Abstract. Understanding the vertical profile of greenhouse gases (GHGs) is crucial for elucidating their sources and sinks, transport pathways, and influence on Earth's radiative balance, as well as for enhancing predictive capabilities for climate change. Remote sensing methods for measuring vertical GHG profiles often involve substantial uncertainties, while in-situ measurements are limited by high equipment costs and operational expenses, rendering them impractical for long-term continuous observation efforts. In this study, we have developed an automatic low-cost and user-friendly multi-altitude atmospheric sampling device designed for small and medium-sized unmanned aerial vehicles (UAVs), balloons, and other flight platforms. A field campaign was carried out in the Mount Qomolangma region, at an average surface altitude of 4300 m above sea level (a.s.l.). During the campaign, we conducted 15 flights and collected 139 samples from the ground surface up to a height of 1215 m using a hexacopter UAV platform equipped with the sampling device. The samples were analyzed using the Agilent gas chromatography (GC) 7890A, enabling the derivation of the vertical profiles for four GHG species (CO_2 , CH_4 , N_2O , and SF_6) within the boundary layer of the Mount Qomolangma region. To enable the long-term monitoring using small UAVs, future efforts should prioritize reducing the weight of the equipment and improving the sampling efficiency.

1 Introduction

Contemporary global warming, predominantly driven by human activities, is an urgent environmental challenge characterized by a significant increase in the atmospheric concentration of greenhouse gases (GHGs), causing a rapid rise in global temperature since the Industrial Revolution (Masson-Delmotte et al., 2019; Friedlingstein et al., 2023). Monitoring the changes in GHG concentration is essential for understanding climate change and promoting environmental protection. Carbon dioxide (CO_2) is the most influential GHG, with its radiative forcing reaching $+1.82 \pm 0.19 \text{ W/m}^2$ in 2019 relative to 1750 (IPCC, 2021), followed by methane (CH_4), nitrous oxide (N_2O) and other GHGs. The concentrations of GHGs are influenced by surface fluxes and atmospheric chemical transport, leading to non-uniform spatial distributions. As a result, measurements of the spatio-temporal distribution of GHG concentrations can be used to derive the sizes of fluxes and the impacts of atmospheric

transports. (Carnell and Senior, 1998; Ren et al., 2011; Xie et al., 2013). For instance, the vertical profiles of CO₂ observed by aircraft were used for diagnosing errors in the simulation of surface CO₂ fluxes (Jin et al., 2024) and have been integrated into inverse modeling of carbon fluxes (Niwa et al., 2012; Jiang et al., 2013). Additionally, the vertical distribution of GHGs 25 serves as a critical input for satellite remote sensing retrieval algorithms, enhancing the accuracy of satellite retrievals (Ramanathan et al., 2018; Bao et al., 2020). This accuracy is critical for atmospheric inversions, whether assimilating satellite data independently (Chevallier et al., 2019) or in conjunction with surface-based measurements (Byrne et al., 2020).

There are two primary methods for obtaining the vertical distribution of atmospheric GHGs: indirect measurements (remote sensing technique) and direct measurements. The first approach involves analyzing the observed characteristic spectrum 30 through space-based satellites or payloads (Buchwitz et al., 2005; O'Dell et al., 2012; Yoshida et al., 2013), ground-based Lidar (Kuma et al., 2021), and high-resolution spectrometers (Wunch et al., 2011). The accuracy of indirect measurement methods is limited by several factors, such as cloud cover, aerosols, and surface reflections. These limitations lead to considerable uncertainty and limited spatial resolution of GHG concentrations, thereby affecting the accuracy of estimation of localized GHG 35 sources and sinks.

35 The direct measurement technique requires the use of specialized equipment capable of accurately measuring the atmosphere's composition, such as the devices using the Cavity Ring-down Spectroscopy (CRDS) technique (Wheeler et al., 1998; Wilkinson et al., 2018). To acquire vertical distribution information, multiple inlets are often installed at different altitudes of a tower, which typically only extends a few hundred meters (Haszpra et al., 2012). Alternatively, lightweight measurement devices can be deployed on aircraft (Sun et al., 2020) or balloons (Li et al., 2014; Bao et al., 2020) to enable in-situ measurements 40 at high altitudes. Sampling devices may also be employed to collect high-altitude air masses for subsequent laboratory analysis. Compared to remote sensing, direct measurements provide higher precision and vertical resolution for GHG data that can be easily tied to calibration standards (e.g. the National Institute of Standards and Technology, NIST scale). Recently, advancements in Unmanned Aerial Vehicles (UAVs) have provided a lightweight, easy-to-operate, and easily recoverable platform for 45 vertical observations. Due to their small size, portability, and low cost, UAVs have emerged as a popular method for obtaining the distribution of atmospheric constituents, effectively overcoming the limitations of traditional methods (Glaser et al., 2003; Neumann and Bartholmai, 2015; Etts et al., 2015; Brosy et al., 2017; Chang et al., 2020).

Many works have used UAVs for in-situ measurements of GHGs, primarily utilizing Non-Dispersive Infrared (NDIR) sensors to measure CO₂ and CH₄ (Kunz et al., 2018; Reuter et al., 2021; Britto Hupsel de Azevedo et al., 2022; Han et al., 2024). While NDIR and other low-cost sensors have the advantage of real-time and continuous monitoring due to their lightweight 50 design, they face challenges such as the need for frequent calibration arising from fluctuations in ambient environments such as pressure, temperature and water vapor content, which vary across locations and altitudes (Liu et al., 2022). In contrast, flask(usually made of metal) sampling methods enable the collection and subsequent laboratory analysis under controlled conditions (Loftfield et al., 1997), but they require labor-intensive flask evacuation and cleaning procedures and are unsuitable for real-time measurements. We have developed a device similar to flask sampling but using aluminum bags, featuring a lighter 55 design, and expanded its capabilities to analyze additional GHG components. Note that our system requires a higher payload capacity and a larger platform size than real-time analysis sensors. This portable device operates automatically and can collect

air samples from multiple altitudes in a short period. Comprehensive indoor tests verified the device's sampling speed and liability for field measurements. The device was used in a five-day campaign of field measurements on Mount Cho Oyu Basecamp (4950 m a.s.l.) and Mount Qomolangma Station (4300 m a.s.l) between 29 September and 03 October 2023. The device was 60 taken by a medium-sized UAV up to 1250 meters above the ground. During the flights, air samples were collected at different altitudes from the ground to the upper air. The samples were then analysed by a chromatography to derive gas concentrations, including CO₂, CH₄, N₂O, and SF₆.

