, average = 7.1 %) of the total number of coccospheres. To check for differences between counts obtained through cross-polarized light microscopy and SEM examination, five samples with varying coccolithophore abundances were analyzed with SEM as outlined above, revealing a good fit between coccosphere and coccolith abundances from both methods (Fig. S4), allowing for comparison.

2.4 Diversity of coccospheres and detached coccoliths

SEM was used for samples from T1 to T6 and L1 (at 5 and 25 m), L2 (at 5 and 50 m) and L3 (at 5 m) in 2015, classifying coccospheres and detached coccoliths according to Young et al. (2003). Between 6 to 11 and 4 to 5 images per filter, depending on magnification, were examined for coccospheres and coccoliths classification, respectively. To estimate the absolute abundances of coccospheres and coccoliths at the species or genus level, the relative abundance of each species or genus was multiplied by the total coccospheres and coccoliths abundances. Due to limited resolution, it was not always possible to differentiate between *G. parvula* and *G. ericsonii* coccospheres, so they were merged into the *G. parvula/ericsonii* category, which is phylogenetically supported (Bendif et al., 2016, 2019). Moreover, as some of the small coccoliths detached from *G. parvula/ericsonii* might be overlooked (2.0 μm in length), the few coccoliths found in distal-shield view, and the coccoliths from *G. huxleyi* (3.6 μm in length) were merged into the *Gephyrocapsa* < 4 μm category. Larger coccoliths (> 5 μm in length) were classified into species or genus, being subtracted from total counts of coccoliths obtained in the same SEM image (see

above) to obtain the number of coccoliths $< 4 \mu\text{m}$. Most rare detached coccoliths were grouped in the miscellaneous category that include *Syracosphaera* spp., *Acanthoica* spp., *Discosphaera tubifera*, *Umbellosphaera* spp., and *Umbilicosphaera* spp. Moreover, the counts of detached coccoliths from *Calcidiscus leptoporus* might contain a few coccoliths of *Oolithotus* spp. as it was not always possible to differentiate them. In all surface samples taken in 2018, as well as in samples L4 to L6 from 2015, species dominating the coccosphere and coccolith pools were identified using cross-polarized light microscopy (63x objective, Zeiss Axioscope 5) following Frada et al. (2010).

145 2.5 Coccolithophore specific PIC quotas

The taxonomic classification of coccospheres and coccoliths was used to estimate the specific PIC quotas of coccospheres + coccoliths (hereinafter referred to as $\text{PIC}_{\text{Cocco}}$) by employing conversion factors according to Young and Ziveri (2000). To obtain the coccolith mass (in pg CaCO_3), the cube of the mean distal-shield length of coccoliths (= biovolume in μm^3) measured in the SEM images (see Table S3) was multiplied by the respective shape factor (K_s taken from Young and Ziveri (2000), and by the density of calcite (2.7 g cm^{-3}). Then, the absolute abundances of coccospheres and detached coccoliths were multiplied by the coccolith mass, and the $\text{PIC}_{\text{Cocco}}$ stocks expressed in mmol C m^{-3} . Before the conversion, the number of coccospheres was converted to coccoliths by using the compilation of coccoliths per coccosphere in Yang and Wei (2003). For *G. huxleyi*, the 17 coccoliths per coccosphere determined by Beaufort et al. (2011) in the study site was applied in agreement with those seen in SEM images. We did not account for variation in coccoliths per coccosphere or in mass content per coccolith among *G. huxleyi* morphotypes. The $\text{PIC}_{\text{Cocco}}$ is then given by the sum of coccolith mass composed by coccospheres and detached coccoliths. This procedure was then applied to all the samples, using the *G. huxleyi* PIC quota (mass = 2.5 pg CaCO_3 per coccolith; see Table S3) as a maximum threshold, a situation observed during blooms (see below).

3 Results

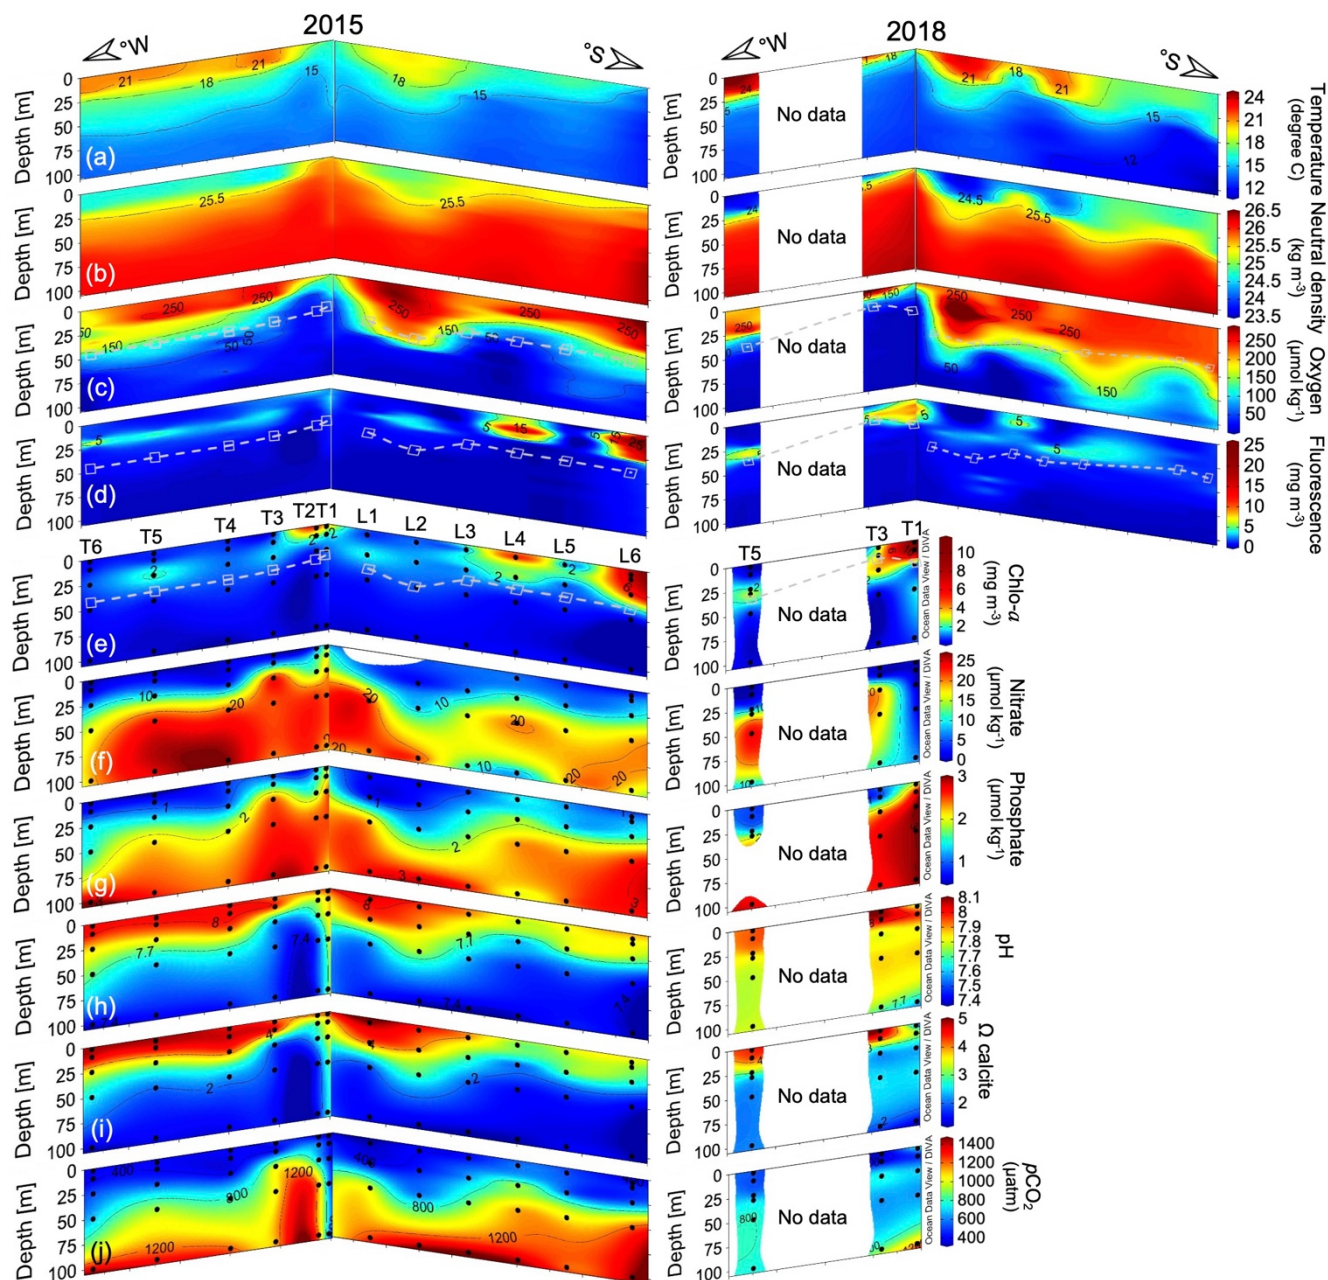

3.1 Oceanographic conditions. Standing stocks of coccolithophores, PIC, POC, and PIC:POC ratios

160 Surface (mixed) layer temperatures exceeded $21 \text{ }^\circ\text{C}$ to the north and offshore, while surface temperatures were below $17 \text{ }^\circ\text{C}$ near the coast, in the north and south of 21° and 24° S latitude in 2015, and south of 29° S in 2018 (Fig. 2a). The pycnocline (Fig. 2b) and oxycline (Fig. 2c) roughly paralleled the thermocline in both years. In 2015, the oxycline was always in the upper 50 m. In 2018, the depth of the oxycline increased to between 50 and 75 m south of 26° S. The estimated Z_{eu} was often near the base of the oxycline (Fig. 2c). At all stations, the oxycline and Z_{eu} were always shallower than 100 m. In these well-illuminated waters, peaks of phytoplankton were observed in both 2015 and 2018 (Fig. 2d-e).

Nitrate and phosphate levels were low above the pycnocline (< 10 and $< 1 \mu\text{M}$, respectively), and increased below (to approximately $20 \mu\text{M}$ and $2 \mu\text{M}$ respectively; Fig. 2f-g). Both pH and Ω calcite declined sharply while $p\text{CO}_2$ increased with depth through the oxycline (Fig. 2h-j). Increased nitrate coincided with higher $p\text{CO}_2$ and lower pH (Fig. S7). In this upwelling zone, high nitrate levels are associated with lower pH (Fig. S7b). At depth, decomposition depletes oxygen while releasing

170 nitrates and CO_2 , and as nitrate-rich waters rise to the surface, they bring low oxygen/low pH and high $p\text{CO}_2$ with them (Fig. S7c-d). The more nitrate present, the more oxygen has likely been consumed in deep waters before upwelling. As interchange with the atmosphere and photosynthesis occurs, oxygen levels rise, $p\text{CO}_2$ decreases, pH increases, and calcite stability increases (higher Ω calcite; Fig. S7d-f). Additionally, high $p\text{CO}_2$ concentrations result in low pH and Ω calcite in these waters (Fig. S7g-i).

175

Figure 2. Spatial variation in physical-chemical-biological parameters along with PIC_{Total} and coccolithophore standing stocks and their contribution to PIC (PIC_{Cocco}) recorded during late-spring 2015 (left) and mid-summer 2018 (right). Temperature (a), neutral density (b), oxygen (c), fluorescence (d), $Chl-a$ (e), nitrate (f), phosphate (g), pH (h), Ω calcite (i), pCO_2 (j), PIC_{Total} (k), coccospheres (l), detached-coccoliths (m), and PIC_{Cocco} sections (n) versus long-lat and depth with sample locations (solid black circles). Continuous profiles shown in (a-d) are 1-m binned. Dashed grey lines indicate the euphotic depth in plots c-e and k-n. PIC = Particulate Inorganic Carbon. All-depth profiles of variables in plots e and k-n are provided in Supplementary Figures S5-S6.

180

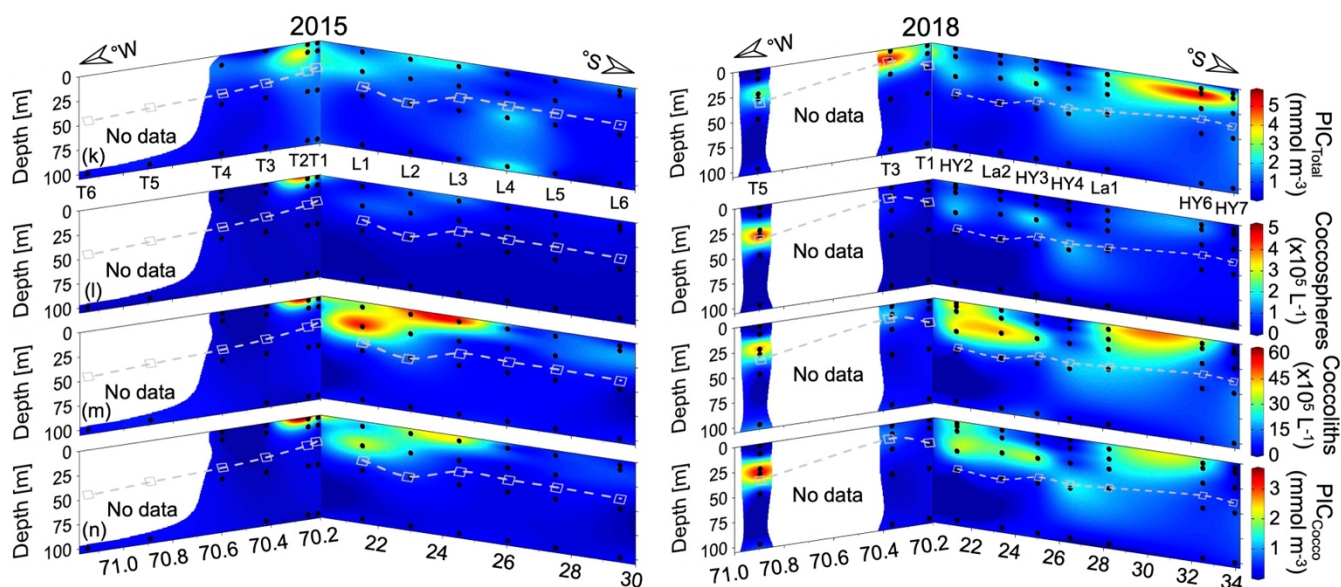

Figure 2. continuation.