The paper is structured as follows: Section 2 provides an overview of the gas collection system, and outlines the sampling and analysis procedures used in this experiment. Section 3 details the field experiments, including site descriptions and a 65 discussion of the results. Finally, Section 4 summarizes the key findings and their implications.

2 Methodology

2.1 Gas collection system

The schematic of the automatic sampling device is shown in Figure 1. Airbags are used to collect air samples. Each airbag is a vacuum-sealed, 1 L aluminum-foil bag, sized appropriately for GC analysis. Ten airbags (illustrated here with four for 70 simplicity) are each equipped with a self-sealing structured polycarbonate (PC) stopcock straight valve and connected to ten micro vacuum pumps through airtight tubing well-sealed tubes, with each pump having an inlet and an outlet. A Hydrophobic (PTFE) filter with a 0.45 μm pore size is attached to the inlet to prevent dust contamination. The outlet is tightly connected to the valve of the sampling bag, allowing collecting air when the valve is opened. All airbags are stored in a storage box to ensure the safety in case of strong wind. A GPS-receiver and a meteorological sensor (iMET XQ2, International Met Systems) form 75 an integrated data acquisition system capable of simultaneously recording time and position (longitude, latitude, altitude), and atmospheric parameters (pressure: 10-1200 hPa; temperature: -90°C to +50°C; humidity: 0-100 % RH). The whole procedure is programmable through a Micro Control Unit (MCU), and the sampling altitudes are pre-set before each flight.

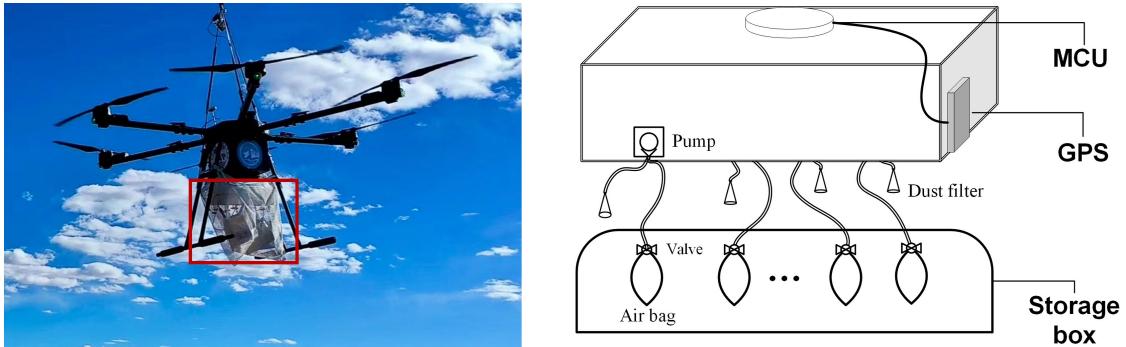

Figure 1. The design of the sampling system and its equipment on a UAV

2.2 Sampling procedure

The size of the gas collection system is $39\text{cm} \times 18\text{cm} \times 12\text{cm}$, and the total weight is 2.4 kg. The peak power of the sampling is about 10.8 W. An extra 12 V small Lithium battery (capacity of 2 Ah, and about 150 g weight) is used to power the pump. The whole system can be carried by UAVs with sufficient capacity. The following operations are performed before each flight: bags must be flushed with high-purity nitrogen at least 5 times before sampling; each bag must be carefully labelled to register its logging information, such as time, location and altitude for future analysis. Precautions must be taken when mounting sensors on UAV to prevent contamination from human activities. The working flow chart (Figure 2) provides a detailed view of the procedure, including pre-processing, parameter configuration, and operational steps.