In late-spring 2015, the highest abundances of coccospheres ($> 3.0 \times 10^5 \text{ L}^{-1}$) and detached coccoliths ($> 45 \times 10^5 \text{ L}^{-1}$), along with $\text{PIC}_{\text{Total}}$ ($> 3 \text{ mmol m}^{-3}$) and $\text{PIC}_{\text{Cocco}}$ quotas ($> 2 \text{ mmol m}^{-3}$), were found in surface or near-surface waters ($< 25 \text{ m}$ depth) closer to the coast at $\sim 20^\circ \text{ S}$ (stations T1-T2), extending south to $\sim 24^\circ \text{ S}$ (stations L1-L3; Fig. 2k-n). Two years later, in mid-summer 2018, the highest surface stocks of coccolithophores (5.2×10^5 coccospheres L^{-1}), $\text{PIC}_{\text{Total}}$ (5.3 mmol m^{-3}), and $\text{PIC}_{\text{Cocco}}$ (3.7 mmol m^{-3}) were found at $\sim 20^\circ \text{ S}$ (stations T3 and T5), as well as southward between $\sim 22\text{-}25^\circ \text{ S}$ and $\sim 28\text{-}33^\circ \text{ S}$ (Fig. 2k-n). Throughout the station depths, $\text{PIC}_{\text{Total}}$ ranged from 0.18 to 3.81 mmol m^{-3} in 2015 and from 0.08 to 5.86 mmol m^{-3} in 2018 (Fig. 2k). Coccosphere abundances reached maxima of 3.9×10^5 and $5.2 \times 10^5 \text{ L}^{-1}$, and abundances of detached coccoliths reached maxima of 63×10^5 and $49 \times 10^5 \text{ L}^{-1}$ in spring 2015 and summer 2018, respectively (Fig. 2l-m). Over these abundance ranges, coccospheres and detached coccoliths varied in direct proportion (Fig. S8). In surface waters (0-30 m), the ratio of coccoliths to coccospheres in 2015 averaged 39 (range: 4-104; $n = 20$) and 40 in 2018 (range: 6-287; $n = 32$). The estimated PIC quotas produced by coccolithophores ranged from 0.02 to 3.60 mmol m^{-3} in 2015 and from 0.01 to 3.69 mmol m^{-3} in 2018 (Fig. 2n). Coccosphere and coccolith abundances, as well as PIC quotas, diminished substantially below 50 m depth ($\sim Z_{\text{eu}}$) (see Fig. S5-S6).

Across all samples, POC ranged from 22.7 to $250.0 \text{ mmol m}^{-3}$ in 2015 and from 26.1 to $501.6 \text{ mmol m}^{-3}$ in 2018. As expected from two biologically-driven carbon sources, POC correlated closely with Chl-*a* (Fig. S9a), and the two-orders-lower $\text{PIC}_{\text{Total}}$ varied significantly with POC (Fig. S9b). Surface $\text{PIC}:\text{POC}$ ratios ranged from 0.002 to 0.030 in 2015 (mean = 0.011, $n = 18$) and from 0.001 to 0.014 in 2018 (mean = 0.007, $n = 10$).

3.2 Diversity of coccospheres and detached coccoliths

In 2015 and 2018, *G. huxleyi* was the numerically dominant coccolithophore south of 20° S (Fig. S10-S11). It co-dominated with *G. parvula/ericsonii* in all 2015 samples at 20° S, where there was no consistent variation in the relative abundance of these taxa (Fig. 3). The relative abundance of larger taxa increased below the Z_{eu} , reaching 0-18 % and 0-15 %, respectively (Fig. 3), as total coccosphere and coccolith abundances declined sharply.

3.3 Distribution of coccolithophore-PIC quotas

After converting the coccospheres and coccoliths densities recorded at ~20° S in 2015 to coccolith-PIC values allometrically, we observed that the majority of the coccolithophore PIC mass ($> 2 \text{ mmol m}^{-3}$) was produced near the coastline in waters shallower than 30 m. Below the Z_{eu} , the sharp decline in the numerical abundances of coccospheres ($< 0.1 \times 10^5 \text{ L}^{-1}$) and detached coccoliths ($< 10 \times 10^5 \text{ L}^{-1}$) decreased coccolithophore PIC pools to below 1 mmol m^{-3} .

Above the Z_{eu} , the coccospheres and detached coccoliths of *G. huxleyi* and *G. ericsonii/parvula* dominated the PIC quotas (Fig. 4a). In contrast, detached coccoliths of numerically rarer taxa, such as *C. leptopus*, *Helicosphaera* spp., and *G. oceanica*, contributed significantly to PIC quotas below the Z_{eu} , often exceeding the contributions of the smaller *Gephyrocapsa* species at most stations (Fig. 4b-c).

A significant positive linear relationship was found between the $\text{PIC}_{\text{Total}}$ and $\text{PIC}_{\text{Cocco}}$ values both in the upper 100 m and across all sampled depths (Fig. 5a-b). In all but three cases, the calculated $\text{PIC}_{\text{Cocco}}$ values were lower than the measured $\text{PIC}_{\text{Total}}$. These exceptions corresponded to a high total numerical abundance of *G. huxleyi*. Another notable exception was station L1 at 25 m, where *C. leptopus* and *Helicosphaera* spp. contributed 51 % and 20 % of the coccosphere PIC (2.23 mmol m^{-3}), and the estimated total $\text{PIC}_{\text{Cocco}}$ (5.1 mmol m^{-3}) was about twice the measured $\text{PIC}_{\text{Total}}$. In the upper 100 m, $\text{PIC}_{\text{Cocco}}$ quotas were primarily comprised of detached coccoliths (67 % of the accounted $\text{PIC}_{\text{Total}}$), with a roughly similar contribution from coccospheres throughout the sampled depths (Fig. 5c). On average, coccoliths were estimated to account for 48 % of the $\text{PIC}_{\text{Total}}$ (Fig. 5c).

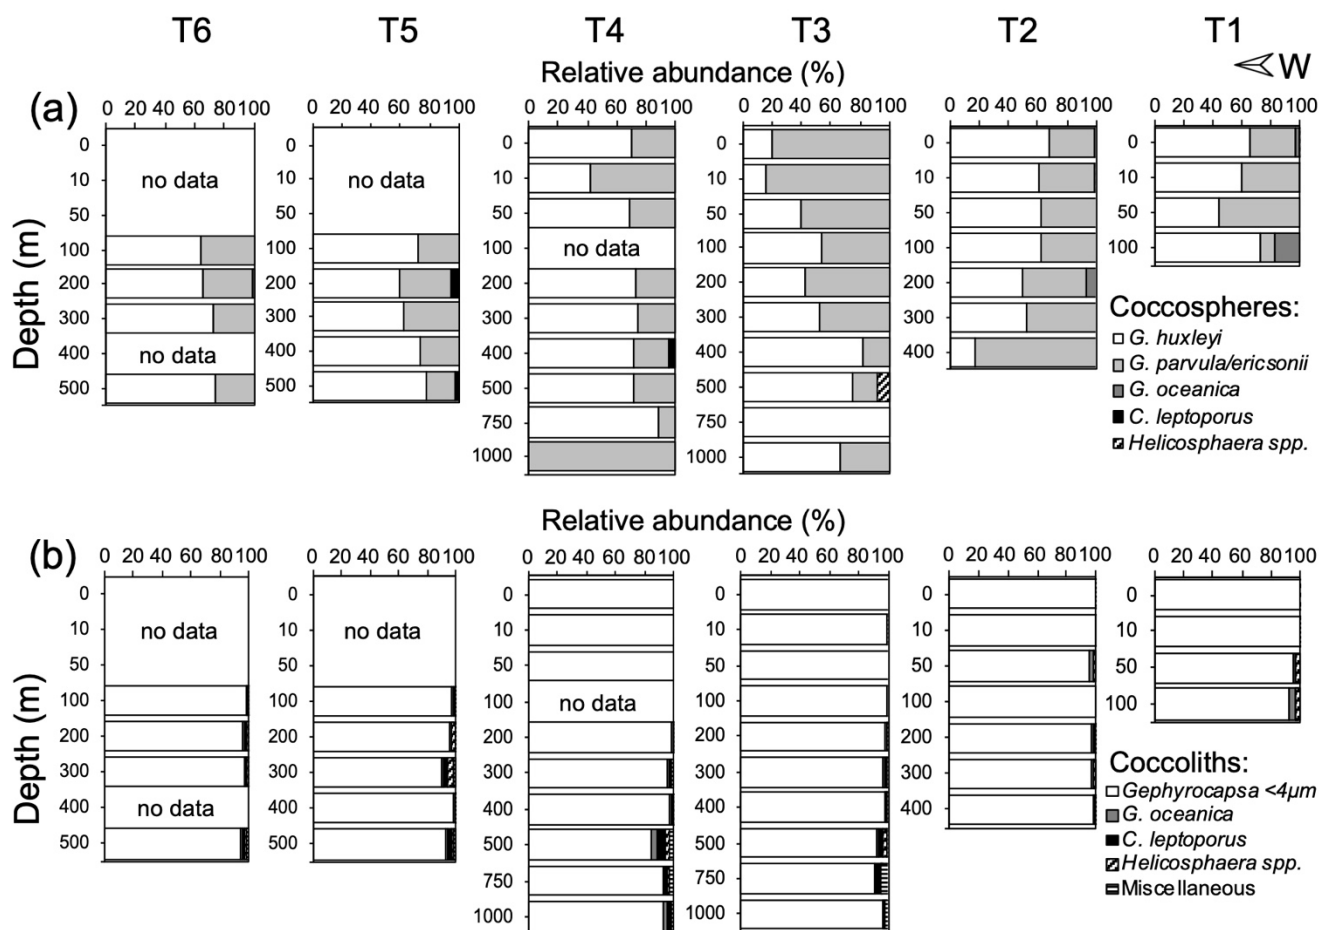

Figure 3: Coccospheres (a) and detached coccoliths (b) relative abundances in waters off Iquique (~20° S) during late-spring 2015.