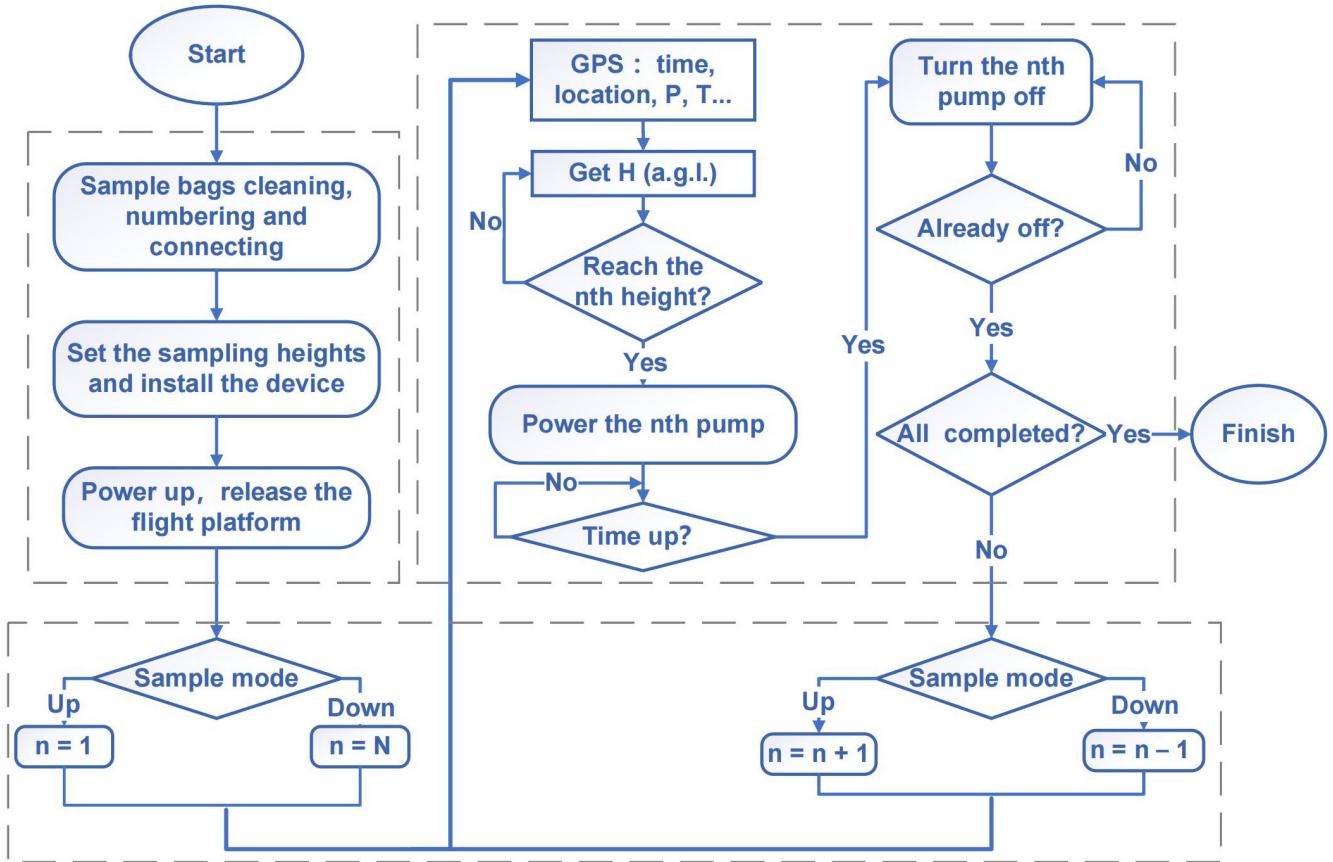

Figure 2. The working flowchart of the gas collection system

During the flights, the real-time altitude is calculated at 1 Hz through pressure p and air temperature T collected from iMET XQ2 by:

$$Z = - \int_{p_0}^p \frac{RT}{g} d \ln p \quad (1)$$

where p_0 is the surface pressure, R is the ideal gas constant $287.05 \text{ J} \cdot (\text{kg} \cdot \text{K})^{-1}$, g is the gravitational acceleration as a constant $9.80665 \text{ m} \cdot \text{s}^{-2}$. Note that temperature and humidity data were not utilized for atmospheric boundary layer analysis due to potential interference from UAV heat sources and unshielded solar radiation, but they do not significantly affect altitude computations. A comparison of altitudes obtained from the iMET XQ2-based calculations with GPS measurements (as shown in Figure S1) indicates that given the short flight durations (less than 40 minutes), the differences are negligible, remaining within 7 meters. This is minimal compared to the vertical sampling resolution of approximately 100 meters.

95 The mobility and flexibility of the UAV platform (Figure 1) make it an ideal autonomous system for vertical profile measurements of greenhouse gases. The sampling system operates in two distinct modes: the ascent (Up) and descent (Down) modes.

100 In the Up mode, the UAV is operated with a relatively constant velocity of about 4 m/s until it reaches the predefined maximum altitude (for example, about 1300 m above ground level). The samplings are collected during the ascent period. To optimize power consumption (Reuder et al., 2016), the system requires a stationary hovering phase at the target altitude to facilitate pump operation (as illustrated in the height stage pattern in Figure 3a).

In the Down mode, the samples are collected during the descent period. The UAV initiates a 10-second hover at the maximum altitude for pump operation, followed by a gradual descent to the launch point (Figure 3b).

105 During the preliminary field campaign, we collected 15 samples exclusively with the Up mode in the two test flights. Maintaining UAV stability during manual altitude adjustments (Figure 3a) is the main challenge of the operation. Our experimental results demonstrate the superiority of the Down mode, which reduces manual intervention and enhances energy efficiency.

Each motor lasts 11-20 seconds and then stops. This sampling procedure repeats until the UAV lands on the ground, and the valves of airbags are closed. Above each valve, there is a sample cap with a silicone septum inside for syringe sampling.