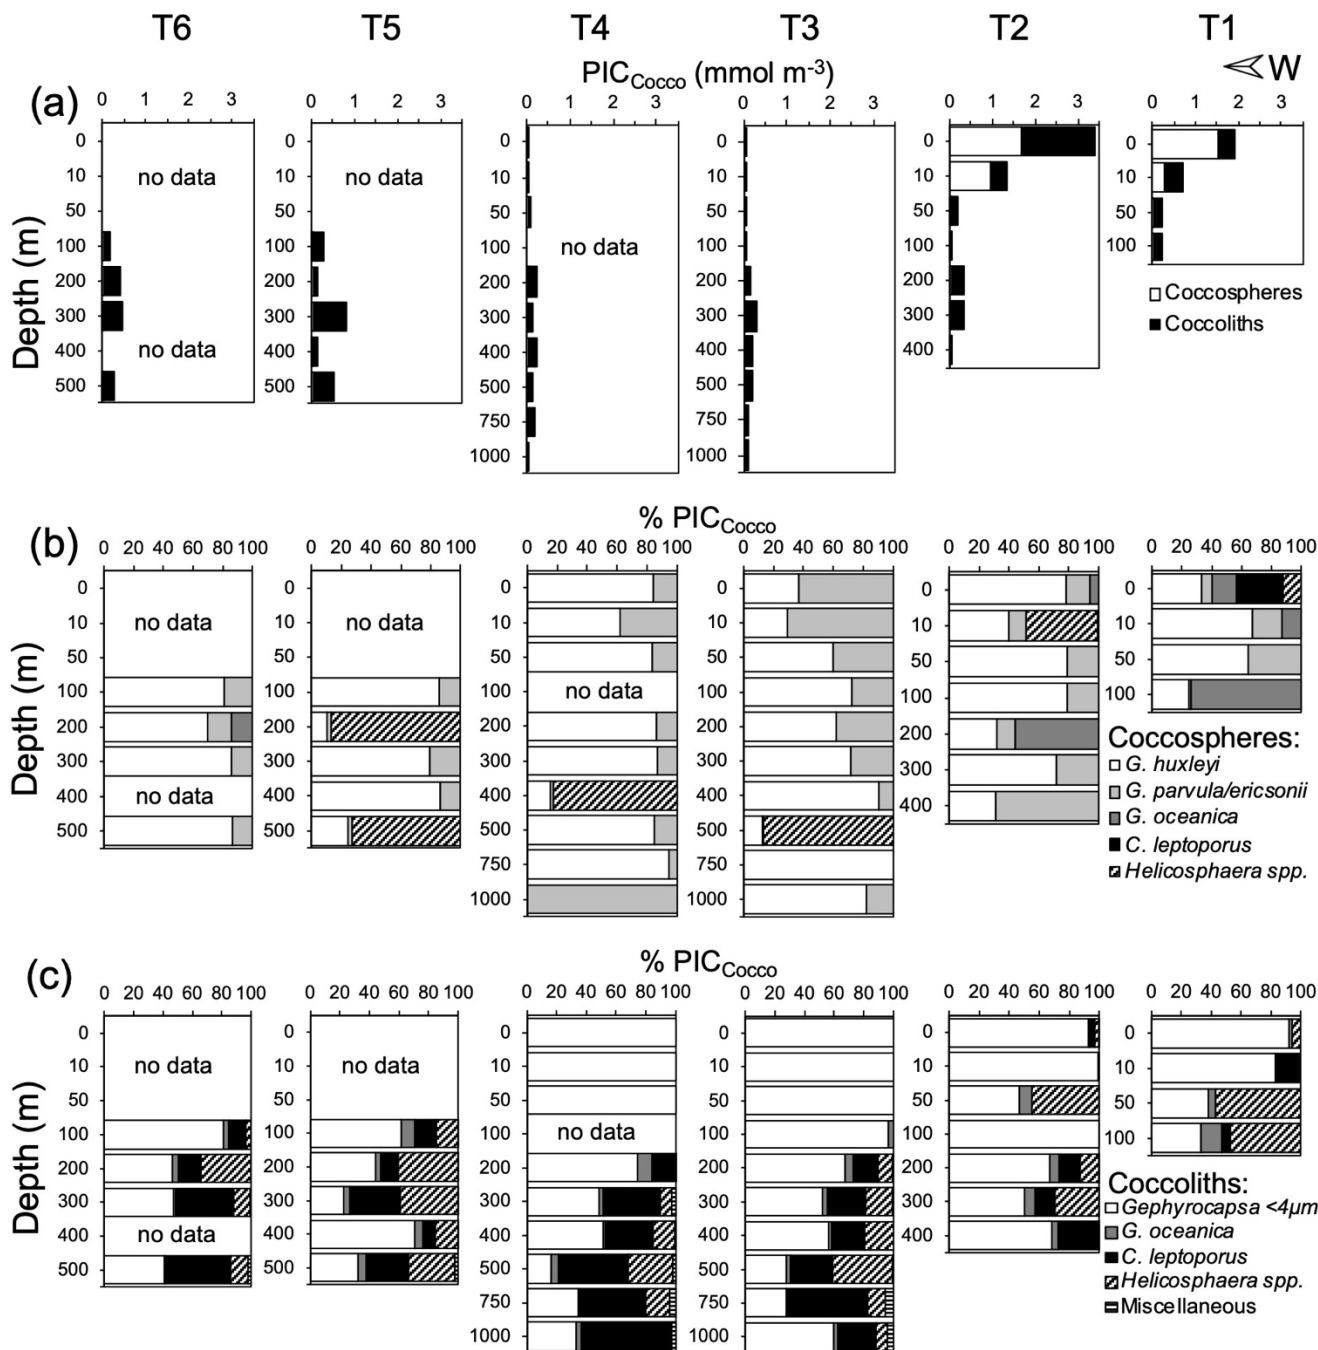

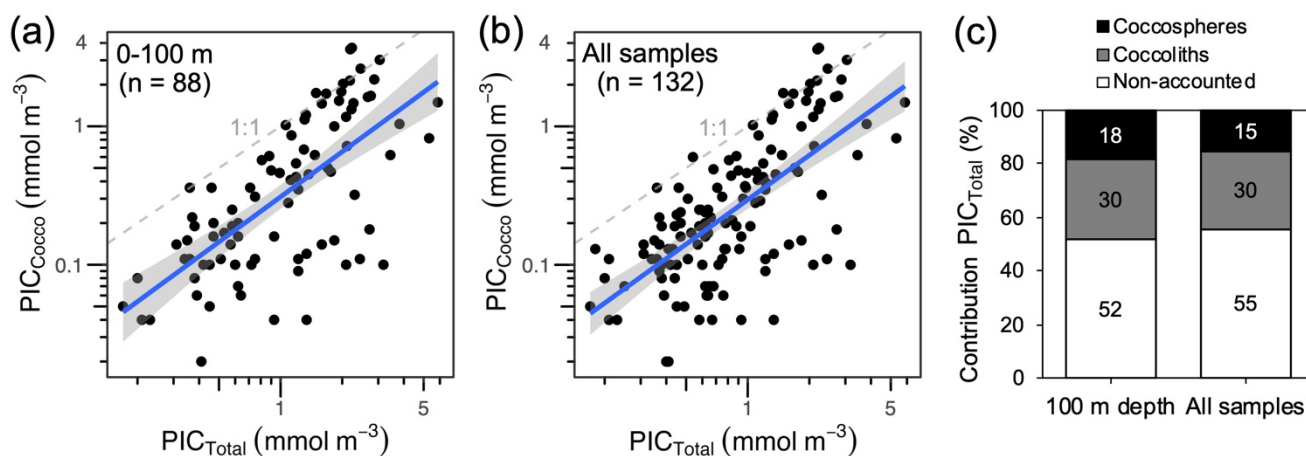

Figure 4: Estimated-PIC masses from coccospheres and detached coccoliths recorded in waters off Iquique (~ 20° S) during late-spring 2015. The contribution to PIC attributed to coccospheres and coccoliths (a), as well the taxonomic breakdown of the contribution of coccospheres (b) and detached coccoliths (c) are given.

assessment of PIC_{Cocco} quota estimation performance over ~ 2 orders of magnitude of PIC_{Total} concentration. PIC = Particulate
Inorganic Carbon.

3.4 Coccoliths and PIC variation across environmental conditions

Cocospheres, detached coccoliths, PIC pools, and the estimated PIC_{Cocco} quotas were marginally higher during mid-summer 2018 than in late-spring 2015 (Fig. 6). The relatively higher SST ($> 21^\circ\text{C}$) recorded westward of the stronger upwelling band
 240 closer to the coast (Fig. 2a), may be associated with these enhanced PIC_{Cocco} quotas. A shallow Z_{eu} , averaging 36 m and ranging from 26 to 50 m across both cruises ($n = 22$ stations; Fig. 2c-e, k-n), was observed, below which there was a sharp decline in coccolithophores and derived PIC (Fig. 6a-c). Overall, the average PIC_{Total} and PIC_{Cocco} quotas below the Z_{eu} decreased by 50 % and 83 %, respectively (Fig. 6c-d).

On average, a notable unimodal thermal response peaking at $\sim 18^\circ\text{C}$ was observed for both PIC_{Cocco} and PIC_{Total} within the Z_{eu}
 245 (Fig. S12a, S13a). The oxycline ($\sim 50\text{-}100 \mu\text{mol kg}^{-1}$) and pHcline (~ 7.7), located near the base of the Z_{eu} (Fig. 2c, h), were associated with decreased PIC levels, particularly in PIC_{Cocco} quotas ($\ll 1 \text{ mmol m}^{-3}$; Fig. S12c and S13c). Above a pH of ~ 7.7 ($\Omega_{calcite} > 2.0$; these two variables were highly correlated), PIC_{Cocco} quotas displayed a clear unimodal relationship, peaking at pH ~ 7.9 ($\Omega_{calcite} \sim 2.5\text{-}4.5$; Fig. S12g, i), while PIC_{Total} showed a monotonic increase (Fig. S13g, i). Nutrients and $p\text{CO}_2$, both essential for phytoplankton growth, were consistently available below the Z_{eu} (Fig. 2f-g), with phosphate being
 250 more limiting than nitrate (Fig. S12e-f). $p\text{CO}_2$ levels below $800 \mu\text{atm}$ corresponded to an average increase in PIC values (Fig. S12h, S13h). Low-to-moderate Chl-*a* levels ($< 4 \text{ mg m}^{-3}$) were associated with enhanced PIC_{Cocco} ($> 2 \text{ mmol m}^{-3}$) and PIC_{Total} quotas ($> 3 \text{ mmol m}^{-3}$), although only PIC_{Cocco} returned to background levels at higher Chl-*a* concentrations (Fig. S12d, S13d).

255 **Figure 6: Violin plots comparing the variation in coccospheres (a), detached coccoliths (b), PIC_{Total} (c), and PIC_{Cocco} (d) above and below the euphotic depth during late-spring 2015 and mid-summer 2018. Only samples taken in the upper 100 m depth are included. The number of samples tested per category is given in parentheses.**

4 Discussion

4.1 Coccolithophore species diversity and dominance off the Southeast Pacific margin

260 Coccospheres and detached coccoliths of *G. huxleyi* were dominant in 2018 at 20° S, as well as south of 20° S in both 2015 and 2018. This pattern is shared with other eastern boundary current systems, where *G. huxleyi* dominates numerically in waters off the Northeast Pacific (Ziveri et al., 1995; Venrick, 2012) and the Southeast Atlantic margins (Siegel et al., 2007; Henderiks et al., 2012). However, in addition to *G. huxleyi*, *G. parvula/ericsonii* were co-dominant members of the coccolithophore communities at ~20° S in 2015. The co-dominance of these three species was previously reported in winter samples from 2013 in the same zone (von Dassow et al., 2018; Díaz-Rosas et al., 2021). Likewise, “small *Reticulofenestra* 265 complex” (presumably mostly *G. parvula*) and “small *Gephyrocapsa* complex” have been previously reported as important in

tropical and equatorial waters further offshore (Hagino and Okada, 2004), so these species are frequently important in these and neighbouring waters. To the south, co-dominance of *G. huxleyi* and *G. muelleriae* has been reported previously (e.g., Díaz-Rosas et al., 2021). Thus, while the coccolithophore richness remains low in the Eastern South Pacific margin, this region exhibits a higher diversity within the genus *Gephyrocapsa* compared to other Eastern Boundary Currents (Henderiks et al., 2012; Venrick, 2012). Standing stocks of larger taxa were only noticeable below the Z_{cu} (~50 m depth). It should be noted that each coccosphere or detached coccolith of *C. leptopus* is equivalent to approximately 80 coccospheres or 45 coccoliths of *G. huxleyi* in terms of PIC. This suggests that the heavier coccoliths of these larger species may sink more efficiently (e.g., Menschel et al., 2016; Guerreiro et al., 2021).

4.2 The chemical PIC measurements as proxy of coccolithophore densities

How much coccolithophores contribute to PIC is an open question, as contributions from other phytoplankton, lithogenic sources (Daniels et al., 2012), and the effects of fragmentation and dissolution in the water column (e.g., Barrett et al., 2014; Subhas et al., 2022) can complicate the relation between PIC and coccolithophores, whether in remote sensing algorithms or as paleoproxy indicators. This emphasizes the value of microscopy counts, which have been found to be effective in quantifying PIC due to coccolithophores (D'Amario et al., 2018; Guerreiro et al., 2021; Ziveri et al., 2023). In this study, the conversion of detached and cell-attached coccoliths to PIC_{Cocco} values showed a direct relationship with PIC_{Total} within 100 m and across all samples, with detached coccoliths contributing significantly to PIC quotas. Microscopically-countable coccoliths and coccospheres account for approximately 50 % of direct PIC measurements. In the relatively narrow shelf in north-central Chile, other potential PIC sources, such as resuspension of biogenic minerals or river discharges of lithogenic material (Daniels et al., 2012), are negligible. However, technical or methodological challenges—including the detection of smaller coccoliths, collapsed coccospheres, and fragmented coccoliths, as well as variability in mass conversion factors and PIC production by other planktonic organisms—may account for the remaining PIC_{Total} . These results support the conclusion that coccolithophores are important contributors to total PIC pools in this OMZ.