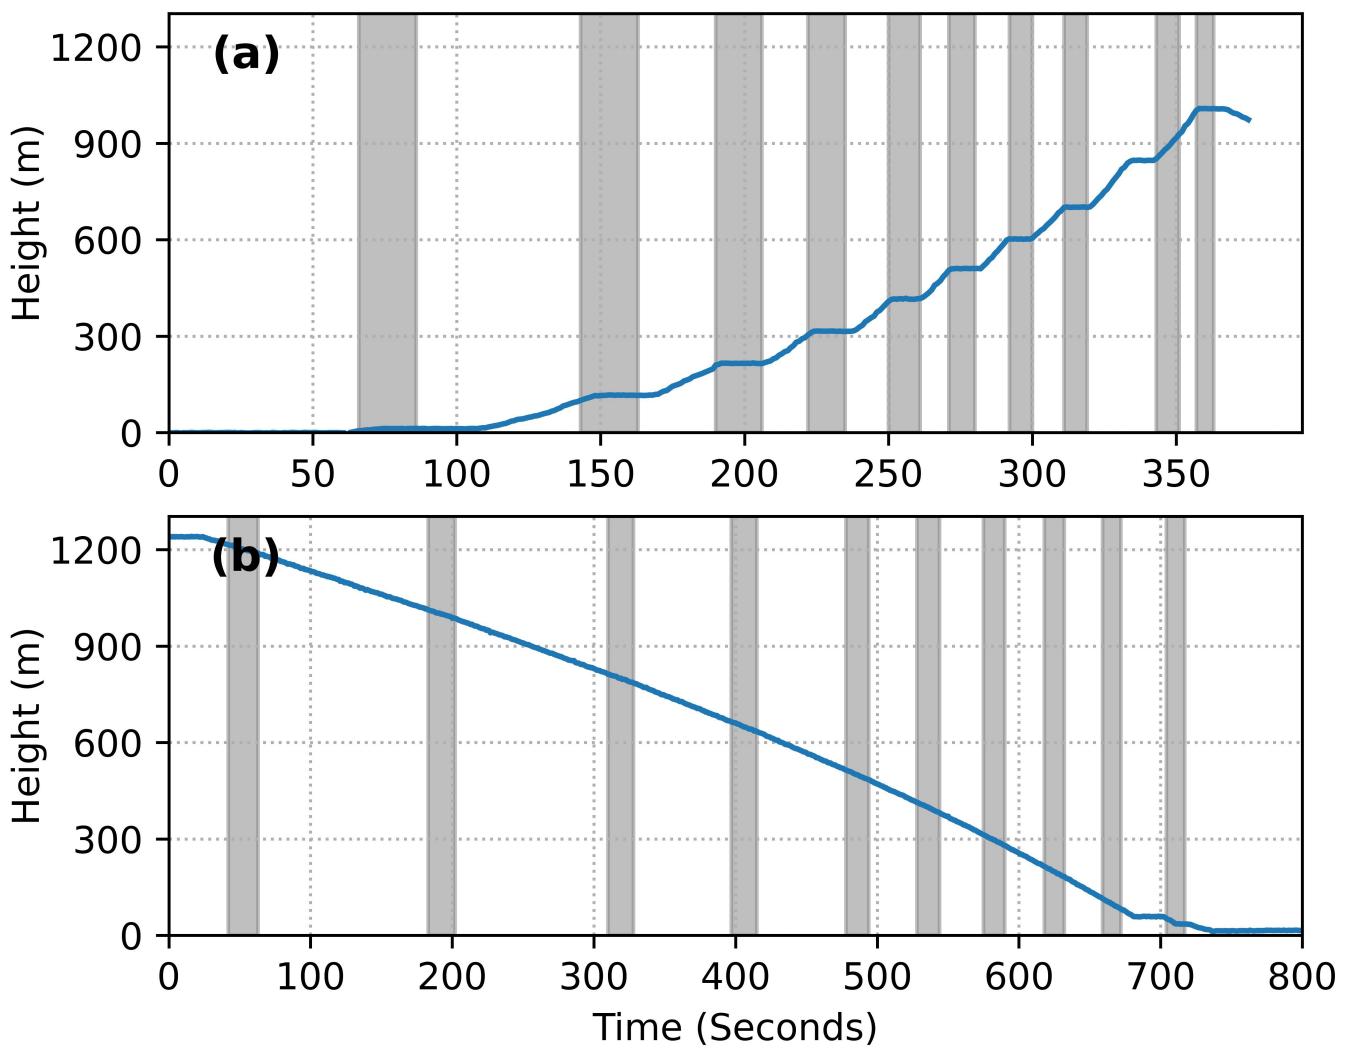

Figure 3. An example of sampling modes. The start times are (a) October 1 at 07:31, and (b) October 5 at 07:47(in local time). The lines indicate flight heights, while the gray shadows represent the operating times of each micro-motor.

2.3 Air sample analysis

110 The air masses collected in the bags are analyzed with an Agilent GC 7890A (<https://www.agilent.com.cn>) for four GHG species (CO₂, CH₄, N₂O, SF₆). The GC measurement is based on the principle that different components within the sample flow at different speeds through the gas chromatography column, enabling precise separation and accurate quantification of individual constituents. We use a 13X molecular sieve (13XMS) to separate CH₄ and a Porapak Q for CO₂. Regarding N₂O and SF₆, they are separated from CO₂ by the Porapak Q column and then backflushed to the detector. The GC is equipped with

115 a Flame Ionization Detector (FID) for detecting CH₄. CO₂ is converted to CH₄ using a nickel converter before being detected by the FID, as the FID only responds to carbon-containing organic compounds. Additionally, an Electron Capture Detector (ECD) is used for N₂O and SF₆. For detailed information about the injector, gas line, valve-driving models, and laboratory accuracy testing, please refer to our previous studies (Yuesi and Yinghong, 2003; Wang et al., 2010). The GC signals, mostly represented by peak area or height due to gas absorption, are directly proportional to gas concentrations. These signals are
120 carefully calibrated with standard gases traceable to NIST scale. A linear regression is established between the peak area and the concentration of standard gases:

$$C = a \cdot \text{Area} + b \quad (2)$$

125 Where *C* represents the concentration of the detected gas, *Area* represents the peak area of the detected gas, and *a* and *b* are coefficients given through calibration with standard gas. The standard gas is injected multiple times (*n*≥7), and the standard deviation of parallel determinations is calculated to determine the detection limit and precision using a specific formula. Each type of GHG is measured in terms of its volume mixing ratio (VMR). The precisions, represented by the coefficients of variation, are 0.18 % for CO₂, 0.99 % for CH₄, 0.22 % for N₂O, and 1.7 % for SF₆ at the average levels of 0.75 ppm for CO₂, 0.02 ppm for CH₄, 0.74 ppb for N₂O, and 0.20 ppt for SF₆. The detection limits of this method are 2.4 ppm for CO₂, 0.07 ppm for CH₄, 2.6 ppb for N₂O and 1.5 ppt for SF₆.

130 3 Field Experiments

3.1 Sites

Field experiments were conducted at two high-altitude stations located in the Tibet Plateau:

135 (1) Cho Oyu basecamp (28.24°N, 86.59°E): This is a newly established temporary station with no greenhouses measurements records before. Its basecamp, located at 4,950 m a.s.l., serves as the starting point for the scientific research team to the summit of Mount Cho Oyu, which is about 8201 m a.s.l., the 6th highest mountain in the world.

(2) Qomolangma Station, CAS (28.36°N, 86.94°E): It is located at 4300 m a.s.l. and is on the northern slope of Mount Qomolangma (8848.86 m a.s.l., the highest mountain in the world). This station was established in 2005 by the Institute of Tibetan Plateau Research, Chinese Academy of Sciences (Ma et al., 2023).

Both sites are located in Tingri County, in Rikaze City, with detailed geographic location and elevation information provided
140 in Figure 4.

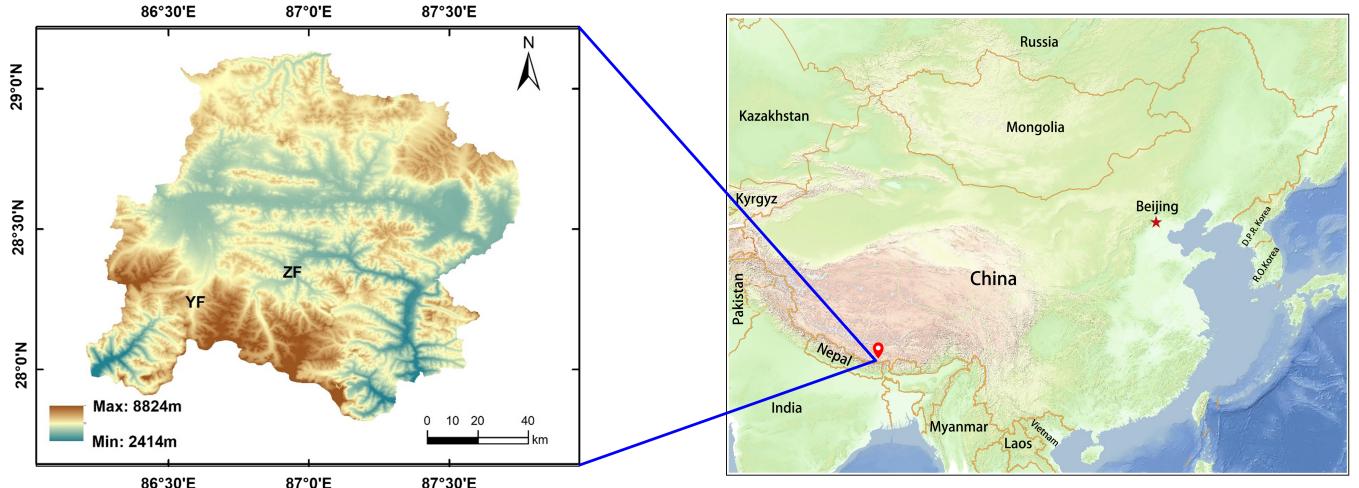

Figure 4. The left panel shows the locations of the experimental sites, both situated in Tingri County: YF corresponds to the Cho Oyu base camp, and ZF corresponds to the Mount Qomolangma Station. The Digital Elevation Model (DEM) data is sourced from the Geospatial Data Cloud (<http://www.gscloud.cn>). The right panel shows the location of Tingri County on the map.

3.2 Results and analysis

Between 29 September and 03 October 2023, three flights were attempted in Cho Oyu, but only one flight succeeded due to bad weather conditions and MCU failures. On 03 October, the system was transported to the Qomolangma Station and 12 flights were successfully conducted in the following 3 days.

145 During each flight, 10 bags were collected at 10 different altitudes, and it took about 40 minutes per flight. The flight and sampling information is listed in Table 1. In total, 139 samples were collected during the whole field campaign. The mean and standard deviation of the four greenhouse gases, as averaged across all samples, are listed in Table 2.

Table 1. Sampling log of GHGs measurements during UAV flights in the Mount Qomolangma Region

Site	Local Date	Local Time	Max height(m)	Number of Samples
YF	2023/10/01	08:32	588.0	5
	2023/10/02	07:31	1007.9	10
	2023/10/03	11:53	1112.3	7
ZF	2023/10/03	15:35	1113.2	9
		07:41	1113.8	10
		09:38	1214.9	10
	2023/10/04	11:28	1213.2	10
		13:31	1212.9	10
		20:05	1214.4	9
		07:42	1215.0	10
		09:47	1213.5	10
	2023/10/05	11:37	1203.5	9
		13:43	1213.8	10
		16:34	1211.7	10
		20:36	1214.6	10

Table 2. Means and standard deviations of gas mixing ratios of all samples

Site	Time	CO ₂ (ppm)	CH ₄ (ppm)	N ₂ O (ppb)	SF ₆ (ppt)
YF	2023/10/01-03	421.13±4.76	1.98±0.01	337.38±1.26	11.86±0.56
ZF	2023/10/03-05	418.35±2.54	2.00±0.02	337.15±1.41	11.76±0.54