4.3 Surface variation in coccolithophores and PIC quotas

Events of increased *G. huxleyi* coccospheres ($> 3.0 \times 10^5 L^{-1}$), along with detached coccoliths ($> 30 \times 10^5 L^{-1}$), were observed in the upper waters during both late-spring 2015 and mid-summer 2018. Consequently, the PIC_{Total} and PIC_{Cocco} quotas rose to 3-5 $mmol m^{-3}$, representing approximately a threefold increase compared to background levels. Coccosphere and detached coccolith densities were particularly high at 20° S, with inshore station T2 in 2015 showing 12×10^6 coccoliths L^{-1} at 2 m depth and offshore station T5 in 2018 showing 10 and 12×10^6 coccoliths L^{-1} at 25 and 30 m depth, respectively. These densities are about an order of magnitude lower than the typical bloom abundances reported in the Southwest Atlantic (Poulton et al., 2013), the North Atlantic (Holligan et al., 1993a), and the Gulf of Maine (Balch et al., 1991).

On average, higher coccolith densities, PIC_{Total} , and PIC_{Cocco} quotas were recorded during mid-summer 2018 compared to late-spring 2015, suggesting potential seasonality in PIC levels. This observation aligns qualitatively with satellite-PIC retrievals

showing PIC concentrations in February 2018 extending further offshore and southward from the inshore 20° S sampled site (see Fig. S14). Such seasonality, even though recorded in separate years, supports global satellite-PIC estimations showing higher inventories off the coasts of Chile and Namibia from austral spring (October-November) peaking in summer (January-February; see Hopkins et al., 2019).

In contrast to the greater excess of detached-coccolith over coccosphere ratios observed during massive blooms (e.g., Balch et al., 1991; Holligan et al., 1993b), lower ratios (< 16) were associated with max. PIC_{Cocco} quotas ($> 3 \text{ mmol m}^{-3}$) at station T2 in 2015 (2 m depth) and station T5 in 2018 (25 and 30 m depth). While these lower ratios might indicate younger populations (Balch et al., 1991; Holligan et al., 1993b; Lessard et al., 2005), cell-attached coccoliths comprised 51-72 % of the PIC_{Cocco} quotas. This could represent the max. standing stocks and PIC quotas attainable in the Southeast Pacific margin (see Table 4 in Díaz-Rosas et al., 2021). Two factors might limit coccolithophore populations from forming massive blooms similar to those seen in the North Atlantic. First, high productivity waters are typically dominated by diatoms, which may outcompete coccolithophores (Menschel et al., 2016). Second, the low pH typical of upwelled water in this region inhibits the growth of many coccolithophore strains (Sciandra et al., 2003; Bach et al., 2011; Meyer and Riebesell, 2015; Müller et al., 2015; von Dassow et al., 2018), even those isolated from the same region, which would presumably be best adapted to tolerate such conditions (von Dassow et al., 2018).

Coccolith PIC stocks varied significantly with SST, with higher PIC levels (PIC_{Cocco} and PIC_{Total}) around 18 °C during late-spring 2015 and mid-summer 2018 (Fig. S13a), suggesting a transition between nutrient-rich coastal upwelling and nutrient-poor offshore waters. Moderate nutrient availability and stratification seem to promote coccolithophore growth, reflected in peak abundances and PIC quotas, particularly in 2018 following stratification due to low SST and SSS water masses (Vargas et al., 2021; Fig. 2a-b). Similar trends were observed off the Santa Barbara coast, where higher temperatures and stratification increased coccolithophore abundance and PIC quotas (Matson et al., 2019). High coccolithophore abundances also occur in upwelling regions like the equatorial Pacific (Balch and Kilpatrick, 1996) and Arabian Sea (Balch et al., 2000), and in semi-oligotrophic areas such as the northern fjords, North Sea and Atlantic Ocean, under high-light conditions (Tyrrell and Merico, 2004; Zondervan, 2007). Coccolithophore blooms and PIC production are boosted after spring diatom blooms in upwelling zones, aligning with Margalef's (1978) successional model, which links their blooms to lower nutrients and turbulence than diatoms. Strong stratification with moderate nutrients favours higher PIC_{Cocco} and PIC_{Total} quotas, and indicating an inverse relationship between coccolithophores and diatoms under varying conditions (Menschel et al., 2016; Díaz-Rosas et al., 2021).

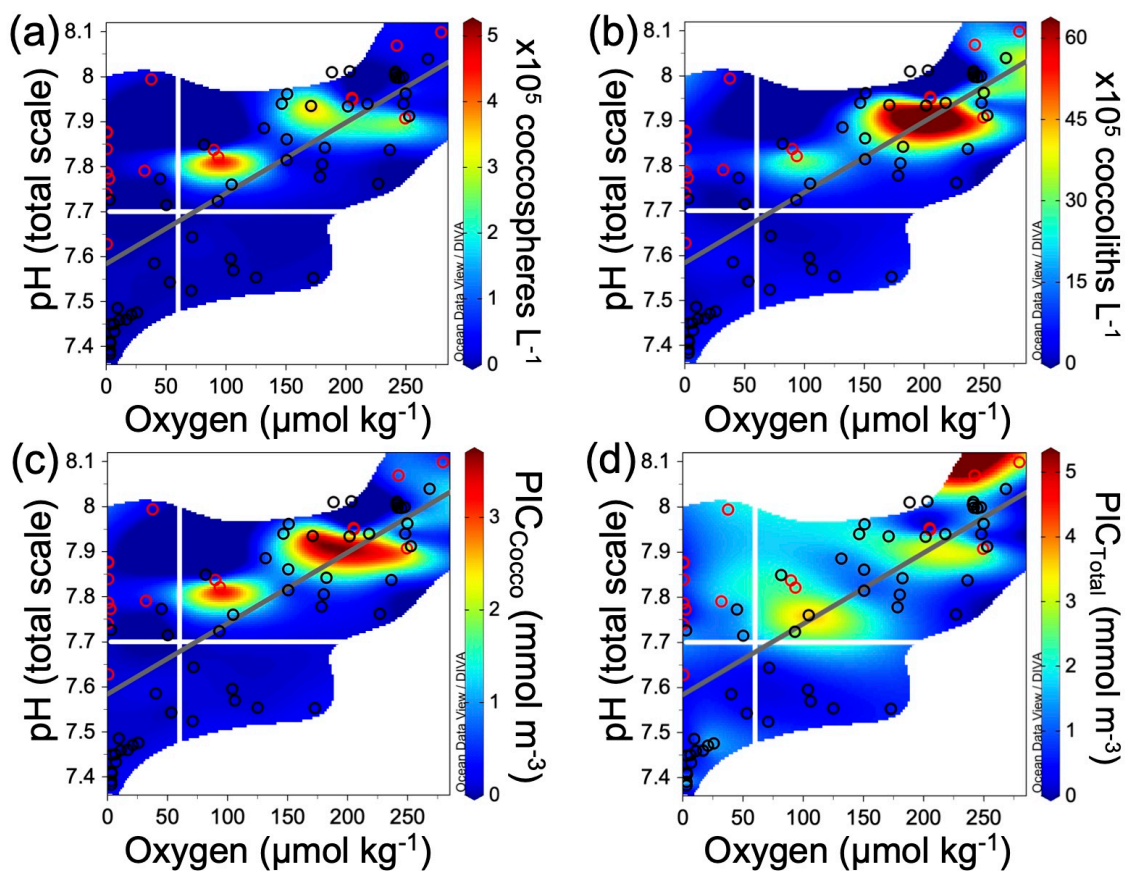

Environmental factors like pHcline and oxycline at the euphotic zone base may limit coccolithophore growth by impacting calcification and photorespiration. Off the Southeast Pacific, oxygen-deficient, acidic subsurface waters show pH and carbonate saturation shift (Ω calcite) to levels expected by 2100 (below 7.7 and 1.0, respectively) (Fig. 7; also see Vargas et al., 2021). The highest PIC quotas were associated with oxygenated waters, indicating phytoplankton reliance on these conditions for survival (Wong et al., 2023).