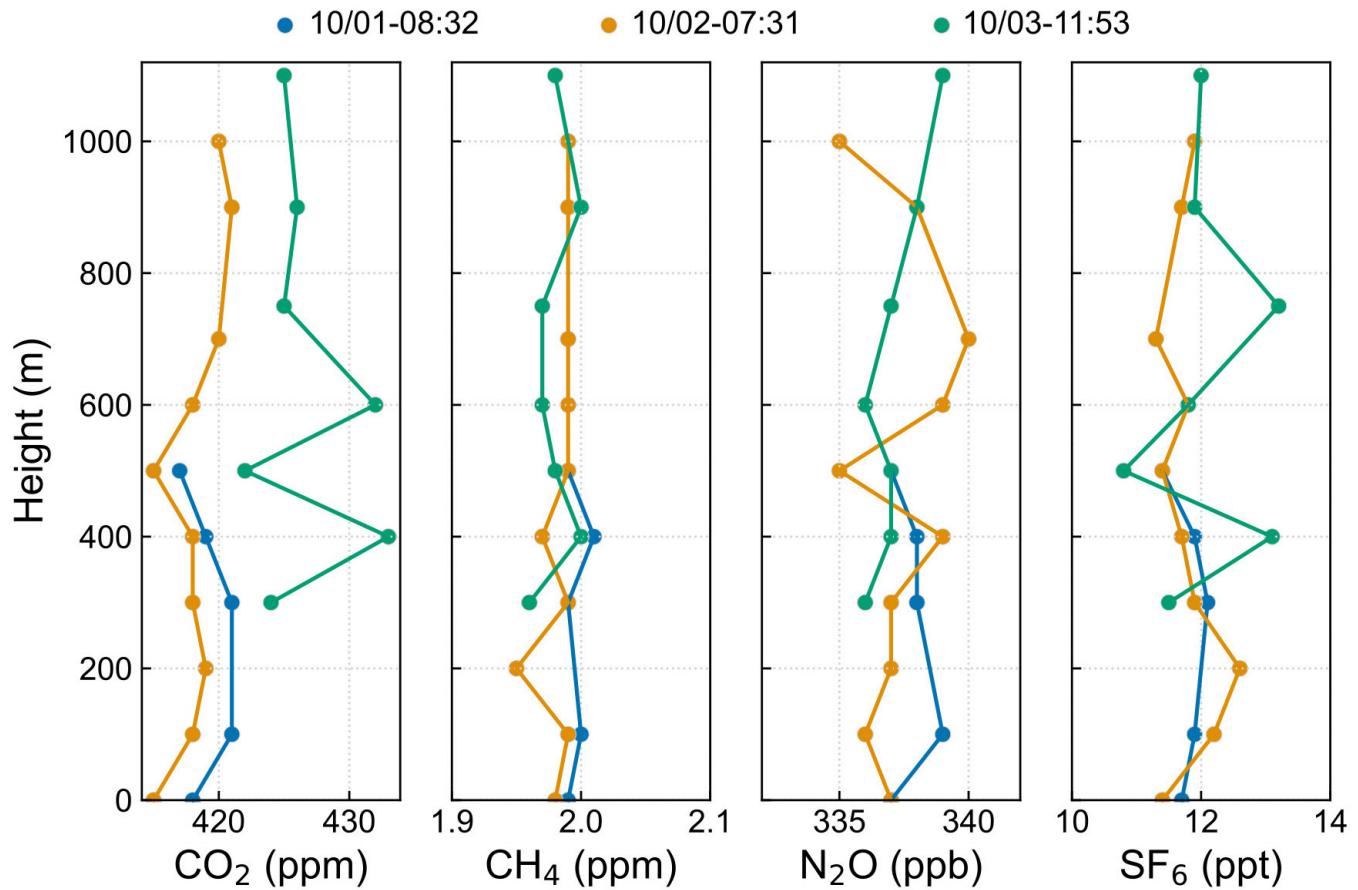

Figure 5. Profiles of 4 components (CO₂, CH₄, N₂O, SF₆) analyzed from Agilent GC 7890A and heights are measured by iMET XQ2 obtained in YF from 01 October to 03 October. The profiles in 01 October and 02 October are measured from ascent, and the profile in 03 October is from a descent.