This study presents the first *in situ* PIC measurements from the OMZ waters off the Southeast Pacific margin, corresponding to late-spring 2015 and mid-summer of 2018. The observed PIC levels were about half those reported across the Great Calcite

Belt during winter or springtime waters off the Bay of Biscay. However, the range of PIC levels observed is consistent with ranges reported during spring off the California coast, and during summer in Patagonian shelf adjacent Atlantic waters (Table 1). Recently, enhanced coccolithophore and PIC pools were observed in February to the west in the central Pacific, with a
335 max. PIC_{Coccco} quota of $\sim 1.3 \text{ mmol m}^{-3}$, representing about one-third of the PIC quotas estimated in this study (Oliver et al., 2023; refer to Table 1). More similar PIC_{Total} quotas were reported by Matson et al. (2019) off the Santa Barbara Channel, with a value of $\sim 5.6 \text{ mmol m}^{-3}$. As an upper threshold of PIC_{Coccco} quotas, the most densely recorded pool of $\sim 400 \times 10^6$ coccoliths L^{-1} in the Gulf of Maine (Balch et al., 1991) and North Atlantic (Holligan et al., 1993a) correspond to approximately 120 mmol m^{-3} via allometric mass conversion.

340 Our dataset revealed relatively high coccolithophore PIC quotas during November and February at the border of the Southeast Pacific “PIC-data desert” (i.e., compared to the Atlantic Ocean; see Balch et al., 2018). In this context, the weekly and monthly satellite-PIC estimations, which did not exceed 1 mmol m^{-3} (average $\sim 0.2\text{-}0.3 \text{ mmol m}^{-3}$; Fig. S14), consistently underestimated these max. PIC quotas by a factor of 3-5. Additionally, satellite-PIC retrievals overestimated the PIC_{Coccco} quotas by a factor of 2-5 across the New Zealand and Drake Passage sectors of the Southern Ocean (Saavedra-Pellitero et al,
345 in press). It has been recently stressed that these optical PIC proxies need to be geographically adjusted (Balch and Mitchell, 2023). The highest PIC_{Coccco} quotas observed between 60 and 200 m depth during spring/summer in the remote Southeast Pacific (Beaufort et al., 2008; Oliver et al., 2023) likely reflect site-dependent biophysical constraints. Overall, these findings highlight the dynamic nature of coccolithophore populations and their PIC contributions, emphasizing the need for ongoing monitoring to understand their ecological roles and responses to environmental changes. Although the data are still limited,
350 and the periods sampled in this study were characterized by stratified summer water column conditions which may be conducive to coccolithophore growth (e.g., Matson et al., 2019), it is noteworthy that this zone, characterized by exceptionally low pH in sub-surface waters frequently brought to the surface by upwelling or breaking waves, does not exhibit a significant deficiency in surface layer PIC standing stocks (Fig. 8a-b).

355

Figure 7. Variation in coccospheres (a), detached-coccoliths (b), $\text{PIC}_{\text{Cocco}}$ (c), and $\text{PIC}_{\text{Total}}$ pools (d) across oxygen and pH levels recorded within 100-m during late-spring 2015 (open black dots) and mid-summer 2018 (open red dots). Horizontal and vertical white lines indicate the expected pH values for 2100 and oxygen contour for the Eastern Equatorial Pacific Ocean proposed by Stramma et al. (2008), respectively. Gray line depicts the least-square model fit curve.

4.4 Subsurface variation in PIC and PIC:POC ratios

Subsurface coccolithophore PIC is mostly due to detached coccoliths. While detached coccoliths of *G. huxleyi* and other small *Gephyrocapsa* remain important, larger and rare species with the heaviest coccoliths, such as *C. leptoporus* and *H. carteri*, became relatively more important to PIC quotas below the Z_{eu} , as seen previously in other regions (e.g., Ziveri et al., 2007; Guerreiro et al., 2021) and even in neighbouring waters (Menschel et al., 2016).

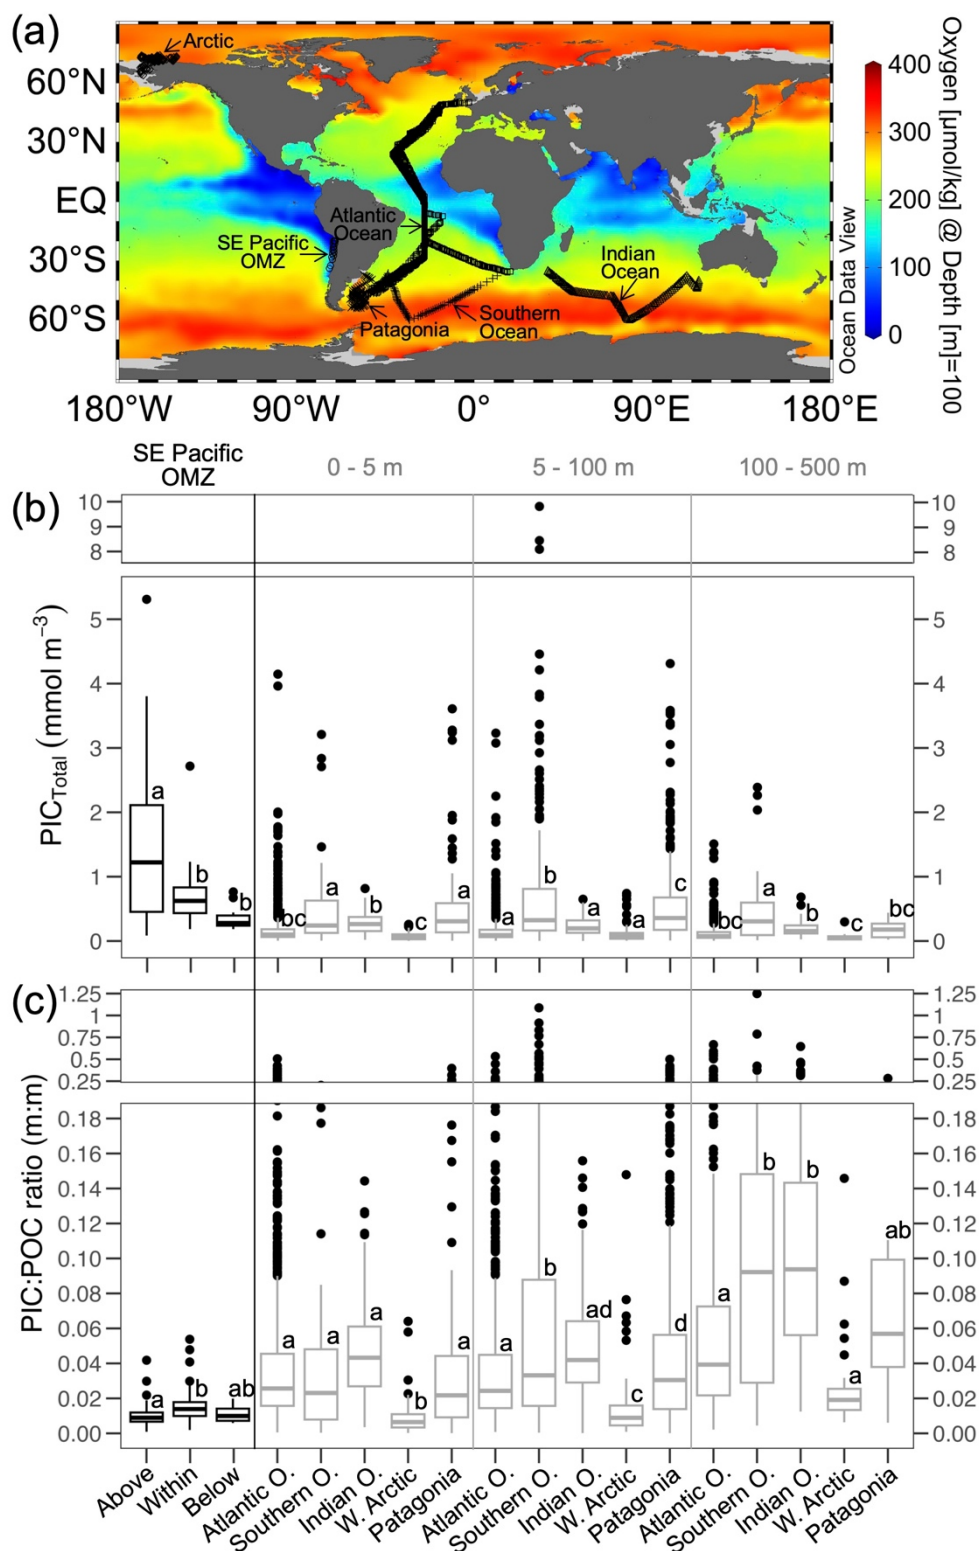

On average, up to two-thirds of the PIC_{Cocco} quotas were present as detached coccoliths (Fig. 5c), similar to records within blooms in the North Atlantic (Fernández et al., 1993; van der Wal et al., 1995) and North Pacific (Ziveri et al., 2023). This detrital material is expected to ballast POC to the deep ocean (e.g., Klaas and Archer, 2002). Additionally, a greater decrease in PIC_{Cocco} than PIC_{Total} below the Z_{eu} (Fig. 6c-d) is consistent with aggregation and fragmentation of coccoliths contributing to the non-accounted PIC_{Total}, which could sink even more POC (Briggs et al., 2020).

Previous research indicated that the transfer of POC from the euphotic zone to the deeper ocean is intensified in OMZs (Cavan et al., 2017; Engel et al., 2017). Significantly elevated PIC:POC ratios recorded within the OMZ-core (Fig. 8c; p -value < 0.05)

380 suggest that sinking particles are enriched in denser inorganic carbon (PIC), enhancing their ‘ballast effect’ and causing them to sink faster (Lee et al., 2009; Iversen and Ploug, 2010). This rapid descent decreases decomposition time in the upper water column, allowing more POC to reach the OMZ. These findings may indicate less POC decomposition below surface waters (e.g., between 100-1000 m; see Weber and Bianchi, 2020), as the ‘ballast effect’ of PIC could limit microbial degradation of POC in the mesopelagic. Ω calcite remained above 1 in the OMZ mesopelagic and the higher PIC:POC ratio in the OMZ layer
385 suggests that dissolution processes (for example in microenvironment of lower Ω calcite) are not fully offsetting the export of PIC from the surface layer. Nevertheless, these PIC:POC ratios were significantly lower compared to those in the Atlantic Ocean, Southern Ocean, and Patagonian shelf (Fig. 8).

Nevertheless, the data suggest that PIC plays a decreased role in POC export from the surface in these OMZ waters: The PIC:POC ratios were significantly lower than other diverse regions for which data are available (Fig. 8). The reasons for this are not yet clear. One possibility is that the intrusion of nutrient-rich but low pH waters into the surface further stimulates POC production from other phytoplankton (e.g., diatoms) over coccolithophores.

390 **Figure 8:** (a) Global map showing annual oxygen content at 100 m depth and sampling points for (b) PIC_{Total} and (c) PIC:POC ratios
above, within, and below the OMZ-core during late-spring 2015 and mid-summer 2018 in the SE Pacific (this study), as well as
surface (< 5 m), sub-surface (5-100 m), and below-surface waters (100-500 m) from other open ocean or coastal margin areas (data
from Balch et al., 2018). Atlantic Ocean dataset comprises six cruises (AMT17-22). According to one-way ANOVAs, PIC_{Total} and
PIC:POC ratios were significantly different among the SE Pacific OMZ-core, and also among the Atlantic Ocean, Southern Ocean,
395 Indian Ocean, Western Arctic, and Patagonian Shelf sample groups ($p < 0.05$), with Tukey post-hoc multiple comparisons depicted
as lowercase letters over each boxplot. Map produced by Ocean Data View (Schlitzer, 2024), with oxygen annual climatology based
on the World Ocean Atlas 2018 (Boyer et al., 2018; García et al., 2018).

5 Conclusions

The examination of the coccolithophores, along with the PIC standing stocks between late-spring 2015 and mid-summer 2018
waters off the Southeast Pacific margin, yielded six conclusions:

- 400 1. Coccolithophores-PIC quotas peak within the first 30 m depth, with slightly higher PIC pools observed in summer 2018
compared to spring 2015. Spring exhibits greater variability and lower mean coccospheres and detached-coccoliths, as well as
derived PIC, compared to summer.
2. *G. huxleyi*, along with *G. parvula/ericsonii*, co-dominate the coccosphere pools, while *G. huxleyi* is the primary contributor
to detached coccoliths in the cross-shelf transect sampled at $\sim 20^\circ$ S. The majority of PIC contributed by coccolithophores is
405 dominated by *G. huxleyi* coccoliths shed during blooms. South of 20° S, the coccospheres and detached coccoliths of *G. huxleyi*
were observed as the most important contributor to biogenic calcium carbonate.
3. Both the PIC_{Total} and PIC_{Cocco} quotas decreased by 50 % and 83 % below the euphotic depth, coinciding with the oxycline
and pHcline.
4. Horizontal and vertical variation in PIC_{Total} and PIC_{Cocco} quotas strongly depends on temperature, along with oxygen and
410 pH levels.
5. PIC quotas were similar to those in other upwelling zones, and a half of max. quotas in the Atlantic Ocean and Bay of
Biscay.
6. Low PIC:POC ratios, compared to other open ocean and coastal margin areas, were more pronounced within the OMZ-core,
suggesting calcification plays a role in POC fluxes to deep ocean and that this role may be decreased in sub-surface OMZs
415 compared to other zones.

Data availability.

All data generated in this study are available upon request from the corresponding author. The scanning electron micrograph
image datasets are accessible at <https://doi.org/10.5281/zenodo.14048319> (Díaz-Rosas et al., 2024). The PIC measurements,
as well as coccosphere and detached coccolith count data, will soon be available in the PANGAEA repository. These data are
420 currently provided in Supplementary Tables S1-S2.

Sample availability.

Supplement.

Author contributions.

FDR (conceptualization, data curation, formal analysis, investigation, methodology, visualization, writing – original draft
425 preparation, writing – review and editing) provided key proof-of-concept ideas, led the study, conducted polarized light and
SEM microscopic analyses and taxonomic characterization of coccospheres and detached coccoliths, examined the
relationships between PIC measurements, coccolithophore pools, and environmental/biological variables, compared PIC and
PIC:POC values with existing repositories, and drafted the initial manuscript. PvD (conceptualization, funding acquisition,
validation, visualization, writing – original draft preparation, writing – review and editing) defined the research goals, led the
430 study, conducted sampling during the 2015 cruise, planned the 2018 sampling, and provided continuous insights into results
interpretation and manuscript structure. CV (funding acquisition, validation, writing – review and editing) guided the
interpretation of results and contributed to characterizing the physical and chemical environments. All co-authors provided
critical feedback and contributed to the final editing of the manuscript.

Competing interest.

435 The contact author has declared that none of the authors has any competing interests.

Acknowledgements.

We thank Dr. William Balch, Dr. Catherine Mitchell, and Dr. David Drapeau for reading and providing valuable discussion
on the manuscript.

Financial support.

440 This study was supported by the National Agency for Research and Development (ANID) of Chile through grants AIM23-
0003 and ICN12_019N for the Millennium Institute of Oceanography (IMO), as well as FONDECYT grant 1181614. Scanning
electron microscopy analysis was performed at the Centro de Investigación en Nanotecnología y Materiales Avanzados (CIEN)
of the Pontificia Universidad Católica de Chile using an SEM instrument purchased with FONDEQUIP grant EQM150101.