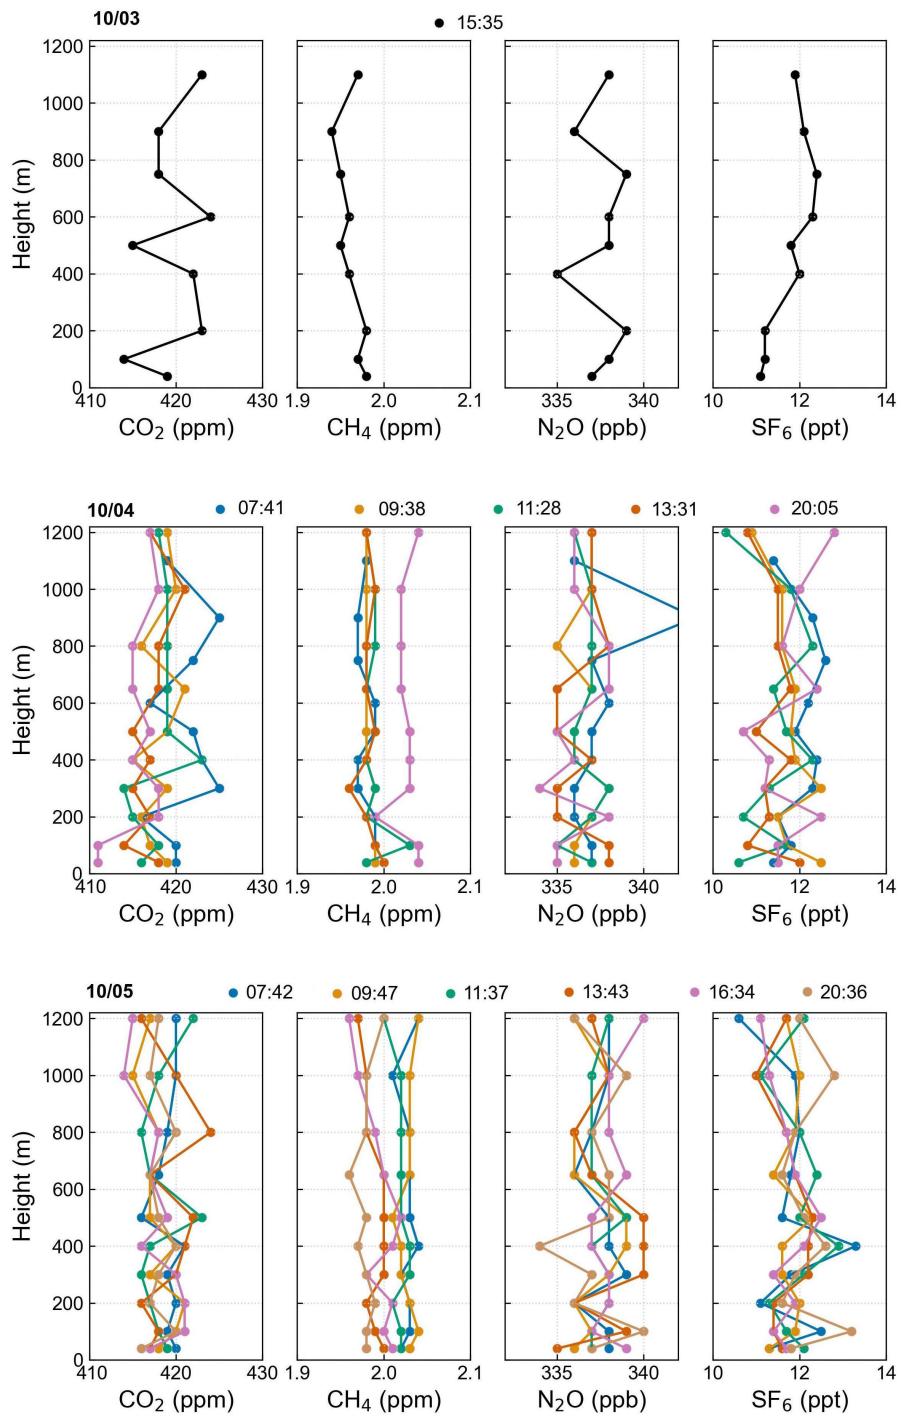

Figure 6. Same as Figure 5, but for ZF from 03 October to 05 October. The profiles are from descent.

Figures 5 and 6 show the vertical distribution of the four species at the Cho Oyu site and Qomolangma Station, respectively. Small fluctuations along altitude are observed in CO₂, N₂O and SF₆ profiles, likely due to atmospheric turbulence, whereas 150 CH₄ exhibit a more stable vertical distribution, ranging between 1.95 and 2.05 ppmv.

To examine the diurnal variation of GHGs, we compute the integral average of their mixing ratios. We also use ERA5 reanalysis data to determine the boundary layer height (BLH). This method allows us to categorize our samples into two distinct groups: those above the boundary layer and those below it. Figure 7 illustrates two time series of mixing ratios for four different species. The series for CO₂, N₂O, and SF₆ show a consistent pattern; however, the variations in CO₂ within the boundary 155 layer height (BLH) are more pronounced than those above it. The downward trend observed on 04 October may reflect the intensification of natural processes due to sunlight and the increase in boundary layer height caused by solar heating. In contrast, CH₄ is well mixed; trends were inversely correlated with BLH and showed a slight increase on the night of 10/04 compared to the daytime. The increase in CH₄ levels exceeded the relative standard deviation (RSD) of our equipment, which may be attributed to local livestock or meadow emissions. Accurately quantifying and assessing the contributions of these factors 160 remains challenging due to limited observational data and insufficient information on emission sources and meteorological conditions.

4 Conclusions

In this study, we developed a simple vertical stratified atmospheric sampling device that can be mounted on a middle-size UAV, a tethered balloon, or the roof of an electrical car, enabling the collection of air samples at different altitudes or locations during 165 a single flight or cruise. After the collection is completed, the gas bag is closed to facilitate subsequent chromatography analysis to obtain the concentration of atmospheric components. At the same time, the device records the atmospheric temperature, pressure, humidity, and the location of each air sample.

The device has the following advantages: 1) its flexible design and adaptability make it suitable for integration with a variety of analytical instruments, enabling three-dimensional monitoring across diverse platforms; 2) its cost is less than US \$ 5000, 170 supporting widespread deployment and facilitating broader adoption in diverse research settings; 3) once the MCU is pre-set before the flight, its automatic operation and quick response time ensure simplicity and ease of use. As a result, this device is well-suited for extended periods of atmospheric observation and is minimally affected by terrain.

A 5-day continuous observation campaign was conducted at the Cho Oyu Base Camp and Qomolangma Station. We integrated the sampling system into a medium-sized hexacopter UAV platform and obtained 15 GHG vertical profiles up to 1215 175 m. While the temporal variations in GHG mixing ratios provide valuable insights, the limited number of data restricts the further analysis on how long-range transport processes and local sources and sinks may have influenced the observed variations. Greenhouse gases like CO₂ exhibit more pronounced variations within the boundary layer, while CH₄ levels rise slightly at night, potentially due to local emissions. This nocturnal increase in CH₄ could be linked to reduced atmospheric mixing during lower BLH, which leads to the accumulation of emissions near the surface. To enable continuous atmospheric monitoring 180 (Kunz et al., 2018; Reuter et al., 2021), we still need to reduce equipment weight for easier long-term deployment. Extending these campaigns to long-term experiments at monthly to seasonal scales would enable the assessment of the GHG distribution, elucidation of their sources and sinks, and disentanglement of the signals from local vertical mixing and long-range transport. It also has the potential to provide the prior value of vertical distributions of GHGs to calibrate and evaluate the satellite retrievals over complex topography, which are never measured before.

185 Although using UAVs or balloons to monitor or inspect GHG distributions at various sites has proven to be useful, this method has its limitations, including a relatively low sample resolution, as only 10 samples are collected. This results in a much coarser atmospheric profile, which is more challenging to relate to the atmospheric boundary layer cycle. Additionally, the weight of the sampling device poses a challenge for smaller UAVs, making it less feasible for lightweight platforms. Adverse weather conditions such as strong winds, can interfere with the safe flight of these devices and the GPS signal. Furthermore, it 190 is not advisable to use this technique for monitoring chemically active gas components in case the gas component may change after sampling. To address these issues, we will continue to optimize the design of the device to improve its performance and adaptability. We expect it to be used in a wider range of applications, such as understanding the sources and formation mechanisms of multiple gas tracers such as air pollutants.

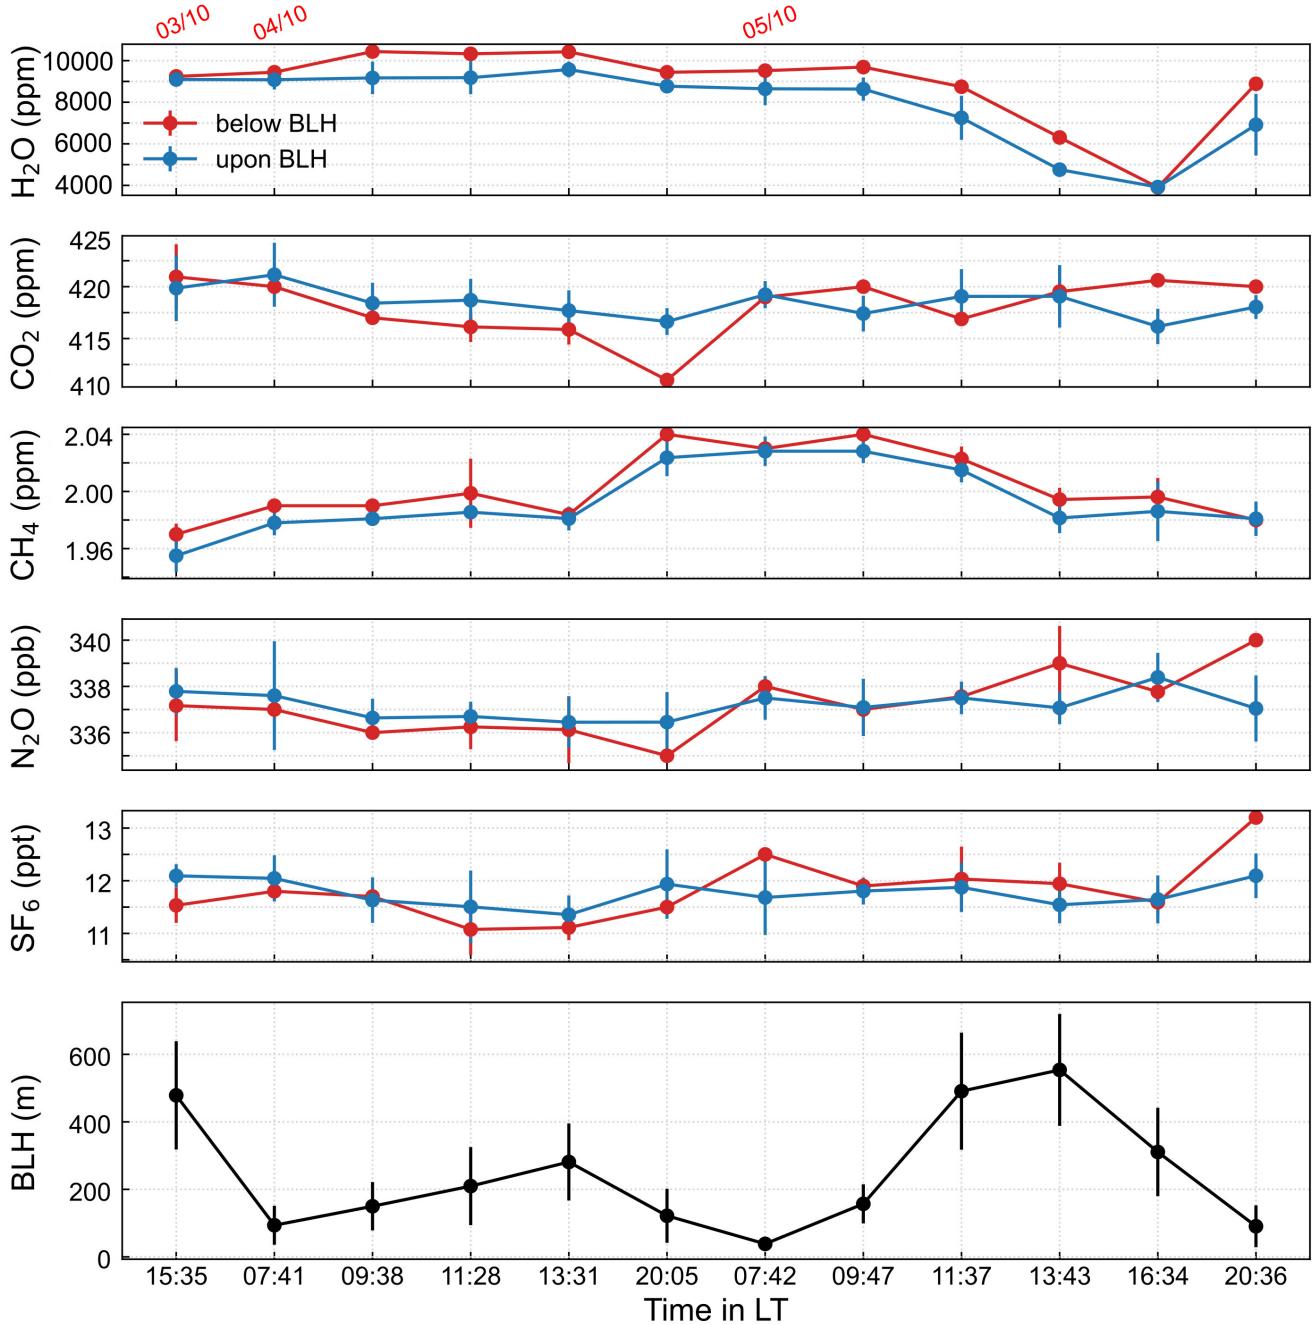

Figure 7. The time series for 5 components (H₂O, CO₂, CH₄, N₂O, SF₆) in ZF from 03 October to 05 October, with mixing ratios using integrated average values, are displayed in the top 5 panels. BLH at the take-off location (28.36°N, 86.94°E) above ground level, sourced from ERA5 data, is displayed in the bottom panel. Error bars represent the standard deviation of values across space.

195 *Data availability.* The observation data are available upon request from the corresponding author(dmz@mail.iap.ac.cn). ERA5 data used in this study are accessible from the ECMWF web page: <https://www.ecmwf.int> (last access: 6 October 2024; Hersbach et al. (2020)).

Author contributions. YZ, CQ, and MD contributed to the manufacturing of the sampling system. YW, MD, MZ, CQ, and YZ designed and conducted the campaign. YW, YZ, and CQ carried out the laboratory analyses, and YZ, MZ, MD, YW, and XT contributed to the preparation of the manuscript.

Competing interests. The authors declare no conflicts of interest.
